Note that the penalty here is data dependent. Moreover, except for the  $\sqrt{\frac{\log k}{Cn}}$  term, the penalized estimator makes the optimal trade-off between the Rademacher complexity, an upper bound on the estimation error, and the approximation error.

#### 1.14.4.4 Hold-out estimates

Suppose out of  $m + n$  iid samples we set aside  $m$  samples where  $m$  is much smaller than  $n$ . Since the hold-out set of size  $m$  is not used in the computation of  $\widehat{f}_n^{(k)}$ , we can estimate  $R(\widehat{f}_n^{(k)})$  by the hold-out estimate

$$U_{n,k} = \sum_{i=1}^m \ell\left(\widehat{f}_n^{(k)}(X_{n+i}), Y_{n+i}\right).$$

By Hoeffding's inequality, the assumption of Theorem 18 holds with  $c = 1$ . Moreover  $\mathbb{E}[U_{n,k}] = R(\widehat{f}_n^{(k)})$ . Therefore, we have

$$\mathbb{E}[R(\tilde{f}_n)] - R(f^*) \leq \min_k \left\{ \mathbb{E}\left[R(\widehat{f}_n^{(k)}) - \widehat{R}(\widehat{f}_n^{(k)})\right] + (R(f_{\mathcal{F}^{(k)}}^*) - R(f^*)) + \sqrt{\frac{\log k}{m}} \right\} + \sqrt{\frac{1}{2m}}.$$

### 1.14.5 Alternatives to uniform convergence

The approach of deriving generalization bounds using uniform convergence arguments is not the only one possible. In this section, we review three techniques for proving generalization bounds based on sample compression, algorithmic stability, and PAC-Bayesian analysis respectively.

#### 1.14.5.1 Sample compression

The sample compression approach to proving generalization bounds was introduced by [33]. It applies to algorithms whose output  $\widehat{f}_{n,S}$  (that is learned using some training set  $S$ ) can be reconstructed from a compressed subset  $S_{\mathbf{i}}$ . Here  $\mathbf{i}$  is a sequence of indices

$$\mathbf{i} = (i_1, i_2, \dots, i_k), \quad 1 \leq i_1 < i_2 < \dots < i_k \leq n,$$

and  $S_{\mathbf{i}}$  is simply the subsequence of  $S$  indexed by  $\mathbf{i}$ . For the index sequence  $\mathbf{i}$  above, we say that its length  $|\mathbf{i}|$  is  $k$ . To formalize the idea that the algorithms output can be reconstructed from a small number of examples, we will define a *compression function*

$$\mathcal{C} : \bigcup_{n=1}^{\infty} (\mathcal{X} \times \mathcal{Y})^n \rightarrow \mathcal{I},$$

where  $\mathcal{I}$  is the set of all possible index sequences of finite length. It is assumed that  $|\mathcal{C}(S)| \leq n$  for an  $S$  is of size  $n$ . We also define a *reconstruction function*

$$\mathcal{R} : \bigcup_{n=1}^{\infty} (\mathcal{X} \times \mathcal{Y})^n \rightarrow \mathcal{Y}^{\mathcal{X}}.$$

We assume that the learning rule satisfies, for any  $S$ ,

$$\widehat{f}_{n,S} = \mathcal{R}(S_{\mathcal{C}(S)}). \quad (14.5)$$

This formalizes our intuition that to reconstruct  $\widehat{f}_{n,S}$  it suffices to remember only those examples whose indices are given by  $\mathcal{C}(S)$ .

The following result gives a generalization bound for such an algorithm.

**Theorem 19.** *Let  $\widehat{f}_n$  be a learning rule for which there exists compression and reconstructions functions  $\mathcal{C}$  and  $\mathcal{R}$  respectively such that the equality (14.5) holds for all  $S$ . Then, we have, with probability at least  $1 - \delta$ ,*

$$R(\widehat{f}_n) \leq \frac{n}{n-k} \widehat{R}(\widehat{f}_n) + \sqrt{\frac{\log \binom{n}{k} + \log \frac{n}{\delta}}{2(n-k)}},$$

where  $k = |\mathcal{C}(S)|$ .

**Proof.** The proof uses the simple idea that for a fixed index set  $\mathbf{i}$ ,  $S_{\bar{\mathbf{i}}}$  is a sample of size  $n - |\mathbf{i}|$  that is independent of  $S_{\mathbf{i}}$ . Here  $\bar{\mathbf{i}}$  denotes the sequence  $[n] \setminus \mathbf{i}$ . By this independence, the risk of any function that depends only on  $S_{\mathbf{i}}$  is close to its empirical average on  $S_{\bar{\mathbf{i}}}$  by Hoeffding's inequality.

Denote the empirical risk of  $f$  calculated on a subset  $S_{\mathbf{i}}$  of  $S$  by  $\widehat{R}_{\mathbf{i}}(f)$ . We have, for any  $f$ ,

$$\widehat{R}_{\overline{\mathcal{C}(S)}}(f) \leq \frac{n}{n-k} \widehat{R}(f),$$

where  $k = |\mathcal{C}(S)|$ . Thus, all we need to show is

$$\mathbb{P}\left[R(\widehat{f}_n) - \widehat{R}_{\overline{\mathcal{C}(S)}}(\widehat{f}_n) \geq \varepsilon_{n,|\mathcal{C}(S)|}\right] \leq \delta,$$

where

$$\varepsilon_{n,k} = \sqrt{\frac{\log \binom{n}{k} + \log \frac{n}{\delta}}{2(n-k)}}$$

To show this, we proceed as follows,

$$\begin{aligned}
 & \mathbb{P} \left[ R(\widehat{f}_n) - \widehat{R}_{\overline{\mathcal{C}(S)}}(\widehat{f}_n) \geq \varepsilon_{n,|\mathcal{C}(S)|} \right] \\
 &= \mathbb{P} \left[ R(\mathcal{R}(S_{\mathcal{C}(S)})) - \widehat{R}_{\overline{\mathcal{C}(S)}}(\mathcal{R}(S_{\mathcal{C}(S)})) \geq \varepsilon_{n,|\mathcal{C}(S)|} \right] \\
 &\leq \mathbb{P} \left[ \exists \mathbf{i} \text{ s.t. } |\mathbf{i}| = k, R(\mathcal{R}(S_{\mathbf{i}})) - \widehat{R}_{\mathbf{i}}(\mathcal{R}(S_{\mathbf{i}})) \geq \varepsilon_{n,k} \right] \\
 &\leq \sum_{\mathbf{i}:|\mathbf{i}|=k} \mathbb{P} \left[ R(\mathcal{R}(S_{\mathbf{i}})) - \widehat{R}_{\mathbf{i}}(\mathcal{R}(S_{\mathbf{i}})) \geq \varepsilon_{n,k} \right] \\
 &\leq \sum_{k=1}^n \sum_{\mathbf{i}:|\mathbf{i}|=k} \exp(-2(n-k)\varepsilon_{n,k}^2) \\
 &= \sum_{k=1}^n \binom{n}{k} \exp(-2(n-k)\varepsilon_{n,k}^2) \\
 &\leq \sum_{k=1}^n \frac{\delta}{n} = \delta.
 \end{aligned}$$

The last step holds because, by our choice of  $\varepsilon_{n,k}$ ,

$$\binom{n}{k} \exp(-2(n-k)\varepsilon_{n,k}^2) = \frac{\delta}{n}.$$
 $\square$

### 1.14.5.2 Stability

*Stability* is a property of a learning algorithm that ensures that the output, or some aspect of the output, of the learning algorithm does not change much if the training data set changes very slightly. This is an intuitive notion whose roots in learning theory go back to the work of Tikhonov on regularization of inverse problems. To see how stability can be used to give generalization bounds, let us consider a result of Bousquet and Elisseeff [34] that avoids going through uniform convergence arguments by directly showing that any learning algorithm with *uniform stability* enjoys exponential tail generalization bounds in terms of both the training error and the leave-one-out error of the algorithm.

Let  $S^{\setminus i}$  denote the sample of size  $n-1$  obtained by removing a particular input  $(x_i, y_i)$  from a sample  $S$  of size  $n$ . A learning algorithm is said to have *uniform stability*  $\beta$  if for any  $S \in (\mathcal{X} \times \mathcal{Y})^n$  and any  $i \in [n]$ , we have,

$$\sup_{(x,y) \in \mathcal{X} \times \mathcal{Y}} |\ell(\widehat{f}_{n,S}(x), y) - \ell(\widehat{f}_{n-1,S^{\setminus i}}(x), y)| \leq \beta.$$

We have the following generalization bound for a uniformly stable learning algorithm.

**Theorem 20.** *Let  $\widehat{f}_n$  have uniform stability  $\beta$ . Then, with probability at least  $1 - \delta$ ,*

$$R(\widehat{f}_n) \leq \widehat{R}(\widehat{f}_n) + 2\beta + (4\beta n + 1) \sqrt{\frac{\log \frac{1}{\delta}}{2n}}.$$

Note that this theorem gives tight bound when  $\beta$  scales as  $1/n$ . As such it cannot be applied directly to the classification setting with 0–1 loss where  $\beta$  can only be 0 or 1. A good example of a learning algorithm that exhibits uniform stability is regularized ERM over a reproducing kernel Hilbert space using a convex loss function that has Lipschitz constant  $C_\ell$ :

$$\forall y, y', y'' \in \mathcal{Y} \subseteq \mathbb{R}, |\ell(y', y) - \ell(y'', y)| \leq C_\ell \cdot |y' - y''|.$$

A regularized ERM using kernel  $K$  is defined by

$$\widehat{f}_n = \underset{f \in \mathcal{F}_K}{\operatorname{argmin}} \widehat{R}(f) + \lambda \|f\|_K^2,$$

where  $\lambda$  is a regularization parameter. Regularized ERM has uniform stability  $\beta$  for  $\beta = \frac{C_\ell^2 \kappa^2}{2\lambda n}$ , where

$$\kappa = \sup_{x \in \mathcal{X}} \sqrt{K(x, x)}.$$

The literature on stability of learning algorithms is unfortunately thick with definitions. For instance, Kutin and Niyogi [35] alone consider over a dozen variants! We chose a simple (but quite strong) definition from Bousquet and Elisseeff above to illustrate the general point that stability can be used to derive generalization bounds. But we like to point the reader to Mukherjee et al. [36] where a notion of *leave-one-out (LOO) stability* is defined and shown sufficient for generalization for any learning algorithm. Moreover, for ERM they show it is necessary and sufficient for both generalization and learnability with respect to a fixed class. Shalev-Shwartz et al. [37] further examine the connections between stability, generalization and learnability in Vapnik’s general learning setting that includes supervised learning (learning from example, label pairs) as a special case.

### 1.14.5.3 PAC-Bayesian analysis

PAC-Bayesian analysis refers to a style of analysis of learning algorithms that output not just a single function  $f \in \mathcal{F}$  but rather a *distribution* (called a “posterior distribution”) over  $\mathcal{F}$ . Moreover, the complexity of the data-dependent posterior distribution is measured relative to a fixed distribution chosen in advance (that is, in a data independent way). The fixed distribution is called a “prior distribution.” Note that the terms “prior” and “posterior” are borrowed from the analysis of Bayesian algorithms that start with a prior distribution on some parameter space and, on seeing data, make updates to the distribution using Bayes’ rule to obtain a posterior distribution. Even though the terms are borrowed, their use is not required to be similar to their use in Bayesian analysis. In particular, the prior used in the PAC-Bayes theorem need not be “true” in any sense and the posterior need not be obtained using Bayesian updates: the bound holds for any choice of the prior and posterior.

Denote the space of probability distributions over  $\mathcal{F}$  by  $\Delta(\mathcal{F})$ . There might be measurability issues in defining this for general function classes. So, we can assume that  $\mathcal{F}$  is a countable class for the purpose of the theorem below. Note, however, that the cardinality of the class  $\mathcal{F}$  never enters the bound explicitly anywhere. For any  $\rho \in \Delta(\mathcal{F})$ , define

$$\begin{aligned} R(\rho) &= \mathbb{E}_{f \sim \rho}[R(f)], \\ \widehat{R}(\rho) &= \mathbb{E}_{f \sim \rho}[\widehat{R}(f)]. \end{aligned}$$

In the context of classification, a randomized classifier that, when asked for a prediction, samples a function from a distribution  $\rho$  and uses it for classification, is called a *Gibbs classifier*. Note that  $R(\rho)$  is the risk of such a Gibbs classifier.

Also recall the definition of *Kullback-Leibler divergence* or *relative entropy*:

$$D(\rho||\pi) = \int_{f \in \mathcal{F}} \log \frac{\rho(f)}{\pi(f)} d\rho(f).$$

For real numbers  $p, q \in [0, 1]$  we define (with some abuse of notation):

$$D(p||q) = p \log \frac{p}{q} + (1-p) \log \frac{1-p}{1-q}.$$

With these definitions, we can now state the PAC Bayesian theorem [38].

**Theorem 21 (PAC-Bayesian Theorem).** *Let  $\pi$  be a fixed distribution over  $\mathcal{F}$ . Then, we have, with probability at least  $1 - \delta$ ,*

$$\forall \rho \in \Delta(\mathcal{F}), D(\widehat{R}(\rho)||R(\rho)) \leq \frac{D(\rho||\pi) + \log \frac{2n}{\delta}}{n-1}.$$

*In particular, for any learning algorithm that, instead of returning a single function  $\widehat{f}_n \in \mathcal{F}$ , returns a distribution  $\widehat{\rho}_n$  over  $\mathcal{F}$ , we have, with probability at least  $1 - \delta$ ,*

$$D(\widehat{R}(\widehat{\rho}_n)||R(\widehat{\rho}_n)) \leq \frac{D(\widehat{\rho}_n||\pi) + \log \frac{2n}{\delta}}{n-1}.$$

To get more interpretable bounds from this statement, the following inequality is useful for  $0 \leq p < q \leq 1$ :

$$\frac{(p-q)^2}{2} \leq \frac{(p-q)^2}{2q} \leq D(p||q).$$

This implies that if  $D(p||q) \leq x$  then two inequalities hold:

$$\begin{aligned} q &\leq p + \sqrt{2x}, \\ q &\leq p + \sqrt{2px} + 2x. \end{aligned}$$

The first gives us a version of the PAC-Bayesian bound that is often presented:

$$R(\widehat{\rho}_n) - \widehat{R}(\widehat{\rho}_n) \leq \sqrt{\frac{2(D(\widehat{\rho}_n||\pi) + \log \frac{2n}{\delta})}{n-1}}.$$

The second gives us the interesting bound

$$R(\widehat{\rho}_n) - \widehat{R}(\widehat{\rho}_n) \leq \sqrt{\frac{2\widehat{R}(\widehat{\rho}_n)(D(\widehat{\rho}_n||\pi) + \log \frac{2n}{\delta})}{n-1}} + 2 \frac{D(\widehat{\rho}_n||\pi) + \log \frac{2n}{\delta}}{n-1}.$$

If the loss  $\widehat{R}(\widehat{\rho}_n)$  is close to zero, then the dominating term is the second term that scales as  $\frac{1}{n}$ . If not, then the first term, which scales as  $\frac{1}{\sqrt{n}}$ , dominates.

## 1.14.6 Computational aspects

So far we have only talked about sample complexity issues ignoring considerations of *computational complexity*. To properly address the latter, we need a formal *model of computation* and need to talk about how functions are represented by the learning algorithm. The branch of machine learning that studies these questions is called *computational learning theory*. We will now provide a brief introduction to this area.

### 1.14.6.1 The PAC model

The basic model in computational learning theory is the Probably Approximately Correct (PAC) model. It applies to learning binary valued functions and uses the 0–1 loss. Since a  $\pm 1$  valued function is specified unambiguously by specifying the subset of  $\mathcal{X}$  where it is one, we have a bijection between binary valued functions and *concepts*, which are simply subsets of  $\mathcal{X}$ . Thus we will use (binary valued) function and concept interchangeably in this section. Moreover, the basic PAC model considers what is sometimes called the *realizable* case. That is, there is a “true” concept in  $\mathcal{F}$  generating the data. This means that  $y_i = f(x_i)$  for some  $f \in \mathcal{F}$ . Hence the minimal risk in the class is zero:  $R(f_{\mathcal{F}}^*) = 0$ . Note, however, that the distribution over  $\mathcal{X}$  is still assumed to be arbitrary.

To define the computational complexity of a learning algorithm, we assume that  $\mathcal{X}$  is either  $\{0, 1\}^d$  or  $\mathbb{R}^d$ . We assume a model of computation that can store a single real number in a memory location and can perform any basic arithmetic operation (addition, subtraction, multiplication, division) on two real numbers in one unit of computation time.

The distinction between a concept and its representation is also an important one when we study computational complexity. For instance, if our concepts are convex polytopes in  $\mathbb{R}^d$ , we may choose a representation scheme that specifies the vertices of the polytope. Alternatively, we may choose to specify the linear equalities describing the faces of the polytope. Their vertex-based and face-based representations can differ exponentially in size. Formally, a *representation scheme* is a mapping  $\text{rep} : (\Sigma \cup \mathbb{R})^* \rightarrow \mathcal{F}$  that maps a representation (consisting of symbols from a finite alphabet  $\Sigma$  and real numbers) to a concept. As noted above, there could be many  $\sigma$ ’s such that  $\text{rep}(\sigma) = f$  for a given concept  $f$ . The size of representation is assumed to be given by a function  $\text{size} : (\Sigma \cup \mathbb{R})^* \rightarrow \mathbb{N}$ . A simple choice of size could be simply the number of symbols and real numbers that appear in the representation. Finally, the size of a concept  $f$  is simply the size of its smallest representation:

$$\text{size}(f) = \min_{\sigma: \text{rep}(\sigma)=f} \text{size}(\sigma).$$

The last ingredient we need before can give the definition of efficient learnability in the PAC model is the representation class  $\mathcal{H}$  used by the algorithm for producing its output. We call  $\mathcal{H}$  the *hypothesis* class and it is assumed that there is a representation in  $\mathcal{H}$  for every function in  $\mathcal{F}$ . Moreover, it is required that for every  $x \in \mathcal{X}$  and any  $h \in \mathcal{H}$ , we can evaluate  $h(x)$  ( $= \text{rep}(h)(x)$ ) in time polynomial in  $d$  and  $\text{size}(h)$ .

Recall that we have assumed  $\mathcal{X} = \{0, 1\}^d$  or  $\mathbb{R}^d$ . We say that an algorithm *efficiently PAC learns*  $\mathcal{F}$  using hypothesis class  $\mathcal{H}$  if, for any  $f \in \mathcal{F}$ , given access to iid examples  $(x_i, f(x_i)) \in \mathcal{X} \times \{\pm 1\}$ ,

inputs  $\varepsilon \in (0, 1)$  (accuracy),  $\delta \in (0, 1)$  (confidence), and  $\text{size}(f)$ , the algorithm satisfies the following conditions:

1. With probability at least  $1 - \delta$ , it outputs a hypothesis  $h \in \mathcal{H}$  with  $R(h) \leq \varepsilon$ .
2. It runs in time polynomial in  $\frac{1}{\varepsilon}, \frac{1}{\delta}, \text{size}(f)$ , and  $d$ .

For examples of classes  $\mathcal{F}$  that are efficiently PAC learnable (using some  $\mathcal{H}$ ), see the texts [12, 18, 20].

### 1.14.6.2 Weak and strong learning

In the PAC learning definition, the algorithm must be able to achieve arbitrarily small values of  $\varepsilon$  and  $\delta$ . A weaker definition would require the learning algorithm to work only for fixed choices of  $\varepsilon$  and  $\delta$ . We can modify the definition of PAC learning by removing  $\varepsilon$  and  $\delta$  from the input to the algorithm. Instead, we assume that there are fixed polynomials  $p_\delta(\cdot, \cdot)$  and  $p_\varepsilon(\cdot, \cdot)$  such that the algorithm outputs  $h \in \mathcal{H}$  that satisfies

$$R(h) \leq \frac{1}{2} - \frac{1}{p_\varepsilon(d, \text{size}(f))}$$

with probability at least

$$\frac{1}{p_\delta(d, \text{size}(f))}.$$

Such an algorithm is called a *weak PAC learning* algorithm for  $\mathcal{F}$ . The original definition, in contrast, can be called a definition of *strong PAC learning*. The definition of weak PAC learning does appear quite weak. Recall that an accuracy of  $\frac{1}{2}$  can be trivially achieved by an algorithm that does not even look at the samples but simply outputs a hypothesis that outputs a random  $\pm 1$  sign (each with probability a half) for any input. The desired accuracy above is just an inverse polynomial away from the trivial accuracy guarantee of  $\frac{1}{2}$ . Moreover, the probability with which the weak accuracy is achieved is not required to be arbitrarily close to 1.

A natural question to ask is whether a class that is weakly PAC learnable using  $\mathcal{H}$  is also strongly learnable using  $\mathcal{H}$ ? The answer, somewhat surprisingly, is “Yes.” So, the weak PAC learning definition only appears to be a relaxed version of strong PAC learning. Moreover, a weak PAC learning algorithm, given as a subroutine or blackbox, can be converted into a strong PAC learning algorithm. Such a conversion is called *boosting*.

A boosting procedure has to start with a weak learning algorithm and boost two things: the confidence and the accuracy. It turns out that boosting the confidence is easier. The basic idea is to run the weak learning algorithm several times on independent samples. Therefore, the crux of the boosting procedure lies in boosting the accuracy. Boosting the accuracy seems hard until one realizes that the weak learning algorithm does have one strong property: it is guaranteed to work no matter what the underlying distribution of the examples is. Thus, if a first run of the weak learning only produces a hypothesis  $h_1$  with slightly better accuracy than  $\frac{1}{2}$ , we can make the second run focus only on those examples where  $h_1$  makes a mistake. Thus, we will focus the weak learning algorithm on “harder portions” of the input distribution. While this simple idea does not directly work, a variation on the same theme was shown to work by Schapire [39]. Freund [40] then presented a simpler boosting algorithm. Finally, a much more practical boosting procedure, called AdaBoost, was discovered by them jointly [10].

AdaBoost counts as one of the great practical success stories of computational learning theory. For more details on boosting, AdaBoost, and the intriguing connections of these ideas to game theory and statistics, we refer the reader to [41].

### 1.14.6.3 Random classification noise and the SQ model

Recall that the basic PAC model assumes that the labels are generated using a function  $f$  belonging to the class  $\mathcal{F}$  under consideration. Our earlier development of statistical tools for obtaining sampling complexity estimates did not require such an assumption (though the rates did depend on whether  $R(f_{\mathcal{F}}^*) = 0$  or not).

There are various *noise models* that extend the PAC model by relaxing the noise-free assumption and thus making the problem of learning potentially harder. Perhaps the simplest is the *random classification noise* model [42]. In this model, when the learning algorithm queries for the next labeled example of the form  $(x_i, f(x_i))$ , it receives it with probability  $1 - \eta$  but with probability  $\eta$ , it receives  $(x_i, -f(x_i))$ . That is, with some probability  $\eta < \frac{1}{2}$ , the label is flipped. The definition of efficient learnability remains the same except that now the learning algorithm has to run in time polynomial in  $\frac{1}{\epsilon}, \frac{1}{\delta}, d, \text{size}(f)$  and  $\frac{1}{1-2\eta_0}$  where  $\eta_0 < \frac{1}{2}$  is an input to the algorithm and is an upper bound on  $\eta$ .

Kearns [43] introduced the statistical query (SQ) model where learning algorithms do not directly access the labeled example but only make statistical queries about the underlying distribution. The queries take the form  $(\chi, \tau)$  where  $\chi : \mathcal{X} \times \{\pm 1\} \rightarrow \{\pm 1\}$  is a binary valued function of the labeled examples and  $\tau \in (0, 1]$  is a tolerance parameter. Given such a query, the oracle in the SQ model responds with an estimate of  $P(\chi(x, f(x)) = +1)$  that is accurate to within an additive error of  $\tau$ . It is easy to see, using Hoeffding's inequality, that given access to the usual PAC oracle that provides iid examples of the form  $(x_i, f(x_i))$ , we can simulate the SQ oracle by just drawing a sample of size polynomial in  $\frac{1}{\tau^2}$  and  $\log \frac{1}{\delta}$  and estimating the probability  $P(\chi(x, f(x)) = 1)$  based on it. The simulation will succeed with probability  $1 - \delta$ . Kearns gave a more complicated simulation that mimics the SQ oracle given access to only a PAC oracle with random misclassification noise.

**Lemma 22.** *Given a query  $(\chi, \tau)$ , the probability  $P(\chi(x, f(x)) = 1)$  can be estimated to within  $\tau$  error, with probability at least  $1 - \delta$ , using*

$$O\left(\frac{1}{\tau^2(1-2\eta)^2} \log \frac{1}{\delta}\right)$$

examples that have random misclassification noise at rate  $\eta < \frac{1}{2}$  in them.

This lemma means that learning algorithm that learns a concept class  $\mathcal{F}$  in the SQ model can also learn  $\mathcal{F}$  in the random classification noise model.

**Theorem 23.** *If there is an algorithm that efficiently learns  $\mathcal{F}$  from statistical queries using  $\mathcal{H}$ , then there is an algorithm that efficiently learns  $\mathcal{F}$  using  $\mathcal{H}$  in the random classification noise model.*

### 1.14.6.4 The agnostic PAC model

The agnostic PAC model uses the same definition of learning as the one we used in Section 1.14.2.3). That is, the distribution of examples  $(x, y)$  is arbitrary. In particular, it is not assumed that  $y = f(x)$  for

any  $f$ . The goal of the learning algorithm is to output a hypothesis  $h \in \mathcal{H}$  with  $R(h) - R(f_{\mathcal{F}}^*) \leq \varepsilon$  with probability at least  $1 - \delta$ . We say that a learning algorithm efficiently learns  $\mathcal{F}$  using  $\mathcal{H}$  in the agnostic PAC model if the algorithm not only outputs a probably approximately correct hypothesis  $h$  but also runs in time that is polynomial in  $\frac{1}{\varepsilon}$ ,  $\frac{1}{\delta}$ , and  $d$ .

The agnostic model has proved to be a very difficult one for exhibiting efficient learning algorithms. Note that the statistical issue is completely resolved: a class  $\mathcal{F}$  is learnable iff it has finite VC dimension. However, the “algorithm” implicit in this statement is ERM which, even for the class of halfspaces

$$\{x \mapsto \text{sign}(\langle w, x \rangle - \theta) : w \in \mathbb{R}^d, \theta \in \mathbb{R}\},$$

leads to NP-hard problems. For instance, see [44] for very strong negative results about agnostic learning of halfspaces. However, these results apply to *proper* agnostic learning only. That is, the algorithm outputs a hypothesis that is also a halfspace. An efficient algorithm for learning halfspaces in the agnostic PAC model using a general hypothesis class would be a major breakthrough.

### 1.14.6.5 The mistake bound model

The mistake bound model is quite different from the PAC model. Unlike the PAC model, no assumption is made on the distribution of the inputs. There is also no distinction between a training phase where the learner uses a batch of examples to learn a hypothesis and a test phase where the risk of the learned hypothesis determines the learner’s expected loss. Instead, learning happens in a series of trials (or rounds) in an *online* fashion. At any given round  $t \in \mathbb{N}$ , the order of events is as follows:

- Learner receives  $x_t \in \mathcal{X}$  where  $\mathcal{X} = \{0, 1\}^d$  or  $\mathbb{R}^d$ .
- Learner outputs a label  $\hat{y}_t \in \mathcal{Y}$ .
- Learner receives the correct label  $y_t = f(x_t)$ .

Note that the basic model assumes that  $f$  is a true function generating the labels (the case when such an  $f$  is assumed to exist is often called the *realizable case*). The identity of this function is, of course, hidden from the learner. The goal of the learner is to minimize the total number of *mistakes* it makes:

$$\sum_{t=1}^{\infty} \ell(\hat{y}_t, f(x_t)),$$

where  $\ell$  is the 0–1 loss. If a learning algorithm can guarantee, for any choice  $f \in \mathcal{F}$  of the true concept, that the total mistake bound will be a polynomial function of  $d$  and  $\text{size}(f)$  as well as the computation per round is polynomial in the same parameters, then we say that the algorithm *efficiently learns  $\mathcal{F}$  in the mistake bound model*.

Recall that, in the PAC model, VC dimension of  $\mathcal{F}$  characterizes learnability of  $\mathcal{F}$  if we ignore computational considerations. Moreover, VC dimension characterizes learnability in the agnostic PAC model as well. In the mistake bound model, it is the Littlestone dimension [45] whose finiteness provides a necessary and sufficient condition for learnability. There is also an *agnostic version* of the mistake bound model where we drop the assumption that  $y_t = f(x_t)$  for some  $f \in \mathcal{F}$ . It is also known that the Littlestone dimension characterizes learnability (ignoring efficiency) even in the agnostic online mistake bound model [46].

The Littlestone dimension of a class  $\mathcal{F} \subseteq \{\pm 1\}^{\mathcal{X}}$  is defined as follows. A  $\mathcal{X}$ -valued tree (or simply an  $\mathcal{X}$ -tree) of height  $t$  is a complete binary tree of height  $t$  whose *internal* nodes are labeled with instances from  $\mathcal{X}$ . A (complete binary) tree of height  $t$  has exactly  $2^t$  leaves which we identify, from left to right, with the  $2^t$  sequences length  $t$   $\pm 1$  sequences ordered lexicographically (with  $-1$  taking precedence over  $+1$  in determining the lexicographic order). For example, the leftmost leaf corresponds to all  $-1$ 's sequence whereas the rightmost leaf corresponds to the all  $+1$ 's sequences. If  $\lambda$  is a leaf, we denote its associated  $\pm 1$  sequence by  $\epsilon(\lambda)$ .

An  $\mathcal{X}$ -tree of height  $t$  is said to be *shattered* by  $\mathcal{F}$  if for each of the  $2^t$  leaves the following is true: there is a function  $f \in \mathcal{F}$  such that the sequence of values taken by  $f$  on the internal nodes on the path from the root to the leaf  $\lambda$  is exactly  $\epsilon(\lambda)$ . The *Littlestone dimension* of  $\mathcal{F}$  is the height of the tallest tree that is shattered by  $\mathcal{F}$ .

It is easy to see that if an  $\mathcal{X}$ -valued sequence  $(x_1, \dots, x_t)$  is shattered by  $\mathcal{F}$  then the  $\mathcal{X}$ -tree of height  $t$  obtained by repeating  $x_i$  across level  $i$  for  $i \in [t]$  is also shattered by  $\mathcal{F}$ . This proves the following relationship between  $\text{VCdim}(\mathcal{F})$  and  $\text{Ldim}(\mathcal{F})$ .

**Theorem 24.** *For any  $\mathcal{F} \subseteq \{\pm 1\}^{\mathcal{X}}$  we have*

$$\text{VCdim}(\mathcal{F}) \leq \text{Ldim}(\mathcal{F}).$$

A converse to the above theorem is not possible. Indeed, the class of threshold functions on  $\mathbb{R}$ :

$$\mathcal{F} = \{x \mapsto \text{sign}(x - \theta) : \theta \in \mathbb{R}\}$$

has  $\text{VCdim}(\mathcal{F}) = 1$  but  $\text{Ldim}(\mathcal{F}) = \infty$ . A finite class  $\mathcal{F}$  has a finite Littlestone dimension satisfying the upper bound  $\text{Ldim}(\mathcal{F}) \leq \log_2(|\mathcal{F}|)$ .

#### 1.14.6.5.1 Halving and weighted majority

Note that we proved risk bounds for a finite class in the probabilistic framework using Hoeffding's inequality along with a simple union bound. Here we show how to deal with a finite class in the online mistake bound model. In the realizable case, a simple algorithm called *halving* is guaranteed to make no more than  $\log_2(|\mathcal{F}|)$  mistakes.

At the beginning of round  $t$ , the halving algorithm considers a subset  $\mathcal{F}_t \subseteq \mathcal{F}$  of the original function class. Predictions are made by taking a majority vote over  $\mathcal{F}_{t-1}$ :

$$\hat{y}_t = \text{sign} \left( \sum_{f \in \mathcal{F}_{t-1}} f(x_t) \right).$$

Therefore, if a mistake is made, then  $|\mathcal{F}_{t-1}|$  reduces by at least a factor of 2. Moreover, the true function is never eliminated since it will always satisfy  $f(x_t) = y_t$ . Therefore, if  $M_t$  is the number of mistakes made by the halving algorithm in  $t$  rounds, then we have

$$1 \leq |\mathcal{F}_t| \leq \frac{|\mathcal{F}_0|}{2^{M_t}} = \frac{|\mathcal{F}|}{2^{M_t}}.$$

This implies that  $M_t \leq \log_2(|\mathcal{F}|)$ . Thus we have proved a mistake bound for halving.

---

**Algorithm 1.** Halving

---

```

Initialize  $\mathcal{F}_0 = \mathcal{F}$ 
for  $t = 1, 2, \dots$  do
  Receive  $x_t$ 
  Predict  $\hat{y}_t$  using a majority vote over  $\mathcal{F}_{t-1}$ 
  Receive true label  $y_t$ 
  if  $\hat{y}_t \neq y_t$  then
     $\mathcal{F}_t = \{f \in \mathcal{F}_{t-1} : f(x_t) = y_t\}$ 
  end if
end for

```

---

**Theorem 25.** *The halving algorithm when run on a finite class  $\mathcal{F}$  enjoys a mistake bound of  $\log_2(|\mathcal{F}|)$ .*

In the non-realizable case, halving does not work directly but a suitable modification does. Since no function in the class can be guaranteed to be correct all the time, it does not make sense to eliminate functions that make mistakes. The crucial idea here is to keep *weights* for different functions in the class. Then, when a function makes a mistake, its weight is multiplied by a factor of  $e^{-\eta} < 1$  where  $\eta > 0$  is a parameter. The prediction are now taken using a *weighted majority* vote over all  $\mathcal{F}$ :

$$\hat{y}_t = \text{sign} \left( \sum_{f \in \mathcal{F}} \rho_{t-1}(f) f(x_t) \right). \quad (14.6)$$

---

**Algorithm 2.** Weighted Majority

---

```

Initialize  $\rho_0(f) = \pi(f)$  for some distribution  $\pi$  over  $\mathcal{F}$ 
for  $t = 1, 2, \dots$  do
  Receive  $x_t$ 
  Predict  $\hat{y}_t$  using a  $\rho_{t-1}$ -weighted majority vote over  $\mathcal{F}_{t-1}$ 
  Receive true label  $y_t$ 
  for  $f \in \mathcal{F}$  do
     $\rho_t(f) = \rho_{t-1}(f) \exp(-\eta \ell(f(x_t), y_t))$ 
  end for
end for

```

---

**Theorem 26.** *At any the end of any given round, let  $M_f$  be the number of mistakes made by a function  $f \in \mathcal{F}$  so far. Then the number of mistakes  $M$  made by weighted majority so far is bounded as*

$$\forall f \in \mathcal{F}, M \leq 2 \cdot \frac{\eta M_f + \log \frac{1}{\pi(f)}}{1 - e^{-\eta}}.$$

In particular, using the uniform distribution  $\pi(f) = 1/|\mathcal{F}|$ , we get

$$\forall f \in \mathcal{F}, M \leq 2 \cdot \frac{\eta M_f + \log |\mathcal{F}|}{1 - e^{-\eta}}.$$

**Proof.** Fix a round index  $T \geq 1$  and let  $M$  and  $M_f$  be defined as the numbers of mistakes in the first  $T$  rounds. Let  $F_t$  be the fraction of weights on the functions that made a mistake on round  $t \leq T$ . Since we make a mistake if and only if  $F_t \geq \frac{1}{2}$ , we have

$$M = \sum_{t=1}^T \mathbf{1} \left[ F_t \geq \frac{1}{2} \right] \leq \sum_{t=1}^T 2F_t. \quad (14.7)$$

Define the total weight

$$W_t = \sum_{f \in \mathcal{F}} \rho_t(f).$$

At round  $t$ , the total weight changes as

$$W_{t+1} \leq (1 - (1 - e^{-\eta})F_t)W_t.$$

Hence the final total weight is

$$W_{T+1} = W_0 \prod_{t=1}^T (1 - (1 - e^{-\eta})F_t).$$

Note that  $W_0 = 1$ . If the function  $f$  made  $M_f$  mistakes, its weight is

$$\rho_{t+1}(f) = \pi(f)e^{-\eta M_f}.$$

Since  $\rho_{t+1}(f) \leq W_{t+1}$ , we have

$$\pi(f)e^{-\eta M_f} \leq \prod_{t=1}^T (1 - (1 - e^{-\eta})F_t).$$

Taking negative logs of both sides reverses the inequality giving

$$\log \frac{1}{\pi(f)} + \eta M_f \geq - \sum_{t=1}^T \log (1 - (1 - e^{-\eta})F_t).$$

Using the elementary but useful inequality  $-\log(1-x) > x$  gives

$$(1 - e^{-\eta}) \sum_{t=1}^T F_t \leq \eta M_f + \log \frac{1}{\pi(f)}.$$

Combining this with the bound (14.7) proves the theorem. □

It turns out we can shave off a factor of 2 in the above mistake bound by using a randomized version of the weighted majority algorithm. Instead of taking the majority vote with the weights  $\rho_{t-1}(f)$ , we can consider a Gibbs classifier that chooses a function  $f_t$  randomly from  $\mathcal{F}$  with probability proportional to  $\rho_{t-1}(f)$  and then outputs  $\hat{y}_t = f_t(x_t)$ . This makes the number of mistakes a random variable but the bound (14.7) turns into an equality without the factor of 2. That is, for the randomized weighted majority algorithm

$$\mathbb{E}[M] = \sum_{t=1}^T F_t.$$

Thus we have the following result.

**Theorem 27.** Suppose that we change the weighted majority step (14.6) to the randomized weighted majority step

$$f_t \sim \rho_{t-1}, \quad \hat{y}_t = \text{sign}(f_t(x_t)).$$

Then, this randomized version of weighted majority satisfies the expected mistake bound

$$\forall f \in \mathcal{F}, \quad \mathbb{E}[M] \leq \frac{\eta M_f + \log \frac{1}{\pi(f)}}{1 - e^{-\eta}}.$$

### 1.14.6.5.2 Perceptron and winnow

We now consider two online algorithms that learn a linear threshold function. *Perceptron* is a classic algorithm that dates back to the 1960s. The *Winnow* algorithm was proposed by Littlestone [45] as a better alternative when there are many irrelevant features in the inputs.

Both algorithms follow the general schema given in Algorithm 3. Perceptron uses the *additive* update rule:

$$\text{LTF-UPDATE}(w_{t-1}, \eta, x_t, y_t) = w_{t-1} - \eta y_t x_t,$$

whereas Winnow uses a *multiplicative* update rule

$$\text{LTF-UPDATE}(w_{t-1}, \eta, x_t, y_t) = \frac{w_{t-1} \odot \exp(-\eta y_t x_t)}{Z_t},$$

where  $\odot$  and  $\exp$  denote entry wise multiplication and exponentiation respectively. The normalization constant  $Z_t = \sum_{j=1}^d w_{t-1,j} \exp(-\eta y_t x_{t,j})$  ensures that the weight vector remains a probability distribution. Also note that in Perceptron, we use the initialization  $w_0 = \mathbf{0}$  whereas Winnow initializes  $w_0$  with the uniform distribution over the  $d$  features.

To give a mistake bound for Perceptron and Winnow, we will assume that we are in realizable case. That is, there is some weight vector  $w^*$  that can perfectly classify all the examples that the learner sees. Moreover, we can assume that there is a *margin* available in the correct classifications. For a correct classification, it should simply be the case that  $y_t \langle w^*, x_t \rangle > 0$ . The margin condition will ensure that there is a lower bound  $\gamma > 0$  such that

$$\forall t, \quad y_t \langle w^*, x_t \rangle \geq \gamma. \tag{14.8}$$

---

**Algorithm 3.** Online Learning of Linear Threshold Functions

---

```

Initialize  $w_0$ 
for  $t = 1, 2, \dots$  do
  Receive  $x_t$ 
  Predict  $\hat{y}_t = \text{sign}(\langle w, x_t \rangle)$ 
  Receive true label  $y_t$ 
  if  $\hat{y}_t \neq y_t$  then
     $w_t \leftarrow \text{LTF-UPDATE}(w_t, \eta, x_t, y_t)$ 
  else
     $w_t \leftarrow w_{t-1}$ 
  end if
end for

```

---

**Theorem 28.** Suppose there exists a  $w^*$  satisfying the margin condition (14.8). Then Perceptron with learning rate  $\eta = 1$  enjoys the mistake bound

$$M \leq \frac{\|w^*\|_2^2 \cdot B_2^2}{\gamma^2},$$

where  $B_2 = \max_t \|x_t\|_2$ .

**Proof.** Let  $T \geq 1$  and note that the number  $M = M_T$  of mistakes till time  $T$  is simply

$$M_T = \sum_{t=1}^T m_t$$

where  $m_t = \mathbf{1}[\hat{y} \neq y_t] = \mathbf{1}[y_t \langle w_t, x_t \rangle \leq 0]$ . Let us calculate how the inner product of  $w_t$  with the vector  $w^*$  evolves. Note that we can write

$$w_t = w_{t-1} + m_t y_t x_t.$$

Thus, we have,

$$\begin{aligned} \langle w^*, w_t \rangle &= \langle w^*, w_{t-1} + m_t y_t x_t \rangle \\ &= \langle w^*, w_{t-1} \rangle + m_t y_t \langle w^*, x_t \rangle \\ &\geq \langle w^*, w_{t-1} \rangle + m_t \gamma, \end{aligned}$$

where the last step is due to the margin assumption (14.8). Summing the above inequality for  $t = 1, \dots, T$  yields

$$\gamma M_T + \langle w^*, w_0 \rangle \leq \langle w^*, w_T \rangle.$$

Since  $w_0 = \mathbf{0}$  and  $\langle w^*, w_T \rangle \leq \|w^*\|_2 \|w_T\|_2$ , we get

$$\gamma M_T \leq \|w^*\|_2 \|w_T\|_2. \tag{14.9}$$

Let us now try to upper bound  $\|w_T\|_2$ . We have,

$$\begin{aligned}\|w_t\|_2^2 &= \|w_t + m_t y_t x_t\|_2^2 \\ &= \|w_t\|_2^2 + 2m_t y_t \langle w_t, x_t \rangle + m_t^2 y_t^2 \|x_t\|_2^2 \\ &\leq \|w_t\|_2^2 + m_t^2 y_t^2 \|x_t\|_2^2,\end{aligned}$$

where the last line is true because  $y_t \langle w_t, x_t \rangle \leq 0$  when  $m_t > 0$ . Also note that  $y_t^2 = 1$ ,  $m_t^2 = m_t$ , and  $\|x_t\|_2 \leq B_2$ . Therefore,

$$\|w_t\|_2^2 \leq \|w_t\|_2^2 + m_t B_2^2.$$

Summing this for  $t = 1, \dots, T$  gives

$$\|w_T\|_2^2 \leq \|w_0\|^2 + M_T B_2^2 = M_T B_2^2.$$

Combining this with (14.9) gives

$$\gamma M_T \leq \|w^*\|_2 \sqrt{M_T} B_2,$$

which gives us the final bound

$$M_T \leq \frac{\|w^*\|_2^2 \cdot B_2^2}{\gamma^2}. \quad \square$$

**Theorem 29.** Suppose there exists a  $w^*$  with positive entries that satisfies the margin condition (14.8). Let  $B_\infty = \max_t \|x_t\|_\infty$ . Then Winnow enjoys the mistake bound

$$M \leq \frac{\log d}{C(\eta)}$$

whenever

$$C(\eta) = \left( \frac{\eta \gamma}{\|w^*\|_1} - \log \left( \frac{e^{\eta B_\infty} + e^{-\eta B_\infty}}{2} \right) \right) > 0.$$

In particular, by setting  $\eta$  optimally, we get,

$$M \leq 2 \frac{\|w^*\|_1^2 \cdot B_\infty^2}{\gamma^2}.$$

**Proof.** Let  $u^* = w^*/\|w^*\|_1$ . Since  $w^* > 0$  (inequality is entrywise),  $u^*$  is a probability distribution. Moreover, Winnow maintains a probability distribution  $w_t$  at all times. We will track the progress of the algorithm using the relative entropy

$$D(u^* || w_t) = \sum_{j=1}^d u_j^* \log \frac{u_j^*}{w_{t,j}}$$

between  $u^*$  and  $w_t$ .

Suppose a mistake occurs at time  $t$ . Then we have,

$$\begin{aligned}
 D(u^{\star}||w_t) - D(u^{\star}||w_{t-1}) &= \sum_{j=1}^d u_j^{\star} \log \frac{w_{t-1,j}}{w_{t,j}} \\
 &= \sum_{j=1}^d u_j^{\star} \log \frac{Z_t}{\exp(\eta y_t x_{t,j})} \\
 &= \log Z_t \sum_{j=1}^d u_j^{\star} - \eta y_t \sum_{j=1}^d u_j^{\star} x_{t,j} \\
 &= \log Z_t - \eta y_t \langle u^{\star}, x_t \rangle \\
 &\leq \log Z_t - \frac{\eta \gamma}{\|w^{\star}\|_1},
 \end{aligned} \tag{14.10}$$

where the last step is due to the margin assumption (14.8). Note that  $y_t x_{t,j} \in [-B_{\infty}, B_{\infty}]$ .  $\square$

For any  $\alpha \in [-B_{\infty}, B_{\infty}]$  and  $\eta > 0$ , we have the inequality

$$e^{\eta\alpha} \leq \frac{1 + \alpha/B_{\infty}}{2} e^{\eta B_{\infty}} + \frac{1 - \alpha/B_{\infty}}{2} e^{-\eta B_{\infty}}.$$

To see this consider a random variable  $Z$  that takes value  $\eta L$  with probability  $(1 + \alpha/B_{\infty})/2$  and takes value  $-\eta L$  with probability  $(1 - \alpha/B_{\infty})/2$ . Then the inequality above is claims that  $\exp(\mathbb{E}[Z]) \leq \mathbb{E}[\exp(Z)]$  which is indeed true by Jensen's inequality. Using the inequality above, we have

$$\begin{aligned}
 Z_t &= \sum_{j=1}^d w_{t-1,j} e^{\eta y_t x_{t-1,j}} \\
 &\leq \sum_{j=1}^d w_{t-1,j} \left( \frac{1 + y_t x_{t-1,j}/B_{\infty}}{2} e^{\eta B_{\infty}} + \frac{1 - y_t x_{t-1,j}/B_{\infty}}{2} e^{-\eta B_{\infty}} \right) \\
 &= \left( \frac{e^{\eta B_{\infty}} + e^{-\eta B_{\infty}}}{2} \right) \sum_{j=1}^d w_{t-1,j} + \left( \frac{e^{\eta B_{\infty}} - e^{-\eta B_{\infty}}}{2B_{\infty}} \right) \sum_{j=1}^d y_t w_{t-1,j} x_{t,j} \\
 &= \left( \frac{e^{\eta B_{\infty}} + e^{-\eta B_{\infty}}}{2} \right) + \left( \frac{e^{\eta B_{\infty}} - e^{-\eta B_{\infty}}}{2B_{\infty}} \right) \sum_{j=1}^d y_t \langle w_{t-1}, x_t \rangle \\
 &\leq \left( \frac{e^{\eta B_{\infty}} + e^{-\eta B_{\infty}}}{2} \right),
 \end{aligned}$$

where the last step is true because, in a mistake round,  $y_t \langle w_{t-1}, x_t \rangle \leq 0$ . Combining this bound on  $Z_t$  with (14.10) gives us, on any mistake round,

$$D(u^{\star}||w_t) - D(u^{\star}||w_{t-1}) \leq -C(\eta),$$

where, we have defined

$$C(\eta) = \frac{\eta\gamma}{\|w^*\|_1} - \log\left(\frac{e^{\eta B_\infty} + e^{-\eta B_\infty}}{2}\right).$$

Thus, for any round,

$$D(u^*||w_t) - D(u^*||w_{t-1}) \leq -C(\eta)m_t,$$

where  $m_t = \mathbf{1}[\hat{y}_t \neq y_t]$ . Summing this over  $t = 1, \dots, T$  gives

$$D(u^*||w_T) - D(u^*||w_0) \leq -C(\eta) \sum_{t=1}^T m_t = -C(\eta)M_T.$$

Since relative entropy is always non-negative  $D(u^*||w_T) \geq 0$ . On the other hand,

$$D(u^*||w_0) = \sum_{j=1}^d u_j^* \log(u_j^* d) \leq \sum_{j=1}^d u_j^* \log d = \log d.$$

Thus, we have

$$-\log d \leq -C(\eta)M_T$$

which gives, whenever  $C(\eta) > 0$ ,

$$M_T \leq \frac{\log d}{C(\eta)}.$$

By choosing  $\eta$  to maximize  $C(\eta)$ , we get

$$\eta = \frac{1}{B_\infty} \log\left(\frac{L + \gamma/\|w^*\|_1}{L - \gamma/\|w^*\|_1}\right)$$

which yields the bound

$$M_T \leq \frac{\log d}{g\left(\frac{\gamma}{B_\infty \|w^*\|_1}\right)},$$

where

$$g(x) = \frac{1+x}{2} \log(1+x) + \frac{1-x}{2} \log(1-x).$$

The second statement of the theorem now follows because  $g(x) \geq x^2/2$  for  $x \in [-1, 1]$ .

## 1.14.7 Beyond the basic probabilistic framework

Our overview of learning theory emphasized the classical setting in which a learning algorithm sees fully labeled data that is an iid draw from an unknown distribution. There are many extensions possible

to this basic setting. We mention a few directions that have been explored by researchers. Many of these continue to evolve actively as new results appear.

*Richer Output Spaces:* We mostly talked about classification and regression. One can certainly consider richer output spaces. The field of *structured prediction* [47] deals with exponentially large output spaces consisting of graphs, trees, or other combinatorial objects. Another output space that arises in ranking applications is the space of permutations of a finite set of objects. There has also been work on learning vector valued functions [48].

*Learning with Dependent Data:* The iid assumption has also been relaxed. Aldous and Vazirani [49], Gamarnik [50] consider Markov chains. Irle [51], Meir [52], Vidyasagar [17], Lozano et al. [53], Mohri and Rostamizadeh [54], Steinwart et al. [55] consider mixing processes. There is also a negative result [56] showing that there is no universally consistent learning algorithm for stationary ergodic processes.

*Learning with Adversarially Generated Data:* As in the mistake bound model, it is possible to develop a theory of learning from online adversarially generated data provided one defines learnability in terms of low regret

$$\sum_{t=1}^T \ell(f_{t-1}(x_t), y_t) - \inf_{f \in \mathcal{F}} \ell(f(x_t), y_t)$$

which compares the performance of the learner's functions  $f_1, \dots, f_T$  to the best function chosen in hindsight (note that the learner has to commit to  $f_{t-1}$  seeing only examples till  $(x_{t-1}, y_{t-1})$ ). Analogues of Rademacher complexity, covering numbers, and fat shattering dimension have been developed [57]. This topic has fascinating connections to information theory and game theory. See [21] for a comprehensive overview.

*Active Learning:* In active learning, we consider situations where the learner has some control over the data it uses to learn. This is in contrast to the basic iid model where the learner passively sees iid data drawn from a distribution. In particularly useful model of active learning, we assume that the learning has access to *unlabeled* points  $X_1, \dots, X_n$  drawn iid from a distribution either all at once (a *pool*) or one at a time (a *stream*). The learner can only query for labels of examples in the pool or the stream. The *label complexity* of the learner is the number of label queries it needs to make in order to achieve a desired accuracy with a given level of confidence. In a lot of situations, unlabeled data is cheap and easy to get. So, it makes sense to charge the learner only for the number of labels it requires. The label complexity of different problems in an active learning has been studied (see, for example, [58] and references therein). Given the practical importance of reducing the number of labels required and the relatively unexplored nature of active learning, a lot remains to be done.

*Semisupervised Learning:* Semisupervised learning refers to learning with labeled data and large amounts of unlabeled data. A lot of work has been done in this area including methods that try to learn classifiers whose decision boundary passed through low density regions of the unlabeled data to graph based methods that use regularization to penalize functions that are nonsmooth along edges of a graph built from unlabeled data. For a good collection of articles on semisupervised learning, see the collection [59]. In the same collection, Balcan and Blum propose a PAC style framework for semisupervised learning.

*Learning Multiple Tasks:* In multitask learning, the learner is faced with learning multiple related tasks. Because of task relatedness, we expect the learner to require fewer samples when the tasks are learned together rather than separately. Many approaches try to encode task relatedness into a

regularization function that couples all the tasks together. Some important advances in our theoretical understanding of multitask learning have been made ([60–63]) but a comprehensive theory, if one exists, remains to be found.

## 1.14.8 Conclusions and future trends

Understanding intelligence and constructing intelligent machines is a great scientific challenge. An understanding of learning is central to an understanding of intelligence. Whether we talk about learning on an evolutionary time scale or learning within the lifespan of an organism, learning plays a crucial role in the development of intelligent behavior. What learning theory has attempted to do so far is provide a solid mathematical framework within which to pose and solve questions regarding the process of learning. Admittedly, the most mature part of learning theory is the theory of supervised learning including classification and regression problems. But this is just a beginning rather than the end. We hope that future research will make learning theory much richer and applicable to a broader variety of problems in both natural and artificial systems.

Learning theory is an interdisciplinary field. It draws ideas and inspiration from a variety of disciplines including biology, computer science, economics, philosophy, psychology, statistical physics, and statistics. It attempts to achieve clarity and rigor by using the language of mathematics to precisely state assumptions and prove results. We expect that interdisciplinary cross-fertilization of ideas will continue to enrich and give new directions to learning theory. For example, learning theory has much to contribute to problems arising in diverse areas such as control [17] and dynamical systems [64], learning in games [65], privacy [66], evolution [67], and mechanism design [68].

---

## Glossary

AdaBoost	Acronym for Adaptive Boosting, a popular boosting algorithm
Bayes classifier	In classification problems with 0–1 loss, a classifier with the least risk
Boosting	The process of converting a weak learning algorithm (that is, one that outputs classifiers whose performance is just a little bit better than random guessing) into a strong one
Concentration inequality	A probabilistic inequality stating that some random variable will not deviate too far from its mean or median
Excess risk	The difference between the risk of a given function and the minimum possible risk over a function class
Empirical risk	Same as risk except that the expectation under the unknown data distribution is replaced with an empirical average over the samples observed
Empirical risk minimization	A learning rule that minimizes the empirical risk to choose a prediction function

ERM	Empirical Risk Minimization
Fat shattering dimension	A scale sensitive generalization of the VC dimension.
Generalization error bound	An upper bound stating that the risk of a learning rule is not going to differ too much from its empirical risk
Kernel	A symmetric positive semidefinite function
Littlestone dimension	A combinatorial quantity associated with a class of binary valued functions. Plays a fundamental role in determining worst case bounds in the online mistake bound model
Loss function	A function used to measure the quality of a prediction given the true label.
Mistake bound model	A model of learning that, unlike the PAC model, does not assume anything about the way data is generated
Model selection	The task of selecting an appropriate statistical model from a family based on available data
PAC model	A computational model for analyzing the resources (time, memory, samples) required for performing learning tasks. Originally defined for the task of binary classification using the 0–1 loss. The acronym PAC stands for “Probably Approximately Correct”
Rademacher complexity	A quantity associated with a function class that measures its capacity to overfit by measuring how well the function class can fit randomly generated $\pm 1$ signs
Regression function	In regression problems with the squares loss, the prediction function with the least risk
Reproducing kernel Hilbert space	A Hilbert space of functions for which there exists a kernel with the reproducing property: point evaluations of functions can be written as linear functionals
Risk	The expected loss of a prediction function under the underlying unknown distribution generating input, output pair
Sample complexity	The number of samples requires to achieve a given level of accuracy (usually with high probability)
Sample compression	An approach to obtaining generalization error bounds for algorithms whose output can be reconstructed from a small number of examples belonging to the original sample
Stability	The property of a learning algorithm that ensures that its output does not change much if the training data set is changed slightly
Supervised learning	The task of learning a functional dependence between an input space and an output or label space using given examples of input, output pairs
Universal consistency	The property of a learning rule to converge to the minimum possible risk as the number of samples grows to infinity

Vapnik-Chervonenkis dimension	A combinatorial quantity associated with a binary valued function class that serves as a measure of the capacity of the function class to overfit the data
VC dimension	Vapnik-Chervonenkis dimension

## 1.15.1 Introduction

Roughly speaking, Neuroinformatics is based on the paradigm to turn ideas from biological neural networks, which serve as very effective information processing units in real life, into efficient artificial machine learning methods in Computer Science. Thereby, the lines between biological motivation and statistical methodology are often blurred, and, today, a thorough mathematical background exists for most techniques from Neuroinformatics independent of their biological counterparts, i.e., Neuroinformatics has become a mature research field on its own independent of its biological roots. There exists a variety of excellent textbooks in this field covering mathematical background as well as modern training algorithms in this context, such as [1–6].

The early beginnings of Neuroinformatics date back to 1943, when McCulloch and Pitts showed the ability of circuits of simple neurons to realize every logical calculation [7]. In 1949, a training paradigm was proposed by Hebb [8], the famous Hebbian learning which states the principle to increase the strength of neurons if they are simultaneously active. This principle forms the base of many learning algorithms which are used today. Algorithmic realizations of Hebbian learning rules for simple neural networks without any intermediate connections have been realized by Rosenblatt [9] and, independently, by Widrow and Hoff [10]. Remarkably, perceptron learning as proposed by Rosenblatt is accompanied by a formal proof of its convergence to a solution if existing. However, research came to a rapid stop after the famous book of Minsky and Papert, “Perceptrons,” has been published. In this book, the authors proved the principled limitation of the Rosenblatt-Perceptron and other simple models [11].

A number of researchers continued to work on relevant topics related to Neuroscience including, e.g., associative memory [12] and the development of the visual system [13]. The breakthrough which brought Neuroscience back to the focus of a large number of researchers was the reinvention of back-propagation for training feedforward neural networks by Rumelhart et al. [14]. This algorithm has been proposed previously by Werbos [15] and it became widely accepted after it has been published a second time. It forms the base for most learning algorithms for multilayer neural networks which are used to date. Today a variety of different learning paradigms, neural architectures, and training algorithms exists which offer efficient tools for machine learning in diverse areas including pattern recognition, robotics, bioinformatics, or natural language processing.

Often, the biological background only plays a minor role in modern applications and neural learning techniques constitute special cases of more general statistical learners such as, e.g., general regression or classification models, generative statistical models, Bayesian techniques, and similar, see textbooks such as [1]. In this context, current problems typically center around the question of how to deal with larger and larger data sets, how to arrive at even more efficient learning techniques, how to integrate prior knowledge and structural constraints, how to make the decisions of neural networks accessible for humans, and similar. These research questions are no longer specific for neural networks, rather they occur in virtually all machine learning scenarios.

However, quite a few recent developments in the context of neural networks have been triggered by biological counterparts, again: deep learning architectures can be traced back to typical processing pipelines in the human visual system and its progressive representation of more and more abstract visual stimuli [16]. At present, deep learning architectures are discussed as one general principle to directly address complex input patterns in neural network architectures without the necessity of complex, domain-specific preprocessing of the given signals. Reservoir computing constitutes another example where biologically motivated paradigms offer a possible solution to long-standing problems in Neuroinformatics. Partially recurrent neural networks deal with time dependent signals as input data, and, thus, have potential impact on areas such as temporal signal processing, speech recognition, or motion generation. Training such networks, however, has been a problem due to inherent numeric difficulties of typical learning algorithms. Reservoir networks are based on a randomly wired recurrent network with very high dimensionality and a very simple readout, similar to intuitive recurrent processing as could happen in the brain [17,18]. They offer a partial answer to the complexity of recurrent neural network training by simply making it superfluous. These issues will be addressed in this chapter in more detail.

The main goal of this chapter is to give a representative picture of different relevant architectures of the “zoo” of neural networks. The emphasis lies on the principled idea behind the respective models and an understanding of their strengths and restrictions with links to further reading. We will give hints on principled training algorithms, and we will discuss mathematical issues which arise when training such networks using given examples. Naturally, this overview is necessarily limited to some of the most important neural architectures which are used today.

---

### 1.15.2 Learning with single neurons

Let us start with a simple problem: we would like to automatically classify handwritten digits, e.g., to automatically read the ZIP code hand written on letters and collected in a US postal office. For this purpose, we accumulate examples where we know the intended digit, assigned to by a person, the *training set*. Depending on the digitalization, we can assume that each example consists of an input vector in, say,  $\mathbb{R}^{64}$ , corresponding to a representation of the digit in a  $8 \times 8$  matrix with gray values. We represent the output class by a number. Generally, inputs stem from  $\mathbb{R}^n$ ,  $n$  being any fixed number, the input dimensionality. Outputs are class labels. For simplicity, we start with only two classes for the moment, 0 and 1. Actually, data sets of such type constitute typical benchmarks for neural classification algorithms even today, two popular data sets being the USPS (see <http://www-stat-class.stanford.edu/~tibs/ElemStatLearn/data.html> file called ZIP code) and the MNIST (see <http://yann.lecun.com/exdb/mnist/>) data sets.

Neural networks offer one possible mechanism to infer a classification describing an unknown regularity based on a finite number of examples. We start with the simplest neural network one can think of: a single neuron, more precisely, the perceptron.

### 1.15.2.1 The simple perceptron

The function of biological neural networks is well investigated and their dynamics can be described referring to the Hodgkin-Huxley model, for example [19]. Biological neurons can be interpreted as signal processing units based on electric currents. While the biological Hodgkin-Huxley model describes the dynamics of the most relevant ions regarding their spatio-temporal location in detail, abstractions in Neuroinformatics integrate over the spatial location of the electric current of all ions, or they even abstract from the precise temporal dynamics, referring to the mean firing rate of neurons.

The *perceptron* constitutes a particularly simple neuron which restricts information to a simple digital signal: 0 or 1 corresponding to active or inactive synapses. This abstraction allows to characterize a perceptron by its function:

$$\mathbb{R}^n \ni x \mapsto H(\mathbf{w}^t x - \theta) \in \mathbb{R},$$

whereby  $\mathbf{w} \in \mathbb{R}^n$  is the so-called *weight-vector* of the neuron, and  $\theta \in \mathbb{R}$  the *bias*. As usual,  $\mathbf{w}^t x$  denotes the dot product of the two vectors.  $H : \mathbb{R} \rightarrow \mathbb{R}$  denotes a nonlinear *activation function*, in the case of the perceptron it is the Heaviside function with

$$H(x) = \begin{cases} 1 & \text{if } x \geq 0, \\ 0 & \text{otherwise.} \end{cases}$$

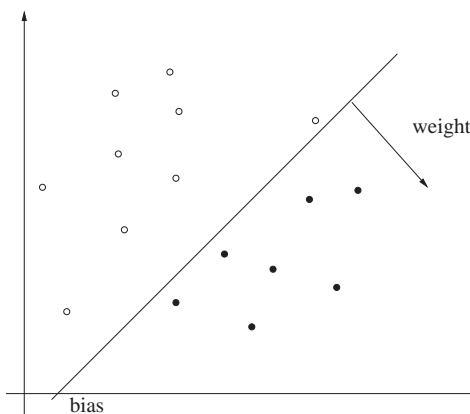

Thus, the neuron computes the weighted sum of inputs, compares the result with the bias, and outputs a signal depending on its *activation*  $\mathbf{w}^t x - \theta$ . This procedure resembles biological neurons which integrate incoming signals and fire depending on their action potential whereby, for the artificial counterpart, spatiotemporal aspects are neglected.

This function has an exact geometric counterpart: a perceptron defines a separating hyperplane of the data. The weight vector  $\mathbf{w}$  determines the orientation of the hyperplane, the bias  $\theta$  the offset. Thus, it defines a simple linear classification boundary, see Figure 15.1. For simple data sets or high dimensionality, a linear classifier is often sufficient to separate a given data set appropriately.

How can we get appropriate parameters  $w$  and  $\theta$  given a set of training data? The *perceptron training algorithm* is a very simple method which can be formulated in a few lines of code:

```
init  $\mathbf{w}, \theta$  randomly
repeat:
    choose a training example  $(x, y)$ 
    if  $H(\mathbf{w}^t x - \theta) \neq y$ 
         $\mathbf{w} := \mathbf{w} + x, \theta := \theta - 1$  if  $y = 1$ 
         $\mathbf{w} := \mathbf{w} - x, \theta := \theta + 1$  if  $y = 0$ 
```

The adaptation rule constitutes an instance of Hebbian learning: given an example which is wrongly classified as 0 but it should be 1, all weight components which receive a positive signal are reinforced by adding the input signal  $x$ . For a wrong classification as 1 which should be 0, the weight components

**FIGURE 15.1**

Two-class classification problem represented by points in the euclidean plane. Since the set is linearly separable, a simple perceptron can serve as classifier. It is uniquely characterized by its weight vector and bias.

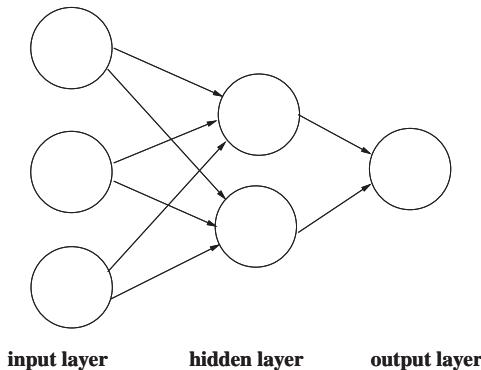

which receive a negative signal are increased. One can show that this learning rule converges towards a solution without errors, if it exists. It finds a solution with a minimum number of errors with high probability, provided the examples are randomly chosen and the best solution found so far is stored [9].

Because of the fact that a perceptron corresponds to a separating hyperplane, training sets which can correctly be classified by a perceptron are called *linearly separable*. Obviously, a perceptron can solve exactly those problems (up to a few errors), which are (almost) linearly separable. For very high dimensional data as present, e.g., in biomedical application dealing with mass spectra or microarrays, this is often the case. In general, decision boundaries are nonlinear in realistic problems. But even if we restrict to linear problems, a few questions arise at this point: how complex is perceptron learning, i.e., what is the number of iterations the algorithm requires until convergence? Can we guarantee, that perceptron learning finds the underlying regularity of the classification which we would like to learn and does not only map the given training set correctly? These two questions concern the *complexity of learning* and the *generalization ability*. We will consider these questions after having defined more general feed-forward neural networks for nonlinear problems.

### 1.15.2.2 Feedforward networks

A feedforward neural network consists of a number of neurons which are connected in an acyclic directed graph. Often, the neurons are arranged in layers, the neurons without predecessors forming the *input layer*, the neurons without successors forming the *output layer*, the ones in between forming the *hidden layer* or hidden layers, see Figure 15.2. Such a network computes a highly nonlinear function by combining the functions of single neurons according to the given connection graph.

Formally, this function can be defined as follows: Assume the number of input neurons is  $n$ , the number of output neurons is  $m$ ,  $w_{ji}$  constitutes the weight of neuron  $i$  pointing from neuron  $j$ , and  $\theta_i$  is the bias of neuron  $i$ . The activation function of every neuron is fixed, often the logistic function

**FIGURE 15.2**

A layered feedforward neural network with one hidden layer.

$\sigma(x) = (1 + \exp(-x))^{-1}$  or the hyperbolic tangent  $\tanh(x)$  are chosen. Such a network computes a function  $f_W : \mathbb{R}^n \rightarrow \mathbb{R}^m$ ,  $x \mapsto (o_{i_1}, \dots, o_{i_m})$ , which maps an input vector to the output values of the output neurons of the network. The function is parameterized by the weights and biases  $W$  in the network. The numbers  $i_j$  constitute the indices of the output neurons. The output  $o_i$  of a neuron  $i$  is recursively defined as follows:

$$o_i = \begin{cases} x_i & \text{if } i \text{ is an input neuron,} \\ \sigma(\sum_{j \mapsto i} w_{ji} o_j - \theta_i) & \text{otherwise.} \end{cases}$$

The activation of a single neuron is abbreviated by the term  $\text{net}_i = \sum_{j \mapsto i} w_{ji} o_j - \theta_i$ . Obviously, such a network can realize highly nonlinear functions. The perceptron activation function is substituted by the sigmoidal function which approximates the perceptron function for large inputs, but which is differentiable. This feature is used to derive training algorithms for multi-layer networks, as we will see below. A single sigmoidal unit can be interpreted as an approximation of a simple perceptron in its saturated regions. Often, however, sigmoidal neurons are activated in their linear area around 0. This feature can be motivated by another observation from biology: taking real values as average firing rate of neurons, a sigmoidal function mirrors the typical transfer dynamics of biological neurons.

A feedforward neural network can not only represent a simple binary classification such as the perceptron, but classification with more than two classes or real-valued functions. How can such a network be trained? Since the activation function  $\sigma$  is differentiable, the following mathematical principle can be taken: Given a set of training patterns of the form  $(x^p, y^p)$  the *mean square error* is defined as the quantity

$$E = 1/2 \cdot \sum_p (f_W(x^p) - y^p)^2.$$

This error measure constitutes a differentiable function which maps the weights  $W$  of the network to a real number indicating whether the current function approximately represents the given data set or not. Training consists in a minimization of this cost function by means of a numeric optimization

method, commonly a variation of a gradient descent. A simple *gradient descent* is given by the following pseudocode

```
init  $W$  randomly
repeat:
   $W := W - \eta \cdot \nabla_W E$ 
```

Thereby,  $\nabla_W E$  constitutes the vector of derivatives of  $E$  with respect to the weights  $w_{ij}$  and biases  $\theta$ .  $\eta > 0$  is a (small) learning rate. Initialization of the weights is usually done with small random values around 0.

A *stochastic gradient descent* decomposes the mean square error into the contributions of single patterns  $E = \sum_p E_p = 1/2 \cdot \sum_p (f_W(x^p) - y^p)^2$  and iteratively adapts according to a randomly chosen pattern:

```
init  $W$  randomly
repeat:
  choose  $p$  randomly,
   $W := W - \eta \cdot \nabla_W E_p$ 
```

This can also be applied in an online scenario where the patterns are not known beforehand but generated during training.

For feedforward networks, a particularly efficient way to compute the derivative  $\nabla_W E_p$  resp.  $\nabla_W E$  is used in the famous *back-propagation algorithm*. Note that the recursive definition of the outputs  $o_i$  allows to compute the derivative of  $o_i$  with respect to weights and biases directly in a recursive way, however, the complexity of this method is  $\mathcal{O}(|W|^2)$ ,  $|W|$  being the number of weights. Back-propagation defines the error terms  $\delta_j = \partial E_p / \partial \text{net}_j$ . It holds

$$\partial E_p / \partial w_{ij} = o_i \cdot \delta_j$$

and

$$\partial E_p / \partial \theta_j = -\delta_j.$$

The error terms  $\delta_j$  can be computed in linear time by back-propagation

$$\delta_j = \begin{cases} (o_j - y_j^p) \cdot \sigma'(\text{net}_j) & \text{if } j \text{ is an output neuron} \\ \sum_{j \rightarrow k} w_{jk} \delta_k \cdot \sigma'(\text{net}_j) & \text{otherwise} \end{cases}$$

propagating the error signals from the output neurons back to the hidden neurons. Note that numeric optimization techniques with a better convergence rate are usually applied today such as, e.g., approximate conjugate gradient techniques or alternative higher order methods. Still, these numeric techniques center around the partial derivatives and its efficient computation by means of back-propagation. Further, simple back-propagation has the benefit that it can be applied in classical batch mode as well as in online scenarios. Batch learning usually refers to the situation where all training examples are known in advance. In such cases, the full error function is available and numerical techniques which take into account, e.g., the curvature of the cost function can be used. In online settings such as, e.g., reinforcement learning or robotics, training data become available on the fly and adaptation has to take place immediately after a novel training example has been presented. In this case, a stochastic gradient descent can be used which corresponds to simple back-propagation applied separately for every given data point.

### 1.15.2.3 The training pipeline

A variety of questions arises in this context:

1. How do we choose the architecture?
2. What can we do if the training error does not decrease?
3. Does the network behave correctly for future patterns if it maps the training data correctly?

#### 1.15.2.3.1 How do we choose the architecture?

There is an easy answer to this question and a more complex one: the easy one—just try it and choose the best architecture you can find. Commonly, the suitability of an architecture is evaluated by means of cross-validation. That means, the architecture is trained on a part of the data set and its mean squared error evaluated on the remaining test set. To reduce statistical effects, this is repeated  $k$  times using disjoint test sets which decompose the given set of training data.

The complex answer to the question of how to choose the architecture puts some light on relevant aspects of feedforward networks: Unlike simple perceptrons, feedforward neural networks are *universal approximators*, i.e., they are capable of approximating every reasonable (e.g., continuous) function on a compact set up to any desired precision provided at least one hidden layer with a sufficient number of hidden neurons is available and an activation function such as the logistic function is used [20]. Hence, feedforward networks can, in principle, represent any regularity arbitrarily well. In consequence, an appropriate architecture can be found for any given training problem. In principle, the number of hidden layers can be restricted to one hidden layer, or, in practice, a small number of hidden layers.

How do we evaluate an architecture? One evaluation measure is the error on the training set. If this is large, the architecture is not expressive enough to represent the regularity which has to be learned. However, if the error is small, this does not necessarily guarantee that the underlying regularity has been learned, only the part represented by the training set is correct. One can think of a neural architecture as a parameterized function class, whereby the number of parameters depends on the number of neurons of the architecture. It has to be guaranteed, that a sufficient number of parameters is available to represent the training data correctly. At the same time it has to be guaranteed that no free parameters of the architecture are left which are not sufficiently specified given the current training set. If so, the output for data points not present in the training set could be random.

This problem is known as *bias-variance-dilemma*: architectures which are too small have a large bias, i.e., a large deviation from the desired outputs already on the training set. Architectures which are too large have a large variance, i.e., the output of patterns not contained in the training set is random because the parameters of the architecture are not determined by the training set.

#### 1.15.2.3.2 How to minimize the training error?

When applying simple back-propagation, training is often a very tedious task. This is due to several properties of the error surface when training neural networks. First of all, the error surface is multimodal and gradient descent methods are often trapped in local optima instead of global (or good) optima of the cost function. This problem is partially unavoidable because the problem of finding a global minimum of the mean squared error for neural networks is an NP-hard problem, as shown, e.g., in [21,22]. Remarkably, NP-hardness is already present when minimizing the mean squared error of a single neuron, or when training simple perceptrons for non-linearly separable data sets.

In practice, complex error surfaces and bad local optima can partially be avoided by simplifications of the training task using data preprocessing. This way, all relevant information is available for the network in explicit form and the dependency of the function value on the inputs is more simple. Standard preprocessing includes, for example, standard procedures such as normalization of the input variables as well as a variety of problem-dependent features, e.g., for image processing (such as filters) or time series analysis (such as Fourier or wavelet transform). Appropriate preprocessing of data can be time consuming and there is no recipe how to solve this problem in general.

Current research connected to Neuroinformatics centers around the question how complex preprocessing can be avoided. Alternatively, how can an appropriate representation of data autonomously be detected by the neural system itself? A very promising approach centers around deep learning, which deals with neural architectures with many hidden layers but a highly regularized and symmetric structure [16]. Intuitively, these architectures can extract complex features from the data by an iterative combination of simple features as represented by parts of those networks. High symmetry such as, e.g., weight sharing in different parts of the network make sure that globally meaningful and uniform local feature extractors result. However, training deep neural networks using back-propagation is usually very difficult if not impossible due to numeric problems, such that alternative iterative learning strategies are usually applied. Recent developments in this field can be found, e.g., at a NIPS 2010 workshop (see <http://deeplearningworkshopnips2010.wordpress.com/schedule/>) or the deep learning web site (see <http://deeplearning.net/>).

The problems which make a simple gradient technique unsuitable for training very deep architectures, also partially occur for standard feedforward networks of reasonable size. Because of the logistic activation function, the error surface of sigmoidal networks is composed of plateaus mixed with very steep parts. This causes oscillation or stagnation of the optimization procedure, depending on the curvature of the surface and the learning rate. Thereby, these effects can occur simultaneously with respect to different parameters which have to be optimized.

Various improvements of simple back-propagation try to overcome these problems such as higher order optimization methods [4]. One particularly powerful and, at the same time, very simple learning schemes which allows to train standard feedforward networks very efficiently is offered by *resilient propagation* (RProp) [23]. The idea is to use a separate adaptive learning rate for every parameter which determines the step size into this direction. The derivative does only contribute the direction of the step, but not its size. The step size is increased if the gradient points into the same direction in consecutive steps (i.e., likely a plateau is present) and it is decreased if the sign changes (i.e., oscillation takes place), whereby bad steps are retracted.

Another very interesting line of research centers around even more efficient training algorithms which do not rely on numeric optimization techniques. The *extreme learning machine* is based on the observation that feed-forward neural networks can approximate every given training set provided enough hidden neurons are available even if the connections of the inputs to the hidden neurons are random. In consequence, the extreme learning machine randomly generates a large hidden layer and only trains the linear readout. Interestingly, this very simple mechanism can yield good results for practical applications [24]. This principle is very similar to reservoir computing, a technique to deal efficiently with recurrent neural networks, which we will discuss below.

### 1.15.2.3.3 Does the network generalize to novel data points?

We have already discussed this issue in the context of how to choose an architecture: if the architecture is too flexible, it maps the training data correctly, but it can behave randomly on novel data points not used for training. Therefore, in practice, the *generalization ability* of a network is often tested by means of a hold out set which has not been used for training, the test set.

However, the question remains whether there exist any guarantees that a small training error also leads to a small test error provided the training set is large enough. Such guarantees can be derived in the framework of statistical learning theory: one can limit the “freedom” which is contained in a network with  $|W|$  parameters. One popular quantity which measures this capacity of a network is offered by the so-called *Vapnik-Chervonenkis dimension* of the function class [25]: The Vapnik-Chervonenkis dimension measures the combinatorial capacity of the architecture, i.e., the number of points for which every possible classification can be realized within the given neural architecture. The VC dimension of a sigmoidal feedforward network can be limited by a polynomial in the number of weights  $|W|$  [26]. Depending on this quantity, the deviation of the empirical error and the generalization error of the network for new examples can be limited with high probability regardless of the underlying distribution [25].

This formalization and test of the ability of a neural architecture to learn an underlying regularity is often referred to as the frequentist point of view, since the generalization error is limited by means of statistical counting arguments. Apart from an explicit posterior bound or estimation of the generalization ability obtained this way, it motivates another objective of neural networks training: a minimization of the training error is often accompanied by additional mechanisms which explicitly reduce the degrees of freedom of the network architecture. A popular example of this paradigm is given by a limitation of the weight sizes, a mechanism which can be linked to Tikhonov regularization in some cases. Another example refers to a pruning of connections, weight sharing, or some other form of regularizer incorporated in the cost function [1, 27]. One particularly popular form of regularization is included in training of the support vector machine or some forms of learning vector quantization, an optimization of the margin of the classifier, as we will explain below.

This frequentist point of view is complemented by a Bayesian treatment as explained, e.g., in the seminal work [27]. Here, instead of focussing on just one architecture which, from a statistical point of view often corresponds to a single parameter setting which is most likely given the current observations, a full probabilistic model is inferred for the data and the range of possible parameters. This includes an inherent regularization of the result such that overfitting does not occur. This benefit is paid for by a more complex training procedure where integrals corresponding to the infinite number of possible parameter settings have to be addressed. Here, a rich repertoire of techniques has been developed which make this problem feasible ranging closed form solutions for specific cases to efficient and general Markov chain Monte Carlo techniques [28].

---

## 1.15.3 Recurrent neural networks

Feedforward architectures are characterized by acyclic graphs. Biological networks possess back-connections. What happens, if we introduce cycles in a neural network? So-called recurrent neural networks consist of neurons which are connected in an arbitrary cyclic graph. Due to these cycles, the

activation of neurons depends on each other, and a simple iterative definition is no longer possible, rather, the dynamics of how the neurons are activated has to be taken into account.

There exist basically two different types of recurrent networks: fully recurrent networks which are used as associative memory, and partially recurrent networks which are used to model dynamic systems and to process time series.

### 1.15.3.1 A brief look at Hopfield networks

*Hopfield networks* are fully recurrent networks where the single neurons resemble perceptrons with Heaviside activation function. Original Hopfield networks are restricted to symmetric connections, i.e.,  $w_{ij} = w_{ji}$ , without self-repression, i.e.,  $w_{ii} \geq 0$ . Because of the recurrence, outputs of neurons are time dependent. Given a state  $o_j(t)$  of the system at a point in time  $t$ , every neuron computes its activation

$$\text{net}_i(t) = \sum_{j \rightarrow i} w_{ji} o_j(t) - \theta_j.$$

Typically, Hopfield networks are driven in asynchronous mode, i.e., at every time point a neuron is picked at random and changes its state according to

$$o_i(t+1) = H(\text{net}_i(t))$$

if discrete time steps are considered. The output of all other neurons is not changed in this step. Alternative to this dynamics, Hopfield networks can be driven in synchronous mode, in which all neurons change their state simultaneously according to the current input. This dynamics is particularly interesting if a generalization to continuous time is considered and the dynamics is described by corresponding differential equations.

It can be shown that, due to the symmetry of weights, Hopfield networks converge towards a *stable pattern* if driven in asynchronous mode, i.e., a state where no neuron changes its activation any more [5]. This way, Hopfield networks can be used as associative memory which assigns a completed pattern to an initial, possibly disrupted initialization. For a synchronous update mode, cycles of length two can occur in discrete time, but convergence is observed in continuous time.

Training Hopfield networks refers to the task to store a given set of patterns as stable states of a networks. A very fast training heuristic is offered by Hebbian learning: the weight  $w_{ij}$  is set proportional to the number of patterns for which the neurons  $i$  and  $j$  have identical activation. This learning rule works reliably for orthogonal or nearly orthogonal patterns. In general, cross-correlations occur and the stored patterns become disrupted.

A more general method consists in a reduction of Hopfield training to a perceptron learning problem [5]. This procedure yields to a solution if existing. It also demonstrates a principled restriction of Hopfield networks: the patterns which can be stored by Hopfield networks correspond to linearly separable data. More general networks which also possess hidden neurons have been proposed: Boltzmann machines substitute the crisp binary-valued activation by probabilistic neurons which states are distributed according to a Boltzmann distribution for a given temperature  $T$  [5]. Training refers to an optimization of this distribution such that it approximates the uniform distribution on a given set of pattern as much as possible as measured by the Kullback-Leibler divergence. Interestingly, Boltzmann

machines can be trained using hidden neurons, such that their storage capability is strictly enhanced as compared to simple Hopfield networks, and they can, in principle, represent every given set of patterns. It turned out that Boltzmann machines have a large potential for the unsupervised training of the layers in deep feedforward networks [16].

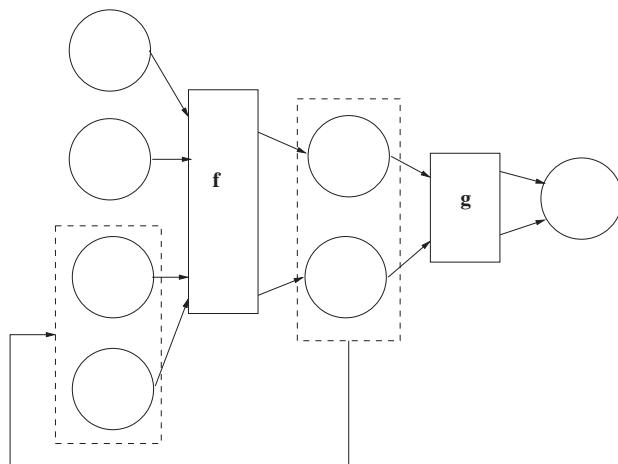

### 1.15.3.2 Recurrent neural networks

*Partially recurrent networks* have only a limited feedback which can be used to model temporal dependencies, e.g., in dynamic systems. This way, temporal sequences can be addressed. The dynamics is driven by the input sequence  $x(t)$  with temporal dependency  $t$ . A standardized dynamics is offered by the following equation

$$\begin{aligned} z(t) &= f(x(t), z(t-1)), \\ o(t) &= g(z(t)). \end{aligned}$$

$x(t)$  is the input at time step  $t$ ,  $z(t)$  describes the internal state of the recurrent network at time  $t$ , and  $f$  and  $g$  are computed by standard feedforward neural networks. See Figure 15.3 for an example. These dynamic equations can be generalized to a continuous dynamics by means of differential equations which characterize the state change over time.

If such a network is used for time series prediction, a sequence  $(x(t), y(t))$  of training patterns is given. Similar to feedforward networks, training can take place by minimization of the mean squared error  $E = 1/2 \cdot \sum_t (y(t) - o(t))^2$ . This can be done by a gradient descent, since the function is differentiable with respect to the weights. Thereby, there exist basically two different methods to compute the gradients within recurrent networks: back-propagation through time and real time recurrent learning.

**FIGURE 15.3**

Partially recurrent neural network in the Elman style, recurrent connections enable a processing of time dependent inputs in their temporal context.

*Back-propagation through time* directly transfers back-propagation to recurrent networks. The key observation consists in the fact that a recurrent network can be substituted by an equivalent feedforward network by unfolding in time. Thereby, the weights are shared between the copies. The gradient with respect to a weight  $w_{ij}$  results from the sum of gradients with respect to all copies of  $w_{ij}$  in this unfolded network. These latter terms can be computed by means of standard back-propagation. The time complexity is  $\mathcal{O}(|W| \cdot T)$ ,  $T$  being the length of the sequence, and the required space is  $\mathcal{O}(|W| \cdot T)$ .

As an alternative, one can compute the derivatives with respect to the weights directly from left to right in the unfolded network based on the recursive definition of the activation of neurons. This procedure has time complexity  $\mathcal{O}(|W|^2 \cdot T)$  but the required space is independent of the maximum time length  $T$ . In particular, the derivatives with respect to copies of  $w_{ij}$  for early time steps are available independent of the remaining time series. Hence, applying the changes according to early time steps directly, this method can also be used in an online scenario. This method is referred to as *real time recurrent learning*.

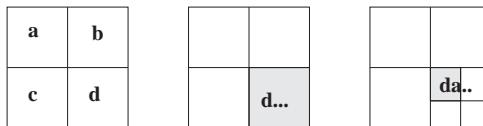

As for training of feedforward networks, several questions occur: how do we choose the architecture? In principle, partially recurrent networks are approximation complete in the sense that they can approximate any dynamic system with continuous transition function on a finite time horizon [29]. For a given training task, the architecture is chosen by cross-validation, as for feedforward networks.

What is the complexity of training recurrent neural networks? Since training feedforward networks constitutes a special case of training recurrent networks, the problem is NP-hard in the worst case. Besides this theoretical result, training recurrent networks turned out to be considerably more difficult than training feedforward networks. Already for small networks containing only two neurons, recurrent neural networks can induce a rich dynamics which includes the full dynamic spectrum ranging from stable states, periodic and quasiperiodic behavior, to chaotic systems [30]. Thereby stable behavior need not be preserved in the course of learning [31] and additional effort has to be taken to guarantee stability of the outcome [32]. Training using a gradient descent faces principled restrictions due to the so-called problem of *long-term dependencies* [33]. This refers to the fact that error signals either blow up within the neural network or vanish when back-propagated over time, such that they can hardly be stored over a long time context. Specific recurrent architectures which address this problem include long short term memory as a prominent example [34] where recurrence is restricted to linear neurons for which gradients can safely be back-propagated.

### 1.15.3.3 Learning without training recurrent connections

An alternative for recurrent neural network training has recently become popular: in reservoir computing, the recurrent part of the network is not trained according to given supervised signals. Instead, a sufficiently rich recurrent part is initialized, and a trainable readout is added to this state representation which can efficiently be trained because the mean squared error for a linear function gives rise to a convex cost function. Reservoir computing includes early approaches such as fractal prediction machines, and the recent popular echo state networks and liquid state machines [17, 35, 36]. Here we only explain the first two, since the latter is based on spiking neurons, which are biologically more plausible, but beyond the scope of this chapter.

Fractal prediction machines directly encode sequences over a finite alphabet by means of fractal codes. Assume the number of symbols is  $s$ . A fixed dimensionality of the internal state space is chosen and the unit hypersquare in this space is decomposed into  $s$  regular hypersquares. A function  $f_a$  is

**FIGURE 15.4**

Fractal encoding of sequences over a finite alphabet, fractal prediction machines encode symbolic sequences in a real vector space in a similar way as recurrent networks with small weights. In the limit, time series give rise to a fractal set in the encoding space.

associated with every symbol  $a$ . The function is the affine mapping which transforms the unit square to the square associated with  $a$ . Starting with a fixed initial value 0, the sequence  $a_1 \dots a_t$  can be encoded as  $f_{a_1} \circ \dots \circ f_{a_t}(0)$ . See Figure 15.4 for an example. Note that the set of points which are obtained by encoding all possible sequences constitutes a fractal set in the considered space. The precision of the location of a code determines the length of the sequence which can uniquely be decoded. On top of this code, a standard network or any alternative classifier can be trained. It has been shown in [36] that these simple models are often as powerful as standard recurrent neural networks. In particular, they exactly resemble the behavior of recurrent networks with small weights, i.e., recurrent neural networks during the initial phase of training.

Echo state networks use a large state space dimensionality such that a rich reservoir is available. The encoding function  $f$  of the recurrent network is given by a simple sigmoidal network with sparse random connections of the neurons and random weights. Thereby, the echo state property must be fulfilled, i.e., the internal state of the network is independent of the initial condition if a long enough recurrence is applied. This can be guaranteed, e.g., by a contractive transition function, which can easily be tested considering the spectral radius of the linear part of the transition. This way, the recurrence constitutes an encoding very similar to fractal encodings due to the echo state property, whereby a rich reservoir accounts for sufficient precision of the representation. On top of this code, a trainable (often even only linear) network is added. Despite their simplicity, echo state machines constitute quite powerful models with successful applications and biological plausibility [17].

It has been shown in [37] that the restriction of the recurrence to contractive mappings has beneficial effects with respect to the generalization ability of the network. For contractive networks, the generalization ability does not depend on the dimensionality of the state space, but on the contraction coefficient of the transition function. Generalization bounds can be obtained which depend on this contraction coefficient and the number of examples used for training. For general recurrent networks, it is not possible to obtain generalization bounds just in terms of the number of network parameters as shown in [38]. Unlike for feedforward networks, the concrete data distribution has to be taken into account to develop generalization bounds for general recurrent networks. Concrete bounds which take the data distribution (possibly as manifested in the training set) into account have been developed in [38], for example.

#### 1.15.3.4 Connection to the Chomsky hierarchy

Interestingly, a very strong link of different types of recurrent networks to classical computing mechanisms exists. The motivation behind this fact can, among other things, be traced back to the question

whether recurrent networks constitute suitable models to explain the perception of natural language by humans. Remarkable results on language processing with recurrent networks have been achieved already by Elman [39], the debate about the suitability of recurrent models for language processing still going on, see, e.g., [40–42].

It has rigorously been shown in [37] that recurrent neural networks with small weights, i.e., contractive transition function are equivalent to definite memory machines, i.e., models which have only a finite time horizon.

For larger weights, a strong connection to finite automata has been established, showing, on the one hand, the possibility to simulate every automaton on an infinite time horizon [43], on the other hand, establishing methods for automata insertion prior to training and automata extraction after training [44]. The capacity of recurrent networks with arbitrary weights, however, is larger. Several approaches succeeded in training networks on simple context free resp. context sensitive languages which include a counting mechanism [34, 45]. This is particularly interesting since natural language is believed to be somewhere between the class of context free and context sensitive languages.

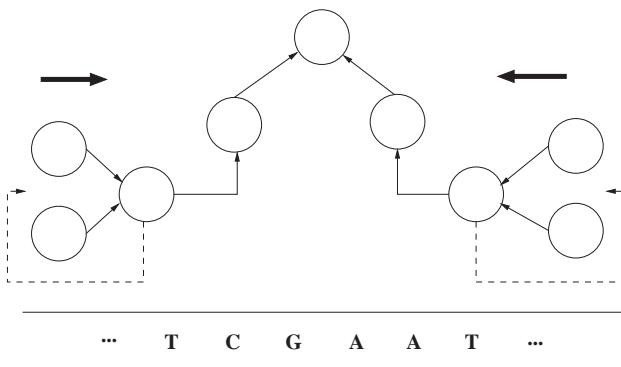

When neglecting learnability of the languages, one can even go a step further and connect recurrent networks to general Turing machines. The notion of simulation of possibly non halting computations with Turing machines in polynomial time has to be established. For this purpose, the Turing band is encoded in the activation of several specific neurons, and a specific neuron is identified which indicates the halting of a computation. Under this condition, it has been shown in [46] that neural networks with rational weights and the so-called semilinear activation function ( $\text{lin}(x) = 0$  for  $x \leq 0$ ,  $\text{lin}(x) = x$  for  $x \in [0, 1]$ ,  $\text{lin}(x) = 1$  for  $x \geq 1$ ) can simulate every Turing machine. A similar result (but requiring exponential time) has been shown for sigmoidal recurrent networks in [47]. Interestingly, recurrent networks with arbitrary (irrational) weights are even more powerful: sigmoidal networks can compute every function (in exponential time) on unary inputs [48]. Recurrent networks with arbitrary weights and the semilinear activation function are in fact equivalent to non-uniform Boolean circuits [46], a class which is beyond Turing computability. Of course, these functions cannot, in principle, be learned from a finite training set, such that the relevance of these results is more of theoretical interest.

### 1.15.3.5 Recurrent networks for structure processing

Partial recurrent neural networks can be used for time series processing, e.g., language, sensor data, financial time series, etc. Thereby, the structure of the data coincides with the dynamics of the network due to the time dependency of the series. A variety of generalizations of recurrent networks has been proposed which extend the applicability to more general data structures.

### 1.15.3.6 Spatial data

Spatial data such as DNA sequences differ from time series in their causality: for time series, strong causality holds in the sense that the future depends on the past but not vice versa. For spatial sequences, entries at the beginning or the end might influence each other without any restriction. Thus, if sequences are processed by recurrent networks, a causality assumption which might not be correct is assumed. In particular, the result of the processing can be different depending on the fact whether sequences are processed from the right or the left. Because of this fact, *bicausal neural networks* have been proposed in the approach [49]. These networks consist of two recurrent neural networks which process the sequence

**FIGURE 15.5**

Bicausal recurrent network for spatial sequence processing, e.g., DNA sequences. Due to two “directions” of the processing, spatial dependencies can be captured by these networks.

simultaneously from the left resp. from the right. The readout processes the output of both networks together such that, at this position, full information is available. The network is trained as a whole, i.e., full information is available also during training, see Figure 15.5. This method has successfully been used for splice site recognition and various tasks in protein structure prediction [49–51].

Another alternative model has been proposed in [52]. This is based on so-called recursive cascade correlation. *Cascade correlation* constitutes a method to simultaneously obtain the architecture and the weights of feedforward networks. It starts with a single output neuron without hidden neurons which is trained on the given training task. Then the following procedure is repeated until the classification result is satisfactory: a hidden neuron is added and connections from the input neuron and all existing hidden neurons to the new one are drawn. These connections are trained such that the correlation of the output of this hidden neuron and the error of the network as exists so far is maximized. The idea behind this procedure is that the hidden neuron can then be used for error correction. After training the connections to the hidden neuron are frozen. After introducing a hidden neuron, all connections to the output are trained such that the classification error is minimized. This procedure is repeated, adding the necessary number of hidden neurons while training the network.

The same procedure can be introduced for recurrent networks whereby a hidden neuron is pointed to by recurrent connections from the neuron itself and all previous hidden neurons. This way, we can introduce functional dependencies not only from the activation in the given time step, but also the previous time step. The principled training procedure is the same as for simple cascade correlation, whereby error signals are back-propagated through the recurrent connections as in back-propagation through time.

A *recurrent cascade correlation network* (RCC), unlike a simple recurrent network, possesses restricted recurrence since no recurrent connections from hidden neurons pointing to neurons introduced earlier are available. This restriction has the effect that RCC is strictly weaker than full recurrent networks since, as shown in [53], RCC networks cannot represent all finite automata, whereas recurrent networks can. However, this restriction has the effect that recurrent connections which refer to later time steps can be introduced as long as this is restricted to hidden neurons which are already frozen.

The resulting dynamic definition is acyclic. These networks, *contextual recurrent cascade correlation*, have been successfully introduced in [52]. They are trained in the same way as RCC networks, but integrate more context suitable for spatial data. It has been shown in [54] that, although these networks are weaker compared to recurrent networks when considering approximation for arbitrary size of the sequences, they are approximation complete when considering approximation in probability. Thus, they can approximate every possibly non-causal function on sequences up to sets of small probability.

### 1.15.3.7 Tree structures

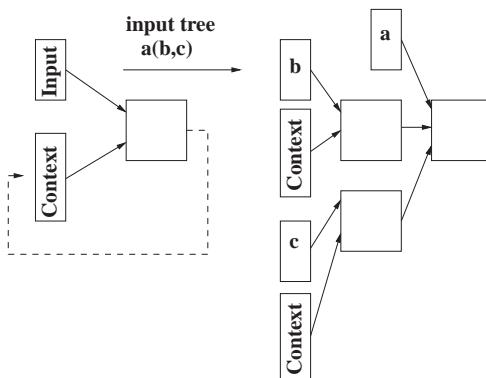

The idea of a time series driving a recurrent network can immediately be transferred to tree structures with limited fan-out since they possess a similar recursive structure. Assume  $v$  is a vertex of a tree with label  $l(v)$ , and  $l$  and  $r$  are the left and right subvertex, respectively. Then the state of a *recursive network* is defined as

$$z(v) = f(l(v), z(l), z(r)).$$

Thus, starting from the leaves of the tree, an output for every vertex of the tree can be obtained by recursive processing of the vertices within the context of their children, see Figure 15.6. These recursive networks have been proposed, e.g., in [55] and successfully been applied to various tasks including fingerprint recognition, logo recognition, classification chemical structures, etc. Interestingly, they constitute universal approximators for mappings on tree structures to real vectors as shown in [56].

### 1.15.3.8 Graph structures

RCC can be extended to *recursive cascade correlation* (RecCC) by using the same recurrence which takes the context of all children of a vertex into account, not just one single successor. It has been shown in [54] that RecCC is approximation complete for tree structures when considering approximation in

**FIGURE 15.6**

Unfolding of a recursive neural network for a given tree structure. The dynamics of standard recurrent networks is extended to tree structures with a fixed fan-out of the vertices.

probability, as beforehand. Interestingly, contextual processing can be added to RecCC in the same way as CRCC: each hidden neuron is equipped not only with recurrent connections referring to the children, but also recurrent connections referring to its parents pointing from all hidden neurons introduced previously. This way, we cannot only process tree structures, but also acyclic graphs with *contextual cascade correlation* (CRecCC). Interestingly, one can show that such networks are approximation complete for functions on tree structures as well as for acyclic graphs which can be pairwise distinguished by at least one path in the graph [54], thus the resulting architecture is quite powerful.

Another approach has been proposed in [57]. The graph neural network processes every vertex in the context of its neighbored vertices in the graph. That means, the activation of a neuron for a specific vertex in the graph is computed as function depending on the labeling of the vertex, and the activation of the neurons for the neighbors of the vertex. Since a graph is usually cyclic, hence activations of neighbored vertices influence each other, this definition depends on the ordering of the computation of the activations. In the graph neural network, the functions implemented by the neurons are restricted to contractive mappings. This way, the standard Banach fixed-point theorem guarantees that, in the limit, a unique activation is computed for every neuron and, thus, the overall dynamics is well defined. In [57], a training algorithm based on gradient descent is proposed which propagates the error signals of stable states of the network. This way, an efficient training procedure arises. Graph networks have been successfully applied, e.g., in the context of web page rankings and applications to chemistry.

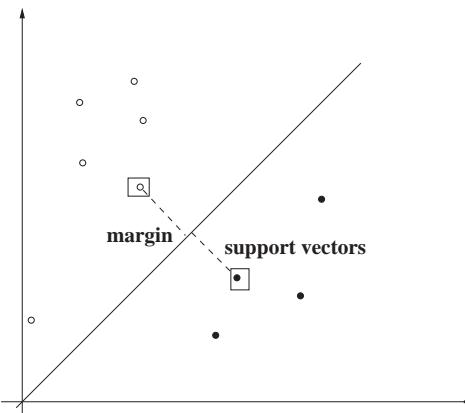

## 1.15.4 Learning by focussing on the generalization ability

So far, networks have been trained in the following way: a fixed architecture and training algorithm is chosen. Then, training aims at a minimization of the error on the training set. This method is referred to as *empirical risk minimization* [25] since, after a limitation of the principled function class by the architecture and training algorithm, the aim is to get an empirical error as small as possible. However, we are not interested in the empirical error, rather the generalization error, i.e., the behavior of the network for unknown examples should be considered. Thus, the goal is twofold: minimization of the empirical error and minimization of the structural freedom of the function beyond the training set.

There exist alternative training methods which explicitly address the so-called *structural risk* during training, i.e., the degrees of freedom which are not necessary to suit the training set.

### 1.15.4.1 Support vector machine

One of the most popular methods based on structural risk minimization is offered by the support vector machine (SVM). First, we consider a linear SVM, which is just a simple perceptron. For simplicity, we neglect the bias (which is often not necessary in practical applications). There are two different methods to limit the generalization ability of a perceptron: on the one hand, the number of parameters (the more parameters, the more data points are necessary to determine the parameters). On the other hand, we can consider the so-called *margin* which is the minimum distance of a training point from the separating hyperplane (see Figure 15.7). The larger the margin, the more tolerance with respect to noise in the training patterns can be observed [25].

**FIGURE 15.7**

A linear classifier with maximum margin; the support vector machine uses the margin trick to reach good generalization also in high dimensional feature space.

#### 1.15.4.1.1 Primal and dual problem

The margin can be parameterized as  $2/\|\mathbf{w}\|$ ,  $\mathbf{w}$  being the weight vector of the perceptron. Therefore, maximizing the margin is equivalent to a minimization of  $\|\mathbf{w}\|^2/2$ . Assume patterns have the form  $(\mathbf{x}^p, y^p)$  with  $y^p$  being in  $\{-1, 1\}$  (instead of  $\{0, 1\}$ ). Then  $\mathbf{x}^p$  is mapped correctly (w.l.o.g. we can assume that the activation of the perceptron is of absolute value at least one) if and only if  $y^p \cdot \mathbf{w}^t \mathbf{x}^p \geq 1$ . This yields to the *primal formulation* of SVM training for a linear SVM without bias:

$$\begin{aligned} &\text{minimize } \|\mathbf{w}\|^2/2 \\ &\text{such that } y^p \cdot \mathbf{w}^t \mathbf{x}^p \geq 1 \text{ for all } p. \end{aligned}$$

Usually, this problem is transferred to the equivalent Wolfe dual problem using the standard Karush-Kuhn-Tucker conditions of quadratic programming [25]:

$$\begin{aligned} &\text{maximize } \sum \alpha_i - 1/2 \cdot \sum \alpha_i \alpha_j y^i y^j (\mathbf{x}^i)^t \mathbf{x}^j \\ &\text{such that } \alpha_i \geq 0. \end{aligned}$$

The Lagrange parameter  $\alpha_i$  will become 0 for all points but the so-called *support vectors* which are vectors closest to the separating hyperplane. The hyperplane can be recovered from the Lagrange parameters by  $\mathbf{w} = \sum \alpha_i y_i \mathbf{x}^i$ .

#### 1.15.4.1.2 Adatron

Usually, this optimization problem is solved using, e.g., efficient interior point methods. However, a very simple optimization scheme is offered by the so-called adatron algorithm [58], a gradient ascent of the dual cost function which takes the constraints into account:

```
init  $\alpha_i = 1$ 
repeat
```

$$\begin{aligned}\alpha_i &:= \alpha_i + \eta \cdot \left(1 - y^i \sum_j \alpha_j y^j (\mathbf{x}^j)^t \mathbf{x}^i\right) \\ \alpha_i &:= \max\{\alpha_i, 0\}\end{aligned}$$

This procedure finds a solution of the perceptron problem which optimizes the margin. Unlike the solution provided by the perceptron algorithm, the solution of a SVM is unique due to the regularization in terms of the margin. The result is robust with respect to its generalization ability. It has been shown in [25] that the VC dimension, i.e., a measure for the degree of freedom within the function class as introduced above, scales inverse with the margin. Thus, the larger the margin, the better theoretical generalization bounds. In addition, the solution with maximum margin turns perceptron training into an efficient polynomial problem: the dual optimization problem can be solved in time  $\mathcal{O}(n^3)$ ,  $n$  being the number of points.

#### 1.15.4.1.3 Alternative formulations

So far, the training algorithm finds a solution if and only if a separating hyperplane without errors exists. In general, this is not possible. For this case, the optimization problem for SVM training can be relaxed introducing *slack variables*  $\xi_p$ :

$$\begin{aligned}&\text{minimize } \|\mathbf{w}\|^2/2 + C \sum_p \xi_p \\ &\text{such that } y^p \cdot \mathbf{w}^t \mathbf{x}^p \geq 1 - \xi_p, \\ &\quad \xi_p \geq 0 \text{ for all } p.\end{aligned}$$

where  $C$  is a positive constant which regulates the number of allowed misclassifications. The Wolfe dual yields

$$\begin{aligned}&\text{maximize } \sum \alpha_i - 1/2 \cdot \sum \alpha_i \alpha_j y^i y^j (\mathbf{x}^i)^t \mathbf{x}^j \\ &\text{such that } C \geq \alpha_i \geq 0.\end{aligned}$$

That is, the size of the Lagrange variables is limited to prevent divergence. Support vectors are the vectors where the Lagrange parameter is non vanishing which includes points closest to the separating hyperplane ( $\alpha_p < C$ ) and misclassified points ( $\alpha_p = C$ ).

Note that, again, due to the regularization, the NP hard problem of training a perceptron in case of errors is substituted by a polynomial optimization problem. This complexity can even be improved. Working set techniques such as sequential minimal optimization [59] can severely speed up SVM training in practical applications, however, without formal guarantees concerning their computational complexity. Provably linear techniques rely on approximation algorithms by means of core set techniques, see, e.g., [60]. There exists a variety of further SVM training schemes which address different problems than simple classification such as regression problems, ranking problems, novelty detection, etc. [61].

#### 1.15.4.2 Kernels

Similar to the simple perceptron the linear SVM is appropriate only for those training sets which are (almost) linearly separable. To extend the applicability, the so-called kernel trick is used. The basic

idea is to include a fixed nonlinear preprocessing  $\Phi$  of the data points before separating the nonlinearly transformed points. If the dimensionality of the feature space is large enough and the preprocessing is sufficiently nonlinear, the image points  $\Phi(\mathbf{x}^p)$  become linearly separable [62, 63].

Two problems arise: on the one hand, the dimensionality becomes large such that the number of free parameters is large and the generalization ability might become weak. This problem is prevented by the fact that the hyperplane with maximum margin is chosen.

#### 1.15.4.2.1 The kernel trick

On the other hand scalar products have to be computed in the feature space. For high dimensionality, this becomes ineffective. To prevent this problem, the *kernel trick* is used: only those  $\Phi$  are chosen for which a mapping  $k$  exists with  $k(\mathbf{x}, \mathbf{y}) = \Phi(\mathbf{x})^t \Phi(\mathbf{y})$ , i.e.,  $k$  provides an alternative efficient computation method for the scalar product of the nonlinear images of two vectors. Note that  $\Phi$  is used within SVM training and evaluation only within a scalar product such that the knowledge of  $k$  is sufficient for SVM training. Functions  $k$  which fulfill the equality  $k(\mathbf{x}, \mathbf{y}) = \Phi(\mathbf{x})^t \Phi(\mathbf{y})$  are called *kernels*. Interestingly, one can check whether a function is a kernel without an explicit knowledge of  $\Phi$ , using, e.g., the so-called Mercer condition [61].

Popular kernels include

1. The *polynomial kernel*  $k(\mathbf{x}, \mathbf{y}) = (\mathbf{x}^t \mathbf{y} + 1)^d$ ,  $d$  denoting the degree. This kernel corresponds to a map  $\Phi$  which builds all monomials of the input dimensions up to degree  $d$ , i.e., the dimensionality of the feature space scales exponentially in the input dimensionality.
2. The *Gaussian kernel*  $k(\mathbf{x}, \mathbf{y}) = \exp(-\|\mathbf{x} - \mathbf{y}\|^2/\sigma^2)$ ,  $\sigma$  being the width of the Gaussians. This kernel corresponds to a map  $\Phi$  with infinite dimensional feature space.

Recently, a kernel inspired by extreme learning machines has been proposed in [64]. The *extreme learning machine kernel* relies on the idea to randomly map data into a feature space by means of a layer of randomly wired hidden neurons. Interestingly, under certain assumptions, the resulting dot product in feature space can be computed explicitly for the limit of an infinite number of neurons.

#### 1.15.4.2.2 Structure kernels

Kernels constitute the interface of the data to the SVM. Thereby, the data need not be restricted to real vectors, rather, every space for which a kernel can be defined is appropriate. A variety of kernels for structural inputs including sequences, trees, and graphs have been proposed. Mathematical closure properties as established in [65, 66] allow to design kernels based on a variety of principles including the reference to projections or substructures and the combination of such procedures. Two different approaches to design structure kernels are very popular: kernels which count the number of common occurrences of substructures, and kernels which base the comparison of structures on probabilistic models.

Substructure kernels include, for example, the *string kernel* and the *spectrum kernel* for sequences, which count common subsequences, whereby the variants differ in the fact whether subsequences need to be contiguous or not and whether exact matches are required [67, 68]. In principle, given two strings  $s_1$  and  $s_2$ , these kernels compute a term  $\sum_{s \subset_k s_1, s' \subset_k s_2} d(s, s')$  whereby  $s \subset_k s_1$  refers to some formalism which specifies that  $s$  is substring of  $s_1$  (contiguous or noncontiguous) and its length is limited to  $k$ .  $d(s, s')$  defines a simple kernel on strings of the same length. The main problem of this definition

consists in the task to design an efficient computation method for this kernel, since the number of possible substrings increases exponentially with the length  $k$ . Basically two ways have been proposed which allow a rather efficient computation: dynamic programming or suffix trees. Generalizations to tree structures are possible as described in [69, 70]. Similar procedures for graph structures face problems because of the complexity of graph isomorphism. Here, an alternative is given by just comparing paths in a graph. The *diffusion kernel* constitutes a concrete method to realize this idea [71].

One of the most popular kernels based on probabilistic models is the *Fisher kernel* [72]. The comparison of two structures is substituted by the comparison of relevant quantities of statistical models fitted to the data. In the case of the Fisher kernel, a manifold of parameterized generative models is considered, e.g., hidden Markov models in the case of sequences. Each data point stems from a most likely parameter setting. The Fisher kernel compares the tangent vectors in these points instead of the structures itself, whereby the natural metric to compare these tangents is based on the Fisher information.

### 1.15.4.3 Learning vector quantization

The SVM provides solutions in terms of support vectors which are points at the boundary or misclassified examples, i.e., the SVM expands solutions in terms of atypical training points. There exist alternatives such as the *relevance vector machine* which selects solutions in terms of typical points, based on a statistical formulation of the training problem [73]. However, we would like to consider an even simpler method which represents solutions in forms of typical points or prototypes: *learning vector quantization* (LVQ) [12]. An LVQ network consists of prototypes which are represented by prototypical locations  $w_i$  in the input space and their output class  $c(w_i)$  which is one of a finite number of possible output classes. An LVQ network computes a classification by means of a *winner takes all* mechanism:

$$\mathbf{x} \mapsto c(\mathbf{w}_i) \quad \text{for which } \|\mathbf{x} - \mathbf{w}_i\| \text{ is minimal,}$$

$\|\cdot\|$  denoting the euclidian metric, see Figure 15.8 for an example. A variety of different intuitive learning algorithms have been proposed which are commonly based on the principle of Hebbian learning and which constitute heuristics. The simplest one, LVQ1, can be described in a few lines:

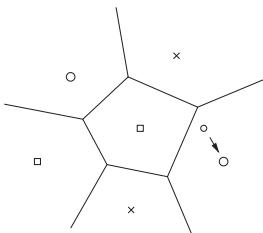

```

init  $w_i$ 
repeat
    choose a training pattern  $\mathbf{x}$  with output class  $y$ 
    determine the closest prototype  $\mathbf{w}_i$ 
    if  $y = c(\mathbf{w}_i)$  adapt  $\mathbf{w}_i = \mathbf{w}_i + \eta(\mathbf{x} - \mathbf{w}_i)$ 
    if  $y \neq c(\mathbf{w}_i)$  adapt  $\mathbf{w}_i = \mathbf{w}_i - \eta(\mathbf{x} - \mathbf{w}_i)$ 

```

Figure 15.9 depicts a learning step.

There exists a variety of alternatives to account for faster convergence or better adaptation to the optimum decision boundary. Only comparably little is known about theoretical guarantees for LVQ such as the convergence of the algorithm. Recently, several prototypical scenarios have been investigated within the framework of so-called online learning [74] which demonstrate the divergence of some algorithms (e.g., LVQ2.1) also in quite simple situations. We would like to introduce one alternative which can be derived as stochastic gradient descent method of a cost function and, therefore, shows quite good numerical stability, *generalized LVQ* (GLVQ)[75].

**FIGURE 15.8**

An LVQ network: the classification is based on the winner-takes-all rule, this way decomposing the input space into receptive fields.

**FIGURE 15.9**

Training of an LVQ network by Hebbian learning; given a data point, its closest prototype is moved towards/away from the data point depending on whether the classification is correct.

Assume patterns  $(\mathbf{x}^p, y^p)$  are available. Denote by  $\mathbf{w}^+(\mathbf{x}^p)$  the prototype closest to  $\mathbf{x}^p$  with the same label and by  $\mathbf{w}^-(\mathbf{x}^p)$  the closest prototype with a different label. Then, GRLVQ minimizes the cost function

$$\frac{1}{2} \sum_p \frac{\|\mathbf{x}^p - \mathbf{w}^+(\mathbf{x}^p)\|^2 - \|\mathbf{x}^p - \mathbf{w}^-(\mathbf{x}^p)\|^2}{\|\mathbf{x}^p - \mathbf{w}^+(\mathbf{x}^p)\|^2 + \|\mathbf{x}^p - \mathbf{w}^-(\mathbf{x}^p)\|^2}$$

by means of a stochastic gradient decent. In some cases, the summands are nonlinearly transformed by a sigmoidal function. Note that the term  $\|\mathbf{x}^p - \mathbf{w}^+(\mathbf{x}^p)\|^2 - \|\mathbf{x}^p - \mathbf{w}^-(\mathbf{x}^p)\|^2$  is negative if and only if  $\mathbf{w}^p$  is correctly classified, thus, the nominator accounts for a correct classification of the data points. The denominator scales this term such that it lies in the interval  $(-1, 1)$ .

We use the shorthand notation  $d^+$  for  $\|\mathbf{x}^p - \mathbf{w}^+(\mathbf{x}^p)\|^2$  and  $d^-$  for  $\|\mathbf{x}^p - \mathbf{w}^-(\mathbf{x}^p)\|^2$ . Taking the derivatives yields the following update rules which are also valid for the classification boundaries, as shown in [76]:

$$\mathbf{w}^+(\mathbf{x}^p) := \mathbf{w}^+(\mathbf{x}^p) + \eta \cdot \frac{2d^-}{(d^+ + d^-)^2} \cdot (\mathbf{x}^p - \mathbf{w}^+(\mathbf{x}^p))$$

for the closest correct prototype and

$$\mathbf{w}^-(\mathbf{x}^p) := \mathbf{w}^-(\mathbf{x}^p) - \eta \cdot \frac{2d^+}{(d^+ + d^-)^2} \cdot (\mathbf{x}^p - \mathbf{w}^-(\mathbf{x}^p))$$

for the closest incorrect prototype, i.e., this method differs from standard LVQ mainly by different scaling terms of the step size. The method is often more robust and yields a better classification accuracy compared to simple LVQ [76].

For LVQ type networks, strong generalization bounds hold in terms of the so-called hypothesis margin of the system. Consider the difference  $d^- - d^+$ , the *hypothesis margin* for pattern  $\mathbf{x}^p$ . Obviously, the larger the term, the more secure the classification of  $\mathbf{x}^p$ . For large margin, the hypothesis can be altered, i.e., the classification boundary can be shifted, without affecting the classification of  $\mathbf{x}^p$ . For small hypothesis margin, already a small shift of the hypothesis will alter the classification. It has been shown in [77] that, for a two-class classification problem, the generalization error of LVQ type networks can be limited by the following inequality:

$$E \leq \hat{E}_\rho + \mathcal{O}\left(\frac{P^2 B^3 \sqrt{\ln(1/\delta)}}{\rho \sqrt{m}} + \frac{\sqrt{\ln(1/\delta)}}{\sqrt{m}}\right),$$

where  $P$  is the number of prototypes,  $B$  the size of the support of the training set,  $\delta$  the confidence of the bound,  $m$  the number of examples, and  $\rho$  a priorly fixed constant.  $E$  denotes the error of the classifier for unknown training samples, i.e., the error we are interested in, and  $\hat{E}_\rho$  denotes the number of examples which are classified with margin smaller than  $\rho$  or misclassified, divided by  $m$ . Hence, the larger the margin achieved by an LVQ classifier, the better the generalization.

Note that GLVQ includes the margin in the cost function, hence it directly aims at margin maximization during training, achieving excellent generalization ability.

#### 1.15.4.4 General metrics

Note that, in principle, every differentiable metric  $d$  can be used in GRLVQ instead of the euclidian one. Substituting this metric into  $d^+$  and  $d^-$  and taking the derivative directly yields to adaptation formulas for training as shown in [78]. The metric can, for example, be derived from an arbitrary kernel (in which case the generalization bounds are still valid), or any other similarity measure (for which the generalization bounds do not necessarily hold.) The choice of the metric as the standard euclidian metric enhanced by *relevance terms* proved particularly suitable for practical applications:

$$d^\lambda(\mathbf{x}, \mathbf{w}) = \sum_i \lambda_i (x_i - w_i)^2,$$

where  $\lambda_i \geq 0$  and  $\sum \lambda_i = 1$ . The quantity  $\lambda_i$  scales input dimension  $i$  according to its relevance, therefore the algorithm is referred to as *generalized relevance LVQ* (GRLVQ) [76]. Thereby, the relevance of the dimensions need not be known a priori, rather, the relevance terms can automatically be determined during training by applying a stochastic gradient decent with respect to both, the prototypes and the relevance terms. The resulting updates for the relevance terms are

$$\lambda_l := \lambda_l + \eta \cdot \sum_p \left( \frac{4d^-}{(d^+ - d^-)^2} \cdot (x_l^p - w_l^+(\mathbf{x}^p))^2 - \frac{4d^+}{(d^+ - d^-)^2} \cdot (x_l^p - w_l^-(\mathbf{x}^p))^2 \right).$$

After every adaptation step, the relevance terms have to be normalized. Note that the generalization bounds are also valid for this more general approach as shown in [77].

A variety of further alternatives have been proposed and successfully applied in practice, whereby the metrics can be equipped with adaptive relevance parameters which are automatically adapted during training by means of a gradient descent. Examples for alternative metrics include specific choices for time series [78,79] or a full adaptive matrix [80].

## 1.15.5 Unsupervised learning

So far, we have considered classification or regression tasks, i.e., input-output pairs have been available. In unsupervised learning, only input vectors are given and the task is to extract useful information from these data. This problem is, of course, rather vague and a variety of different application domains exists: data preprocessing and dimensionality reduction, data visualization, data clustering, data compression, data mining, etc. We will consider a few popular approaches within this framework.

### 1.15.5.1 Unsupervised training of single neurons

Assume a stream of vectors  $\mathbf{x}^p$  is given. For simplicity, we assume that the expectation  $E(x_i^p)$  of each component is 0, otherwise, we can easily normalize every dimension. We assume that a single neuron is given with the identity as activation function and bias 0, i.e., it computes the function

$$\mathbf{x} \mapsto y = \mathbf{w}' \mathbf{x}.$$

Since we do not exactly know what we should do, we can formulate simple Hebbian learning in this scenario

$$\mathbf{w} := \mathbf{w} + \eta \cdot y \cdot \mathbf{x},$$

which, for positive output, reinforces those weights of the neuron which receive a positive input signal, for negative  $y$ , it is vice versa. However, unfortunately, this simple rule diverges, i.e., the size of  $\mathbf{w}$  becomes infinite.

#### 1.15.5.1.1 Oja's rule

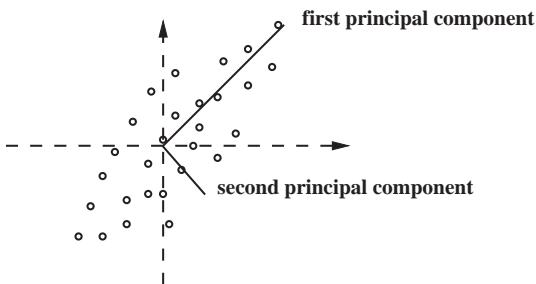

*Oja's rule* introduces an additional correction to Hebb learning [5]:

$$\mathbf{w} := \mathbf{w} + \eta \cdot (y \cdot \mathbf{x} - y^2 \cdot \mathbf{w}).$$

What is the behavior of this dynamics? We define the correlation matrix  $C$  by  $E(\mathbf{x}\mathbf{x}^t)$ . For a finite set of samples this is proportional to the sum  $\sum_p \mathbf{x}^p (\mathbf{x}^p)^t$ . Now consider the function  $-1/2 \cdot \mathbf{w}' C \mathbf{w}$ . A stochastic gradient descent of this function yields an update proportional to  $\mathbf{x}\mathbf{x}^t \mathbf{w} = y\mathbf{x}$ , i.e., it yields the Hebb term as introduced above. Obviously, the above function is smaller the larger the size of  $\mathbf{w}$ , hence the divergence. One can show that the additional correction term introduced by Oja's rule also optimizes this function, but it restricts the solution to  $\|\mathbf{w}\| = 1$  [5].

Thus, Oja's rule leads to a vector  $\mathbf{e}$  with  $\|\mathbf{e}\|^2 = 1$  such that  $\mathbf{e}' C \mathbf{e}$  is maximum. The matrix  $C$  is a symmetric positive (semi-)definite matrix, therefore it can be diagonalized, i.e., there exist  $n$  eigenvectors  $\mathbf{e}_i$  with  $\|\mathbf{e}_i\|^2 = 1$  and eigenvalues  $\lambda_i$  such that  $C\mathbf{e}_i = \lambda_i \mathbf{e}_i$ , and the matrix  $C$  is the diagonal matrix with entries  $\lambda_i$  when represented in the base  $\mathbf{e}_i$ . (Here we assume that  $C$  is positive definite and the eigenvalues are pairwise different.) The optimum  $\mathbf{e}$  is nothing else but the eigenvector corresponding to the largest eigenvalue  $\lambda_1$ .

The decomposition of  $C$  into its eigenvectors is also called *principal component analysis* (PCA) and the eigenvectors are the *principal components*. They have an intuitive meaning: the principal components are pairwise orthogonal, and the first principal component is the direction of the data with largest

**FIGURE 15.10**

Principal components of a data set: the directions with maximum variation are captured this way.

variance, the second one is the direction with second largest variance, and so on, see Figure 15.10. Therefore, PCA is often used for data preprocessing and data compression since they preserve as much information in terms of variances of the points as possible. Oja's rule does nothing else but extract the dimension with maximum information in this sense.

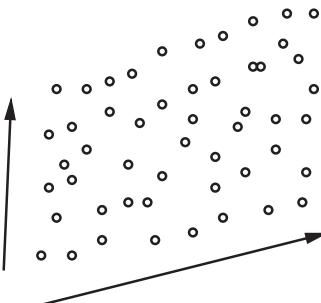

Extensions of Oja's rule to extract more than only the first principle component exists by repeated application of Oja's rule and decorrelation of the directions, e.g., Sanger's rule.

### 1.15.5.1.2 Independent component analysis

*Independent component analysis* (ICA) [81] is, in some sense, dual to PCA. As for PCA,  $n$ -dimensional patterns  $\mathbf{x}$  are observed, which are generated by unknown sources  $\mathbf{s}$ . Both, PCA and ICA assume that the observations are generated by a linear mapping  $\mathbf{x} = \mathbf{A} \cdot \mathbf{S}$  with  $\mathbf{A} = \mathbf{W}^{-1}$ ,  $\mathbf{W}$  denoting the weights of the trained neurons. The goal of PCA is to recover these sources under the assumption that they are pairwise orthogonal and they explain as much information as possible with respect to the variance, which is relevant, e.g., for compression. ICA tackles the problem that the sources are mixed as in real life, e.g., the mixing of different speakers in a cocktail party where the original speakers should be retrieved from a mixture of different speakers. These signals are usually not orthogonal. The assumption of ICA is, that the signals are (almost) independent (and non Gaussian since, otherwise, the mixture would just look the same).

The task of ICA is, thus, to retrieve the sources  $\mathbf{s} = \mathbf{A}^{-1}\mathbf{x}$  from a mixed signal  $\mathbf{x}$  such that the signals  $s_1, s_2, \dots$  are as independent as possible. See Figure 15.11 for an example where two independent uniformly distributed sources are mixed, here, the task is to retrieve the two directions of the parallelogram. Now the question occurs how to measure independence? It is assumed that the expectation of each component of  $\mathbf{x}$  is 0 and the variance is 1, further, it is assumed that they are uncorrelated. If these assumptions are not fulfilled, data have to be preprocessed accordingly, so called *whitening*.

Independence of sources can be measured by the mutual information  $I(\mathbf{x}) = \sum_i H(x_i) - H(x_1, \dots, x_n)$  where  $H(\mathbf{x}) = -\sum P(x_i) \log P(x_i)$  denotes the entropy. For whitened data it holds  $I(\mathbf{x}) = \text{const} - \sum_i J(x_i)$  where  $J(x) = H(x_G) - H(x)$  is the negentropy which compares the variable  $x$  to a Gaussian variable  $x_G$ . Thus, minimizing the mutual information is the same as maximizing the negentropy, i.e., minimizing the Gaussianity of a source. Thus, we have to find sources which are

**FIGURE 15.11**

Linear mixture of two independent uniform distributions; unlike principal component analysis, independent component analysis aims at retrieving these dimensions.

minimum Gaussian to find independent sources. A classical measure for the Gaussianity of a variable is the kurtosis  $\text{kurt}(x) = E(x^4) - 3E(x^2)^2$ . This is maximized by one of the first ICA methods by means of a simple gradient ascent, obtaining the first independent component. Proceeding this way, all independent components can be obtained.

However, the optimization of kurtosis is not very robust. Therefore, alternatives have been proposed, among them fast-ICA, which approximates the negentropy and maximizes this approximation by a fast fixed point method resulting in the update:

$$\mathbf{w} := E(\mathbf{x}g(\mathbf{w}^t \mathbf{x})) - E(g'(\mathbf{w}^t \mathbf{x}))\mathbf{w}$$

followed by normalization where  $\mathbf{x}$  is the whitened signal and  $g$  a non quadratic function such as  $g(x) = -\exp(-x^2/2)$ .

#### 1.15.5.1.3 Nonlinear components

Both, PCA and ICA retrieve linear mixtures. This gives quite remarkable results in a variety of applications such as blind source separation of signals. However, in practice, there is no guarantee that sources are mixed in a linear way. Therefore, both ICA and PCA have been extended to nonlinear methods, e.g., introducing kernelization [61].

Here, we shortly mention another very intuitive method. Assume, as before, signals  $\mathbf{x}$  are given. PCA finds directions such that as much information as possible is preserved, i.e., one can think of PCA as a form of compression or dimensionality reduction. Consider a simple feedforward network with  $n$  inputs and outputs and one hidden layer with  $n' < n$  neurons,  $n$  being the dimensionality of the data. Assume this network is trained such that it approximates the identity on a given set of patterns  $\mathbf{x}^P$ . Since  $n' < n$ , the hidden layer serves as an encoder layer where the information of the data has to be compressed. Thus, the transformation of the hidden neurons likely resembles directions similar to the first principle components, since these directions allow a fairly effective encoding. Naturally, transformation within the vector space spanned by the first components do not alter this result. This idea can immediately be transferred to nonlinear directions: instead of just one hidden layer, more than one hidden layer is added. This way, the encoding function becomes nonlinear.

### 1.15.5.2 Slow feature analysis

Another recent approach to blind source separation and, more generally, to retrieve semantically meaningful information in a stream of observations is offered by slow feature analysis (SFA) [82]. The idea is to nonlinearly transform time dependent input signals such that the results have small variation over time, the function depends on one time step only, and the results are orthogonal to avoid trivial solutions. This way, the technique is forced to extract signals which do not change quickly over time; these signals correspond to potentially meaningful semantic entities in the given data. Under certain assumptions on the form of the nonlinear transformation, the problem can be solved algorithmically by a standard eigenvalue problem for preprocessed signals. Slow feature analysis has proven beneficial in diverse areas ranging from brain computer interfaces to image processing.

### 1.15.5.3 Training topographic maps

Unlike PCA and ICA, topographic maps combine several neurons which are trained in an unsupervised way, whereby the neurons are cooperating. This way, complex behavior such as topographic ordering according to local PCA directions can be achieved.

#### 1.15.5.3.1 Self organizing map

The self-organizing map (SOM) has been proposed by Kohonen [12] as a plausible learning method to achieve a topographic mapping of signals as can be observed in the human cortex. A SOM consists of a number of neurons which are equipped with a weight  $\mathbf{w}_i \in \mathbb{R}^n$  representing the typical sensor signal for this neuron, and a neighborhood structure of the neurons  $n(i, j)$ . Often, the neighborhood structure is induced by a regular lattice structure such as a square, hexagonal, or hyperbolic lattice. A SOM computes a *winner takes all* function just as LVQ networks  $\mathbf{x} \mapsto i$  where  $\|\mathbf{x} - \mathbf{w}_i\|$  is minimum. Thus, a new signal is mapped to a position in the map.

#### 1.15.5.3.2 Online training

Training takes place such that a topographic mapping is found which faithfully represents the input signals. Online SOM training differs from LVQ in the fact that the neighborhood structure is taken into account:

```

init
repeat
  choose  $\mathbf{x}$ 
  determine the winner neuron  $\mathbf{w}_{i_0}$ 
  adapt all neurons  $\mathbf{w}_i := \mathbf{w}_i + \eta \cdot \exp(-n(i, i_0)/\sigma^2) \cdot (\mathbf{x} - \mathbf{w}_i)$ 
  decrease  $\eta$  and  $\sigma$ 

```

Hence, all neurons are adapted whereby the strength of the adaptation is defined by a Gaussian function around the winning neuron.  $\sigma$  defines the neighborhood range of the adaptation.

Neighbored neurons in the map represent neighbored regions in the space of stimuli. If a two-dimensional map is used, a SOM can be used for data visualization: data are assigned to the place in the plane which corresponds to the respective winning neuron.

The degree of topology preservation of the resulting map can be measured using, e.g., the topographic product (if the curvature of the manifold is not too strong) or the topographic function [83]. Both measures relate the neighborhood structure in the lattice space to the neighborhood structure in the input space.

Despite the simple training model, the mathematics of SOM is rather difficult and, in several parts, still unexplored [84, 85]. Important topics concern the convergence of SOM to a topology preserving state, and the relation of the weight distribution to the data density. For both questions, only preliminary solutions (e.g., for low dimensional settings or constant learning rate) could be found so far. If the notion of the winner of  $x$  is changed to the neuron  $w(x) = i$  with average smallest distance, i.e., smallest  $\sum_j \exp(-n(i, j)/\sigma^2) \|w_j - x\|^2$ , a cost function which is also valid for continuous input distributions can be found [86]

$$\int \sum_i \delta_{w(x)}^i \sum_j \exp(-n(i, j)/\sigma^2) \|w_j - x\|^2 P(x) dx.$$

$\delta_i^j$  denoting the Kronecker symbol. In this case, a version of SOM with a slightly changed winner notation constitutes a stochastic gradient descent of this cost function.

#### 1.15.5.3.3 Batch training

SOM training can be accelerated by an alternative optimization scheme, *batch training*. This assumes that training data  $x^i$  are given a priori. Then batch optimization proceeds as follows:

```

init
repeat
    compute the winner  $w(x^p) = \operatorname{argmin}_i \sum_j \exp(-n(i, j)/\sigma^2) \|w_j - x^p\|^2$  for every  $x$ 
    compute the weights  $w_i = \frac{\sum_j \exp(-n(i, w(x^j))/\sigma^2) x^j}{\sum_j \exp(-n(i, w(x^j))/\sigma^2)}$ 
    decrease  $\sigma$ 

```

It has been shown in [87] that this procedure converges in a finite number of steps towards a (local) optimum of the cost function defined by Heskes [86]. However, this procedure is quite sensitive to initialization due to the rapid convergence. Therefore, the weights should be initialized properly, e.g., along the first two principal components of the data.

Interestingly, batch training can be transferred to more general metrics by the so-called generalized median. Assume only pairwise distances  $d(x^i, x^j)$  are available, but no embedding vector space of the data. The *median SOM* optimizes a lattice by restricting prototype locations to the location of example data points. The distance of prototypes and data points can be easily computed this way, and the winner of every data point can be determined as beforehand. Instead of an explicit formula for  $w_i$ , the prototype  $w_i$  is chosen as the location  $x_l$  for which  $\sum_j \exp(-n(i, w(x^j))d(x^l, x^j))$  is minimum. This algorithm also converges in a finite number of steps [87].

#### 1.15.5.3.4 Consciousness

For standard SOM, the final prototypes are arranged within the input space. Thereby, the number of input signals for which a neuron becomes winner is usually not the same for different prototypes.

Rather, regions of the data space with few input stimuli are emphasized, i.e., neurons which are located in regions of the data space with sparse coverage are less often winner compared to neurons in densely covered regions. This is suboptimal from an information theoretic point of view: prototypes are used in an optimum way if the winner frequency is the same for every neuron. There exists a variety of mechanisms which prevent this behavior and which introduce so-called *magnification control* in neural training [88].

A very popular and fast heuristics is offered by the *de Sieno-algorithm* [89]. During online training, each neuron adapts its mean winner frequency after the presentation of pattern  $\mathbf{x}$  by

$$p_i := p_i + B \cdot (\delta_{w(\mathbf{x})}^i - p_i),$$

where  $0 < B \ll 1$ . The winner is determined based on the distance which is enhanced by a conscious mechanism. Denote the number of neurons by  $N$ . The optimum winner frequency is  $1/N$ . The distance is altered by a term which relates this optimum frequency to the current one, emphasizing neurons with low winner frequency. Thus, the winner is

$$w(\mathbf{x}) = \operatorname{argmin}_i \|\mathbf{x} - \mathbf{w}_i\|^2 - C \cdot (1/N - p_i),$$

where  $C > 0$  is a constant. The size of  $C$  allows to determine the strength of consciousness learning in comparison to the standard Kohonen rule.

### 1.15.5.3.5 Neural gas

SOM is beneficial if data should be visualized. However, if only a clustering or topographic map should be obtained, the choice of a fixed prior topology limits the quality of the result in case this topology does not coincide with the data topology. *Neural gas* (NG) constitutes an alternative topographic mapping which determines the neighborhood cooperation in dependence of the data, resulting in an optimum lattice structure [90,91]. Unlike SOM, the resulting connections are not regular such that visualization requires additional work.

Neural gas can be derived from the cost function

$$\int \sum_{i,j} \exp(-r_i(\mathbf{x})/\sigma^2) (\|\mathbf{w}_j - \mathbf{x}\|^2 P(\mathbf{x}) d\mathbf{x}.$$

$r_i(\mathbf{x})$  denotes the rank of neuron  $i$  when the distances  $\|\mathbf{x} - \mathbf{w}_j\|^2$  are sorted according to their size, i.e., the rank is 0 for the winner, 1 for the second closest prototype, etc. Neural gas learning constitutes a stochastic gradient descent on this cost function, resulting in the update:

```

init
repeat
  choose  $\mathbf{x}$ 
  determine the ranks  $r_i(\mathbf{x})$ 
  adapt  $\mathbf{w}_i := \mathbf{w}_i + \eta \exp(-r_i(\mathbf{x})/\sigma^2) (\mathbf{x} - \mathbf{w}_i)$ 
  decrease  $\sigma$  and  $\eta$ 

```

Obviously, during adaptation, the neighborhood cooperation is given by the rank of the neurons with respect to an input pattern. One can introduce explicit connections which constitute an optimum lattice by connecting neurons if they are the first and second winner for at least one pattern [90].

Similar to SOM, an alternative *batch optimization scheme* exists given fixed patterns  $\mathbf{x}^j$ :

```

init
repeat
    determine the ranks  $r_i(\mathbf{x}^j)$ 
    adapt  $\mathbf{w}_i := \frac{\sum_j \exp(-r_i(\mathbf{x}^j)/\sigma^2) \mathbf{x}^j}{\exp(-r_i(\mathbf{x}^j)/\sigma^2)}$ 
    decrease  $\sigma$ 

```

Similar to SOM, this version can be adapted to proximity data not contained in a real-vector space.

Like SOM, neural gas does not yield to a uniform winner frequency of the prototypes. Rather, the prototype distribution and the data distribution follow a power law with exponent  $m/(m + 2)$  where  $m$  is the intrinsic dimension of the data manifold. This is different from the information theoretic optimum 1 in particular for low dimensional intrinsic dimensionality. A variety of magnification control schemes exist for NG and batch NG, see, e.g., [83, 92].

There exists a variety of alternatives to the standard SOM which rely on different fundamental mathematical principles such as a constraint mixture modeling proposed in the context of the generative topographic mapping [93], or information theoretic approaches [94].

#### 1.15.5.4 Extensions to structures

Albeit topographic mapping depends on the distance of data points only, the algorithms require an underlying Euclidean vector space for the updates of prototypes. If complex data are dealt with, the Euclidean distance is often not appropriate. There exist two principled approaches to extend unsupervised topographic maps to general data structures: one can equip the dynamics with recurrent connections, such that time series, tree structures, or general graph structures can be dealt with, resulting in architectures very similar to supervised recursive networks for structures. Examples for such approaches can be found in [95, 96].

Alternatively, a problem specific dissimilarity measure can be taken. Examples include alignment for biological sequence data, compression distance for text, graph distances for structures, and similar. In the last years, extensions of methods such as SOM and NG to kernels or general relational data described by pairwise dissimilarities have been proposed. Median SOM or NG, as mentioned above, constitute very simple (but also very limited) approaches.

As an alternative, kernel NG extends the standard NG cost function to a kernel mapping by means of the identity

$$\|\Phi(\mathbf{x}) - \Phi(\mathbf{w})\|^2 = k(\mathbf{x}, \mathbf{x}) - 2k(\mathbf{x}, \mathbf{w}) + k(\mathbf{w}, \mathbf{w})$$

assuming a kernel  $k$  with corrsponding feature map  $\Phi$  is given. For a linear combination  $\mathbf{w} = \sum \alpha_i \Phi(\mathbf{x}_i)$ , this reduces to a term which depends on the Gram matrix of the data only. Online adaptation of the coefficients  $\alpha_i$  or batch adaptation can be derived thereof, see [97, 98].

Instead of a kernel, a general dissimilarity measure can be chosen, because of the equality

$$\|\mathbf{x} - \sum \alpha_i \mathbf{x}_i\|^2 = [D^t \alpha]_i - 1/2 \cdot \alpha^t D \alpha,$$

where  $\alpha$  refers to the vector of coefficients which sums up to one, and  $D$  denotes a symmetric dissimilarity matrix storing the pairwise dissimilarities of  $\mathbf{x}_i$ . This formula allows a direct transfer of batch

learning to general dissimilarity data [99]. Unlike for kernels, however, these adaptations correspond to vector operations in the so-called pseudo-Euclidean embedding of the given dissimilarity matrix, where negative eigenvalues can occur in the dot product. In consequence, the NG algorithm is no longer guaranteed to converge to a local optimum of the cost function. Because of quadratic optimization being NP hard in such spaces, this is partially unavoidable.

## 1.15.6 Applications

Corresponding to the wide variety of neural architectures, these techniques populate nearly every possible application area one can think of. Applications can be found from commercial areas, e.g., in the context of the financial market, to standard tools in bioinformatics such as prediction of the secondary structure of proteins, up to hot research topics such as humanoid robotics. Thus, rather than accumulating a list of application scenarios, a list of typical tasks the different architectures are used for follows:

*Feed-forward network*: Classification, regression tasks.

*Recurrent network*: Associative memory, time series prediction and generation, dynamic system modeling; can be extended to deal with structures.

*Support vector machine*: Today, SVMs constitute the standard tool for classical regression and classification tasks.

*Learning vector quantization*: Multiclass classification, relevance learning, data compression and inspection.

*ICA/PCA/SFA*: Blind source separation, data preprocessing.

*Topographic mapping*: Data mining and visualization.

## 1.15.7 Open issues and problems

We have already discussed some open problems when considering the single architectures. In general, many open problems center around the following issues:

- How can the system be made more autonomous? Neural networks constitute very efficient methods provided a human has shaped the learning problem in a suitable way, e.g., as regression problem. Unlike human learners, however, neural networks are hardly capable of structuring a complex learning problem themselves, and of actively extracting important structures inherent in the scenario. Deep learning and autonomous learning are two topics which are currently discussed in this frame.
- How can neural systems learn from very few examples? Humans are capable of rapid learning and reasonable actions albeit they have experienced only few, probably only one example of how to react. In contrast, typical neural systems require a number of examples to perform valid generalization. This problem is tackled in topics such as instantaneous learning, or models to tackle the problem of compositionality, i.e., the capability of dealing with entirely novel combinations of data where only the parts are known, but they have never been experienced in this combination.
- How can neural systems deal with complex structures? At present, most neural systems still deal with standard Euclidean vectors. Great strides towards more general data structures such as graph

structures or dissimilarity data have been made in the context of recursive approaches or structure kernels. Still, however, problems such as the computational complexity, or structured outputs pose major challenges in this realm.

- How can neural systems be interpreted? Many neural networks offer high quality solutions, but, due to their distributed representation of information, a human can hardly understand why a neural network proposes a certain output. The question of how neural networks can be inspected by humans has been tackled in the literature at several places, but no universally accepted solution exists. Approaches deal with rule extraction, or visualization, for example, but usually still require knowledge of the systems to be interpretable. With problems becoming more and more complex, often a human-in-the-loop approach is taken to eventually arrive at the relevant information. For such approaches, human insight is vital for success. Current research can be found in the field of visual analytics, for example.
- How can larger and larger problems be addressed? Electronic data are getting more and more common, such that larger and larger data sets have to be dealt with. This opens the way to new research areas such as, e.g., the necessity for streaming algorithms which require at most one loop over the data sets, or parallelization schemes to make solutions feasible, thereby relying, e.g., on possibilities as offered by cloud computing or the map-reduce framework.

---

### 1.15.8 Implementation, code, and data sets

It becomes more and more common in Neuroinformatics that publications in the field are accompanied by links where to retrieve the corresponding programs and data sets. Further, the field of neural networks constitutes a standard topic taught at many universities, often accompanied by demo-source code or applets. In consequence, a huge number of code and benchmark data sets can be found all over the web.

Here, we list a few sites where program packages and data sets can be found, whereby the list is necessarily far from being complete, even far from being representative:

- The by far mostly used data repository with more than 200 data sets of different type is the UCI Machine learning repository at <http://archive.ics.uci.edu/ml/>.
- Large data sets are regularly published in the frame of the KDD contest pagination <http://www.kdd.org/kddcup/index.php>.
- A series of challenges with publicly available data is organized in the frame of the PASCAL network of excellence <http://www.pascal-network.org/?q=node/15>.
- Very large datasets of images with different preprocessing as well as a semantic annotation are prepared in the project ImageNet <http://www.image-net.org/>.
- A popular open source java package including machine learning tools and preprocessing is offered by Weka <http://www.cs.waikato.ac.nz/ml/weka/>.
- A (probably a bit old but still one of the largest open source software packages) simulator for neural networks is SNNS <http://www.ra.cs.uni-tuebingen.de/SNNS/>.
- Another relatively novel full-featured neural network simulator for all usual platforms is offered by Emergent [http://grey.colorado.edu/emergent/index.php/Main\\_Page](http://grey.colorado.edu/emergent/index.php/Main_Page).

---

## 1.15.9 Conclusions and future trends

Basically, a variety of different models and training algorithms has been introduced, including the popular standard algorithms such as perceptron training, back-propagation, recurrent networks, support vector machine, learning vector quantization, self organizing maps, and neural gas. Obviously, this is not a homogeneous set of models, rather different models with different motivations, biological relevance, heuristic motivation, or mathematical formulation exist. Thereby, the concrete algorithms are often surprisingly simple, formulated in just a few lines of code. However, both, mathematics behind these models as well as further algorithmic development are non trivial and subject of ongoing research.

---

## Glossary

Adatron	an online training algorithm which finds a linear separation of data with maximum margin
Back-propagation	efficient way to compute the gradients in a feed-forward neural network, standard training algorithm for such networks
Boltzmann machine	associative memory with probabilistic neurons, can involve hidden neurons
Cascade correlation	training algorithm which simultaneously determines the weights and the architecture of a feed-forward network
Chomsky hierarchy	hierarchy of formal languages based on the complexity of the rules of the underlying grammar, includes the standard model of what can be addressed by digital computation as the highest level
Convex optimization	optimization of a convex function in a convex set, under this condition any local optimum is a global one, such that efficient methods can be designed
Cross-validation	a technique for estimating the performance of a predictive model by means of a repeated split of the given data
Deep learning	learning multiple levels of representation autonomously, e.g., using deep convolutional networks or deep auto-encoders
Extreme learning machine	a feed-forward architecture where the first layer is random and only the output is trained
Feed-forward network	neural network with a dynamics determined by an acyclic graph for regression or classification tasks
Gradient descent	optimization method for a differentiable function by means of iterative adaptation steps into the direction of the steepest descent

Hebbian learning	learning paradigm which emphasizes connections in between neurons if they are simultaneously active
Hodgin-Huxley model	differential equations which describe the action potential of a biological neuron
Hopfield network	fully recurrent neural network used as associative memory
Independent component analysis	technique to decompose a linear mixture of signals in independent sources
Kernel	implicit nonlinear embedding function of data in a high dimensional feature space
Learning vector quantization	prototype-based classification algorithm trained by means of Hebbian learning
Long-short term memory	recurrent network where error back-propagation is restricted to linear units to avoid numerical difficulties
Magnification factor	quantity which characterizes the distribution of prototypes as compared to the underlying data in topographic maps
Mean squared error	common cost function to evaluate the quality of a neural network on a given data set
Neural gas	topographic mapping with data driven neighborhood cooperation
NP-hard problem	problem which is at least as hard as the famous satisfiability (SAT) problem, no efficient solution is known today
Oja learning rule	unsupervised learning rule for a single neuron to perform online principal component analysis
Perceptron	a single neuron used as a linear classifier
Principal component analysis	procedure to transform data corresponding to the directions of highest statistical variation
Real time recurrent learning	training algorithm to train recurrent networks in an online scenario
Recurrent neural network	neural network with cyclic connections to simulate associative processing or dynamical systems
Relational clustering	clustering data which are characterized by pairwise dissimilarities (relations) only
Relevance learning	automatic adaptation of the relevance of input dimensions according to a given task
Reservoir computing	recurrent neural networks based on a randomly connected rich recurrent reservoir and a trainable linear readout
Self-organizing map	unsupervised learning method for neurons arranged in lattice structure to arrive at a topographic mapping of given stimuli
Slow feature analysis	technique to extract slowly changing entities from dynamic stimuli
Support vector machine	learning principle which separates data linearly in a nonlinear high-dimensional feature space by optimizing the margin
Synapse	junctions between biological neurons

Topographic mapping	arrangement of neurons such that they represent stimuli according to their underlying topology
Vapnik-Chervonenkis dimension	combinatorial measure to judge the capacity of a function class

## Nomenclature

$\mathbf{X}$	The data matrix with each row as an observation
$\kappa(\mathbf{x}, \mathbf{z})$	The kernel function with input vectors $\mathbf{x}$ and $\mathbf{z}$
$\langle \mathbf{x}, \mathbf{z} \rangle$	The inner product between two vectors $\mathbf{x}$ and $\mathbf{z}$
$\phi(\mathbf{x})$	The mapping of $\mathbf{x}$ to the feature space $F$
$\mathbf{I}_n$	The $n \times n$ identity matrix
$K$	The kernel matrix with entry $K_{ij}$ being the kernel function value for the $i$ th and $j$ th inputs
$\ \mathbf{w}\ $	The Euclidean norm of the vector $\mathbf{w}$
$\text{trace}(K)$	The trace of the matrix $K$
$\text{cov}(x, u)$	The covariance between two random scalar variable $x$ and $u$
$\text{var}(x)$	The variance of the random scalar variable $x$
$\mathbf{x} \succeq (\preceq) \mathbf{z}$	The vector $\mathbf{x}$ is larger (less) than the vector $\mathbf{z}$ elementwise
$K \succeq 0$	The matrix $K$ is positive semidefinite

---

### 1.16.1 Introduction

Data often possess some intrinsic regularities which, if revealed, can facilitate people to understand data themselves or make predictions about new data from the same source. These regularities are called patterns, and pattern analysis, which has been studied broadly such as in statistics, artificial intelligence and signal processing, deals with the automatic detection of patterns in data.

The development of pattern analysis algorithms can be summarized with three important stages [1]. In the 1950s and 1960s, efficient algorithms such as the perceptron [2] were used. They are well understood and effective for detecting linear patterns, though were shown to be limited in complexity. In the 1980s, with the introduction of both the backpropagation algorithm for multi-layer networks

[3] and decision trees [4,5], pattern analysis underwent a nonlinear revolution. These methods made a high impact to efficiently and reliably detect nonlinear patterns, though they are largely heuristical with limited statistical analysis and often get trapped with local minima. In the 1990s, the emerging of kernel methods [1,6] for which support vector machines (SVMs) [7,8] are the earliest and foremost influential finally enabled people to deal with nonlinear patterns in the input space via linear patterns in high dimensional spaces. This third generation of pattern analysis algorithms are well-founded just like their linear counterparts, but wipe off the drawbacks of local minima and limited statistical analysis which are typical for multi-layer neural networks and decision trees. Since the 1990s, the algorithms and application scopes of kernel methods have been extended rapidly, from classification to regression, to clustering and many other machine learning tasks.

The approach of kernel methods has four key aspects: (i) Data are embedded into a Euclidean feature space; (ii) Linear relations are sought in the feature space; (iii) Algorithms are implemented so that only inner products between vectors in the feature space are required; (iv) The products can be directly computed from the original data by an efficient “short-cut” known as a kernel function (or kernel for short). This is also known as the kernel trick. The idea of using kernel functions as inner products in a feature space is not new. It was introduced into machine learning in 1964 with the method of potential functions [9] and this work is mentioned in a footnote of Duda and Hart’s pattern classification book [10]. Through this route, the authors of [7] noticed this idea, combined it with large margin hyperplanes in the later SVMs and thus introduced the notion of kernels into the mainstream of the machine learning literature.

Although basic kernel methods are rather mature techniques, research combining them with other techniques is still going on, e.g., kernels have been successfully applied to multi-view learning, semi-supervised learning and multitask learning problems [11–16]. This forms a continual impetus along the line of research on kernel-based learning methods. More importantly, recent work on multiple kernel learning [17] has promoted the study of kernel methods to a new level. This article reviews both classical and some recent research developments on kernel methods, with emphases on the “plug-and-play” flavor of kernel methods.

The rest of this article is organized as follows. Section 1.16.2 introduces the kernel trick and properties and types of kernels, which constitute the foundations of kernel methods. In addition to the kernel ridge regression method presented in Section 1.16.2, Section 1.16.3 reviews some fundamental kernel methods including kernel principal component analysis, kernel canonical correlation analysis, kernel Fisher discriminant analysis, support vector machines, and Gaussian processes. Section 1.16.4 discusses the computational issues of kernel methods and algorithms towards their efficient implementations. Section 1.16.5 briefly surveys the recent developments on multiple kernel learning. Section 1.16.6 presents some practical applications of kernel methods and SVMs. Finally, open issues and problems are discussed in Section 1.16.7 after a brief concluding summary of the article.

## 1.16.2 Foundations of kernel methods

In this section, we first illustrate key concepts for kernel methods from kernel ridge regression, and then discuss properties of valid kernels. Finally, kernel design strategies are introduced.

### 1.16.2.1 The kernel trick: ridge regression as an example

Consider the problem of finding a homogeneous real-valued linear function

$$g(\mathbf{x}) = \langle \mathbf{w}, \mathbf{x} \rangle = \mathbf{x}^\top \mathbf{w} = \sum_{i=1}^n w_i x_i, \quad (16.1)$$

that best interpolates a given training set  $S = \{(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_m, y_m)\}$  of points  $\mathbf{x}_i \in \mathbb{R}^n$  with corresponding labels  $y_i \in \mathbb{R}$ . A commonly chosen measure of the discrepancy between a function output and the real observation is

$$f_g((\mathbf{x}, y)) = (g(\mathbf{x}) - y)^2. \quad (16.2)$$

Suppose the  $m$  inputs of  $S$  are stored in the matrix  $\mathbf{X}$  as row vectors, and the corresponding outputs constitute vector  $\mathbf{y}$  with  $\mathbf{y} = [y_1, \dots, y_m]^\top$ . Hence we can write  $\xi = \mathbf{y} - \mathbf{X}\mathbf{w}$  for the vector of differences between  $g(\mathbf{x}_i)$  and  $y_i$ . Ridge regression corresponds to solving the following optimization with a simple norm regularizer

$$\min_{\mathbf{w}} \mathcal{L}_\lambda(\mathbf{w}, S) = \min_{\mathbf{w}} \lambda \|\mathbf{w}\|^2 + \|\xi\|^2, \quad (16.3)$$

where  $\lambda > 0$  defines the relative tradeoff between the norm and loss. Setting the derivative of  $\mathcal{L}_\lambda(\mathbf{w}, S)$  with respect to the parameter vector  $\mathbf{w}$  equal to 0 gives

$$\mathbf{X}^\top \mathbf{X}\mathbf{w} + \lambda \mathbf{w} = (\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I}_n)\mathbf{w} = \mathbf{X}^\top \mathbf{y}, \quad (16.4)$$

where  $\mathbf{I}_n$  is the  $n \times n$  identity matrix. Thus we get the primal solution (referring to the explicit representation) for the weight vector

$$\mathbf{w} = (\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I}_n)^{-1} \mathbf{X}^\top \mathbf{y}, \quad (16.5)$$

from which the resulting prediction function  $g(\mathbf{x})$  can be readily given.

Alternatively, from (16.4) we get

$$\mathbf{w} = \mathbf{X}^\top \frac{1}{\lambda} (\mathbf{y} - \mathbf{X}\mathbf{w}) = \mathbf{X}^\top \boldsymbol{\alpha} = \sum_{i=1}^m \alpha_i \mathbf{x}_i, \quad (16.6)$$

where parameters  $\boldsymbol{\alpha} = [\alpha_1, \dots, \alpha_m]^\top \triangleq \lambda^{-1}(\mathbf{y} - \mathbf{X}\mathbf{w})$  are known as the dual variables. Substituting  $\mathbf{w} = \mathbf{X}^\top \boldsymbol{\alpha}$  into  $\boldsymbol{\alpha} = \lambda^{-1}(\mathbf{y} - \mathbf{X}\mathbf{w})$ , we obtain

$$\boldsymbol{\alpha} = (\mathbf{X}\mathbf{X}^\top + \lambda \mathbf{I}_m)^{-1} \mathbf{y}, \quad (16.7)$$

which is called the dual solution. The dual solution expresses the weight vector  $\mathbf{w}$  as a linear combination of the training examples. Denote the term  $\mathbf{X}\mathbf{X}^\top$  by  $\mathbf{K}$ . It follows that  $\mathbf{K}_{i,j} = \langle \mathbf{x}_i, \mathbf{x}_j \rangle$ . Now the resulting prediction function is formulated as

$$g(\mathbf{x}) = \mathbf{x}^\top \mathbf{w} = \mathbf{x}^\top \mathbf{X}^\top \boldsymbol{\alpha} = \left\langle \mathbf{x}, \sum_{i=1}^m \alpha_i \mathbf{x}_i \right\rangle = \sum_{i=1}^m \alpha_i \langle \mathbf{x}, \mathbf{x}_i \rangle. \quad (16.8)$$

There are two ingredients embedded in the dual form of ridge regression: computing vector  $\boldsymbol{\alpha}$  and evaluation of the prediction function. Both operations only involve inner products between data inputs.

Since the computation only involves inner products, we can substitute for all occurrences of  $\langle \cdot, \cdot \rangle$  a kernel function  $\kappa$  that computes  $\kappa(\mathbf{x}, \mathbf{z}) = \langle \phi(\mathbf{x}), \phi(\mathbf{z}) \rangle$  and we obtain an algorithm for ridge regression in the feature space  $F$  defined by the mapping  $\phi : \mathcal{X} \mapsto \phi(\mathbf{x}) \in F$ . This is an instantiation of the kernel trick for ridge regression and results in the kernel ridge regression algorithm. Through kernel ridge regression we can perform linear regression in very high-dimensional spaces efficiently, which is equivalent to performing non-linear regression in the original input space.

### 1.16.2.2 Properties of kernels

**Definition 1 (Kernel function).** A kernel is a function  $\kappa$  that for all  $\mathbf{x}, \mathbf{z}$  from a nonempty set  $\mathcal{X}$  (which need not be a vector space) satisfies

$$\kappa(\mathbf{x}, \mathbf{z}) = \langle \phi(\mathbf{x}), \phi(\mathbf{z}) \rangle, \quad (16.9)$$

where  $\phi$  is a mapping from the set  $\mathcal{X}$  to a Hilbert space  $F$  that is usually called the feature space

$$\phi : \mathcal{X} \mapsto \phi(\mathbf{x}) \in F. \quad (16.10)$$

To verify whether a function is a valid kernel, one approach is to construct a feature space for which the function value for two inputs corresponds to first performing an explicit feature mapping and then computing the inner product between their images. An alternative approach, which is more widely used, is to investigate the finitely positive semidefinite property [1, 6, 18–20].

**Definition 2 (Finitely positive semidefinite function).** A function  $\kappa : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$  satisfies the finitely positive semidefinite property if it is a *symmetric* function for which the kernel matrices  $K$  with  $K_{ij} = \kappa(\mathbf{x}_i, \mathbf{x}_j)$  formed by restriction to any finite subset of  $\mathcal{X}$  are positive semidefinite.

The feasibility of the above property for characterizing kernels is justified by the following theorem [1, 6, 21].

**Theorem 3 (Characterization of kernels).** A function  $\kappa : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$  which is either continuous or has a countable domain, can be decomposed as an inner product in a Hilbert space  $F$  by a feature map  $\phi$  applied to both its arguments

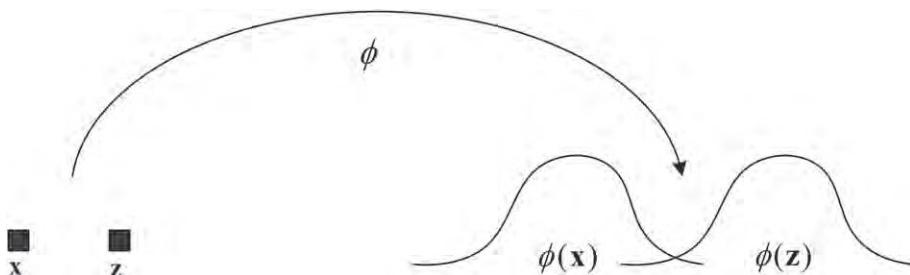

$$\kappa(\mathbf{x}, \mathbf{z}) = \langle \phi(\mathbf{x}), \phi(\mathbf{z}) \rangle \quad (16.11)$$

if and only if it satisfies the finitely positive semidefinite property.

A Hilbert space  $F$  is defined as an inner product space that is complete where completeness means that every Cauchy sequence of elements of  $F$  converges to an element in this space. If the separability property is further added to the definition of a Hilbert space, where a space is separable if there is a countable set of elements from this space such that the distance between each element of this space and some element of this countable set is less than any predefined threshold, the existence of “kernels are continuous or the domain is countable” in Theorem 3 is then necessary.

The Hilbert space constructed in proving Theorem 3 is called the reproducing kernel Hilbert space (RKHS) because the following reproducing property of the kernel resulting from the defined inner product holds

$$\langle f_F(\cdot), \kappa(\mathbf{x}, \cdot) \rangle = f_F(\mathbf{x}), \quad (16.12)$$

**FIGURE 16.1**

One instantiation of the feature mapping using a Gaussian kernel.

where  $f_F$  is a function of the function space  $F$ , and function  $\kappa(\mathbf{x}, \cdot)$  is the mapping  $\phi(\mathbf{x})$  which actually represents the similarity of  $\mathbf{x}$  to all other points in  $\mathcal{X}$ , as shown in Figure 16.1 [6].

By construction,  $f_F(\cdot)$  takes the form of an arbitrarily-weighted linear combination of countable images of the original inputs. For any two such functions

$$f_{F1}(\cdot) = \sum_{i=1}^{\ell_1} \alpha_i \kappa(\mathbf{x}_i, \cdot), \quad f_{F2}(\cdot) = \sum_{j=1}^{\ell_2} \beta_j \kappa(\mathbf{x}'_j, \cdot) \quad (16.13)$$

where  $\ell_1, \ell_2 \in \mathbb{N}$ ,  $\alpha_i, \beta_j \in \mathbb{R}$  and  $\mathbf{x}_i, \mathbf{x}'_j \in \mathcal{X}$ , the dot product is defined as

$$\langle f_{F1}(\cdot), f_{F2}(\cdot) \rangle \triangleq \sum_{i=1}^{\ell_1} \sum_{j=1}^{\ell_2} \alpha_i \beta_j \kappa(\mathbf{x}_i, \mathbf{x}'_j). \quad (16.14)$$

The inner product space or pre-Hilbert space formed by  $f_F(\cdot)$  is then completed to form the Hilbert space  $F$  where the mathematical trick “completion” refers to adding all limit points of Cauchy sequences to the space [6].

It should be noted that there are different approaches to constructing feature spaces for any given kernel. Besides the above construction, the Mercer kernel map [22], though not mentioned much here, is also widely applicable, especially in the SVM literature. The feature spaces constructed in different ways can even have different dimensions. However, since we are only interested in dot products, these spaces can be regarded as identical.

For some kernels, the feature map and feature space can be explicitly built with a simple form. For instance, consider the homogeneous quadratic kernel

$$\kappa(\mathbf{x}, \mathbf{z}) = \langle \mathbf{x}, \mathbf{z} \rangle^2, \quad (16.15)$$

which can be reformulated as

$$\kappa(\mathbf{x}, \mathbf{z}) = (\mathbf{x}' \mathbf{z})^2 = \mathbf{z}' (\mathbf{x} \mathbf{x}') \mathbf{z} = \langle \text{vec}(\mathbf{z} \mathbf{z}'), \text{vec}(\mathbf{x} \mathbf{x}') \rangle, \quad (16.16)$$

where  $\text{vec}(A)$  stacks the column of matrix  $A$  on top of each other in the manner that the first column situates at the top. The feature map corresponding to  $\kappa$  would be  $\phi(\mathbf{x}) = \text{vec}(\mathbf{x} \mathbf{x}')$ . The feature space can be the Euclidean space with dimensionality being the total number of entries of  $\text{vec}(\mathbf{x} \mathbf{x}')$ .

### 1.16.2.3 Types of kernels

The use of kernels provides a powerful and principled approach to modeling nonlinear patterns through linear patterns in a feature space. Another benefit is that the design of kernels and linear methods can be decoupled, which greatly facilitates the modularity of machine learning methods.

Representative kernels include the linear kernel  $\kappa(\mathbf{x}, \mathbf{z}) = \langle \mathbf{x}, \mathbf{z} \rangle$ , inhomogeneous polynomial kernel

$$\kappa(\mathbf{x}, \mathbf{z}) = (\langle \mathbf{x}, \mathbf{z} \rangle + R)^d \quad (16.17)$$

where  $d$  is the degree of the polynomial and parameter  $R \in \mathbb{R}$ , and the Gaussian radial basis function (RBF) kernel (Gaussian kernel for short) with parameter  $\sigma > 0$

$$\kappa(\mathbf{x}, \mathbf{z}) = \exp\left(-\frac{\|\mathbf{x} - \mathbf{z}\|^2}{2\sigma^2}\right). \quad (16.18)$$

The polynomial kernel (16.17) can be expanded by the binomial theorem as

$$(\langle \mathbf{x}, \mathbf{z} \rangle + R)^d = \sum_{s=0}^d \binom{d}{s} R^{d-s} \langle \mathbf{x}, \mathbf{z} \rangle^s. \quad (16.19)$$

Hence, the features for each component in the sum together form the features of the kernel. In other words, we have a reweighting of the features of the homogeneous polynomial kernel

$$\kappa(\mathbf{x}, \mathbf{z}) = \langle \mathbf{x}, \mathbf{z} \rangle^s, \quad s = 0, \dots, d, \quad (16.20)$$

where one construction of the feature map corresponding to kernel (16.20) is using a vector with entries being all ordered monomials (e.g.,  $x_1x_2$  and  $x_2x_1$  are treated as separate features) of degree  $s$ , that is, each entry is an instantiation of product  $x_{j_1} \dots x_{j_s}$  with  $j_1, \dots, j_s \in \{1, \dots, n\}$  [6]. The parameter  $R$  allows the control of the relative weightings of the monomials with different degrees. The weight formulation  $\binom{d}{s} R^{d-s}$  indicates that increasing  $R$  decreases the relative weighting of higher order monomials [1].

For the Gaussian kernel (16.18) the images of all points have norm 1 in the feature space as a result of  $\kappa(\mathbf{x}, \mathbf{x}) = 1$ . It can be obtained by normalizing  $\exp(\langle \mathbf{x}, \mathbf{z} \rangle / \sigma^2)$

$$\begin{aligned} \exp\left(-\frac{\|\mathbf{x} - \mathbf{z}\|^2}{2\sigma^2}\right) &= \exp\left(\frac{\langle \mathbf{x}, \mathbf{z} \rangle}{\sigma^2} - \frac{\langle \mathbf{x}, \mathbf{x} \rangle}{2\sigma^2} - \frac{\langle \mathbf{z}, \mathbf{z} \rangle}{2\sigma^2}\right) \\ &= \frac{\exp(\langle \mathbf{x}, \mathbf{z} \rangle / \sigma^2)}{\sqrt{\exp(\|\mathbf{x}\|^2 / \sigma^2) \exp(\|\mathbf{z}\|^2 / \sigma^2)}}. \end{aligned} \quad (16.21)$$

Because an exponential function can be arbitrarily closely approximated by polynomials with positive coefficients

$$\exp(x) = \sum_{i=0}^{\infty} \frac{1}{i!} x^i, \quad (16.22)$$

the function  $\exp(\langle \mathbf{x}, \mathbf{z} \rangle / \sigma^2)$  is arguably a kernel. Therefore, the Gaussian kernel (16.18) is a polynomial kernel of infinite degree, and its features can be all ordered monomials of input features with no restriction placed on the degrees. However, with increasing degree the weighting of individual monomials falls off as  $i!$  [1].

One appeal of using kernel methods is that kernels are not restricted to vectorial data, making it possible to apply the techniques to diverse types of objects. Not surprisingly, kernels can be designed

for sets, strings, text documents, graphs and graph-nodes [1]. For these kernels, we would not elaborate here. However, an effective design of kernels has to be embedded with some prior knowledge on how to characterize similarity between data.

We now focus on two types of kernels induced by probabilistic models, marginalization kernels and Fisher kernels. These techniques are useful for combining generative and discriminative methods for machine learning. The marginalization kernels are defined as follows.

**Definition 4 (Marginalization kernels).** Given a set of data models  $M$  and a prior distribution  $P_M$  on  $M$ , the probability that an example pair  $\mathbf{x}$  and  $\mathbf{z}$  is generated together can be computed as

$$P_M(\mathbf{x}, \mathbf{z}) = \sum_{m \in M} P(\mathbf{x}|m)P(\mathbf{z}|m)P_M(m). \quad (16.23)$$

If we consider the mapping function

$$\phi : \mathbf{x} \mapsto (P(\mathbf{x}|m))_{m \in M} \in F \quad (16.24)$$

in a feature space  $F$  indexed by  $M$ ,  $P_M(\mathbf{x}, \mathbf{z})$  corresponds to the inner product

$$\langle f, g \rangle = \sum_{m \in M} f_m g_m P_M(m) \quad (16.25)$$

between  $\phi(\mathbf{x})$  and  $\phi(\mathbf{z})$ .  $P_M(\mathbf{x}, \mathbf{z})$  is referred to as the marginalization kernel for the model class  $M$ .

The above computation can be viewed as a marginalization operation for the probability distribution of triples  $(\mathbf{x}, \mathbf{z}, m)$  over  $m$  (with conditional independence of  $\mathbf{x}$  and  $\mathbf{z}$  given a specific model  $m$ ), and therefore comes the name marginalization kernels. The assumption of conditional independence is a sufficient condition for positive semi-definiteness. For an input, marginalization kernels treat the output probability given one model as a feature. Since the information from a single model is quite limited, they usually adopt multiple different models to reach a representation of the input.

Fisher kernels, defined by [23,24], are an alternative way of extracting information, usually from a single generative model, however. The single model is required to be smoothly parameterized so that derivatives of the model with respect to the parameters is computable. An intuitive interpretation of Fisher kernels is that it describes data points by the variation of some quantity (say the log of the likelihood function) caused by slight parameter perturbations.

**Definition 5 (Fisher score and Fisher information matrix).** For a given setting of the parameters  $\boldsymbol{\theta}^0$  (e.g., obtained by the maximum likelihood rule) the log-likelihood of a data point  $\mathbf{x}$  with respect to the model  $m(\boldsymbol{\theta}^0)$  is defined to be  $\log P(\mathbf{x}|\boldsymbol{\theta}^0)$ . Consider the gradient vector of the log-likelihood

$$\mathbf{g}(\boldsymbol{\theta}, \mathbf{x}) = \left( \frac{\partial \log P(\mathbf{x}|\boldsymbol{\theta})}{\partial \theta_i} \right)_{i=1}^N, \quad (16.26)$$

where  $\boldsymbol{\theta} \in \mathbb{R}^N$ . The Fisher score of a data point  $\mathbf{x}$  with respect to the model  $m(\boldsymbol{\theta}^0)$  is  $\mathbf{g}(\boldsymbol{\theta}^0, \mathbf{x})$ . The Fisher information matrix with respect to the model  $m(\boldsymbol{\theta}^0)$  is given by

$$\mathbf{I}_{\text{Fisher}} = \mathbb{E} \left[ \mathbf{g}(\boldsymbol{\theta}^0, \mathbf{x}) \mathbf{g}(\boldsymbol{\theta}^0, \mathbf{x})^\top \right], \quad (16.27)$$

where the expectation is over the distribution of the data point  $\mathbf{x}$ .

The Fisher score embeds a data point into the feature space  $\mathbb{R}^N$ , and provides direct constructions of kernels.

**Definition 6 (Fisher kernel).** The invariant Fisher kernel with respect to the model  $m(\theta^0)$  for a given setting of the parameters  $\theta^0$  is defined as

$$\kappa(\mathbf{x}, \mathbf{z}) = \mathbf{g}(\theta^0, \mathbf{x})^\top \mathbf{I}_{Fisher}^{-1} \mathbf{g}(\theta^0, \mathbf{z}). \quad (16.28)$$

The practical Fisher kernel is defined as

$$\kappa(\mathbf{x}, \mathbf{z}) = \mathbf{g}(\theta^0, \mathbf{x})^\top \mathbf{g}(\theta^0, \mathbf{z}). \quad (16.29)$$

The invariant Fisher kernel is computationally more demanding as it requires the computation and inversion of the Fisher information matrix. It is named “invariant” because the resulting kernel would not change if we reparameterize the model with an invertible differentiable transformation  $\psi = \psi(\theta)$ . Suppose  $\tilde{\kappa}$  is the transformed kernel. It follows that

$$\mathbf{g}(\theta^0, \mathbf{x})^\top = \left( \left( \frac{\partial \log P(x|\psi)}{\partial \psi_i} \right)_{i=1}^N \right)^\top \mathbf{J}(\psi) = \mathbf{g}(\psi^0, \mathbf{x})^\top \mathbf{J}(\psi^0), \quad (16.30)$$

where matrix  $\mathbf{J}(\psi^0)$  is the Jacobian of the transformation  $\psi$  evaluated at  $\psi^0$  [1]. Now we have

$$\begin{aligned} \tilde{\kappa}(\mathbf{z}_1, \mathbf{z}_2) &= \mathbf{g}(\psi^0, \mathbf{z}_1)^\top \mathbb{E} \left[ (\mathbf{J}(\psi^0)^{-1})^\top \mathbf{g}(\theta^0, \mathbf{x}) \mathbf{g}(\theta^0, \mathbf{x})^\top \mathbf{J}(\psi^0)^{-1} \right]^{-1} \mathbf{g}(\psi^0, \mathbf{z}_2) \\ &= \mathbf{g}(\theta^0, \mathbf{z}_1)^\top \mathbb{E} \left[ \mathbf{g}(\theta^0, \mathbf{x}) \mathbf{g}(\theta^0, \mathbf{x})^\top \right]^{-1} \mathbf{g}(\theta^0, \mathbf{z}_2) \\ &= \kappa(\mathbf{z}_1, \mathbf{z}_2). \end{aligned} \quad (16.31)$$

Hence, the invariant Fisher kernel is desirable if the choice of parameterizations is somewhat arbitrary. But for this kernel there is a caveat when the natural approximation of the Fisher information matrix by its empirical estimate is used

$$\hat{\mathbf{I}}_{Fisher} = \hat{\mathbb{E}} \left[ \mathbf{g}(\theta^0, \mathbf{x}) \mathbf{g}(\theta^0, \mathbf{x})^\top \right] = \frac{1}{m} \sum_{i=1}^m \mathbf{g}(\theta^0, \mathbf{x}_i) \mathbf{g}(\theta^0, \mathbf{x}_i)^\top, \quad (16.32)$$

in which case  $\hat{\mathbf{I}}_{Fisher}$  is the empirical covariance matrix of the Fisher scores. The invariant Fisher kernel is thus equivalent to whitening the scores. The negative effect is that we may amplify noise if some parameters are not relevant for the information, and therefore the signal to noise ratio is possibly reduced. This can be regarded as the cost of the invariance.

Apart from the kernels introduced so far, more complicated kernels can be constructed with them as building blocks. The following theorem [1] lists some strategies for kernel constructions.

**Theorem 7 (Kernel constructions).** Let  $\kappa_1, \kappa_2$ , and  $\kappa_3$  be valid kernels,  $\phi$  any feature map to the domain of  $\kappa_3$ ,  $a \geq 0$ ,  $f(\cdot)$  any real-valued function, and  $\mathbf{B}$  a positive semi-definite matrix. Then the following functions are valid kernels:

- $\kappa(\mathbf{x}, \mathbf{z}) = \kappa_1(\mathbf{x}, \mathbf{z}) + \kappa_2(\mathbf{x}, \mathbf{z})$ ,
- $\kappa(\mathbf{x}, \mathbf{z}) = a\kappa_1(\mathbf{x}, \mathbf{z})$ ,

- $\kappa(\mathbf{x}, \mathbf{z}) = \kappa_1(\mathbf{x}, \mathbf{z})\kappa_2(\mathbf{x}, \mathbf{z})$ ,
- $\kappa(\mathbf{x}, \mathbf{z}) = f(\mathbf{x})f(\mathbf{z})$ ,
- $\kappa(\mathbf{x}, \mathbf{z}) = \kappa_3(\phi(\mathbf{x}), \phi(\mathbf{z}))$ ,
- $\kappa(\mathbf{x}, \mathbf{z}) = \mathbf{x}^\top \mathbf{Bz}$  (for now  $\mathbf{x}$  and  $\mathbf{z}$  are vectorial data).

### 1.16.3 Fundamental kernel methods

In this section, we introduce some fundamental kernel methods ranging from unsupervised learning to supervised learning. These methods have a large popularity either because they are among the first uses of kernels or because they address very fundamental learning problems.

#### 1.16.3.1 Kernel principal component analysis

Principal component analysis (PCA) finds a set of orthogonal directions which forms a subspace to maximize variances. In this way, data can be reconstructed with minimal quadratic error. Suppose the inputs of the data set  $S$  given in Section 1.16.2.1 is centered with mean  $\mathbf{0}$ . The direction that maximizes the variance can be found by solving the following problem

$$\begin{aligned} & \max_{\mathbf{w}} \mathbf{w}^\top \mathbf{Cw} \\ & \text{s.t. } \|\mathbf{w}\| = 1, \end{aligned} \quad (16.33)$$

where  $\mathbf{C} = \frac{1}{m} \mathbf{X}^\top \mathbf{X}$  is the covariance matrix (strictly speaking, an empirical estimate of the covariance) of the input data. The solution is given by the eigenvector of  $\mathbf{C}$  corresponding to the largest eigenvalue with the objective value being the eigenvalue. The direction of the second largest variance can be searched for in the subspace orthogonal to the direction already found. This results in the eigenvector corresponding to the second largest eigenvalue. It is readily provable that PCA projects data into the space spanned by the  $k$  largest eigenvectors of  $\mathbf{C}$  if we would like to find a  $k$ -dimensional subspace. The new coordinates by which we represent the data are known as principal components. Although centering data before performing PCA is not a must, it has the advantage of reducing the overall sum of the eigenvalues and thus removing irrelevant variance arising from data shift [1].

The kernel PCA [25] extends the linear PCA algorithm to extracting nonlinear structures in terms of kernels. Now we provide a simple derivation of the kernel PCA by exploiting the relationship between  $\mathbf{X}^\top \mathbf{X}$  and  $\mathbf{XX}^\top$  [1]. It is easy to show that these two matrices have the same rank. More interestingly, their eigen-decompositions correspond to each other. Suppose that  $\mathbf{w}, \lambda$  is an eigenvector-eigenvalue pair for  $\mathbf{X}^\top \mathbf{X}$ , then  $\mathbf{Xw}, \lambda$  is for  $\mathbf{XX}^\top$

$$(\mathbf{XX}^\top)\mathbf{Xw} = \mathbf{X}(\mathbf{X}^\top \mathbf{X})\mathbf{w} = \lambda \mathbf{Xw}, \quad (16.34)$$

and conversely, if  $\alpha, \lambda$  is an eigenvector-eigenvalue pair for the matrix  $\mathbf{XX}^\top$ , then  $\mathbf{X}^\top \alpha, \lambda$  is for  $\mathbf{X}^\top \mathbf{X}$

$$(\mathbf{X}^\top \mathbf{X})\mathbf{X}^\top \alpha = \mathbf{X}^\top (\mathbf{XX}^\top)\alpha = \lambda \mathbf{X}^\top \alpha. \quad (16.35)$$

This gives a dual representation for the eigenvector of  $\mathbf{X}^\top \mathbf{X}$  from the eigen-decomposition of  $\mathbf{XX}^\top$ .  $\mathbf{XX}^\top$  is actually a kernel matrix if we replace each row  $\mathbf{x}_i^\top$  of  $\mathbf{X}$  by its image  $\phi(\mathbf{x}_i)^\top$  in a feature space, and  $\mathbf{X}^\top \mathbf{X}$  would be the scaled covariance matrix without centering.

Centering data in a feature space is not so simple as in the original space. Suppose that a kernel  $\kappa$  is adopted with the kernel matrix  $\mathbf{K}$  computed from the original data. Centering data in the feature space corresponds to defining a new feature map  $\hat{\phi}(\mathbf{x}) = \phi(\mathbf{x}) - \frac{1}{m} \sum_{i=1}^m \phi(\mathbf{x}_i)$ . The new kernel matrix for the centered data would be

$$\hat{\mathbf{K}} = \mathbf{K} - \frac{1}{m} \mathbf{j} \mathbf{j}^\top \mathbf{K} - \frac{1}{m} \mathbf{K} \mathbf{j} \mathbf{j}^\top + \frac{1}{m^2} (\mathbf{j}^\top \mathbf{K} \mathbf{j}) \mathbf{j} \mathbf{j}^\top, \quad (16.36)$$

where  $\mathbf{j}$  is the all 1s vector [1]. Suppose that  $\hat{\alpha}, \hat{\lambda}$  is an eigenvector-eigenvalue pair for the kernel matrix  $\hat{\mathbf{K}} = \hat{\mathbf{X}} \hat{\mathbf{X}}^\top$  where  $\|\hat{\alpha}\| = 1$  and the  $i$ th row of  $\hat{\mathbf{X}}$  is  $\hat{\phi}(\mathbf{x}_i)^\top$ . Then  $\hat{\mathbf{X}}^\top \hat{\alpha}$  is the eigenvector of the covariance matrix  $\frac{1}{m} \hat{\mathbf{X}}^\top \hat{\mathbf{X}}$  which has the same eigenvectors with  $\hat{\mathbf{X}}^\top \hat{\mathbf{X}}$ . Usually we require that the final projection vector is normalized, that is,  $\|\hat{\mathbf{X}}^\top \hat{\alpha}\| = 1$ . Because for  $\|\hat{\alpha}\| = 1$  we have

$$\|\hat{\mathbf{X}}^\top \hat{\alpha}\|^2 = \hat{\alpha}^\top \hat{\mathbf{X}} \hat{\mathbf{X}}^\top \hat{\alpha} = \hat{\alpha}^\top \hat{\mathbf{K}} \hat{\alpha} = \hat{\lambda}, \quad (16.37)$$

to meet  $\|\hat{\mathbf{X}}^\top \hat{\alpha}\| = 1$ ,  $\hat{\alpha}$  should be further divided by  $\sqrt{\hat{\lambda}}$ . Hence, the  $k$  projection directions derived from kernel PCA should be

$$\left\{ \frac{1}{\sqrt{\hat{\lambda}_i}} \hat{\mathbf{X}}^\top \hat{\alpha}_i \right\}_{i=1}^k, \quad (16.38)$$

where  $\{\hat{\alpha}_i, \hat{\lambda}_i\}_{i=1}^k$  are the  $k$  leading eigenvector-eigenvalue pairs for the kernel matrix  $\hat{\mathbf{K}}$  and the norms of  $\{\hat{\alpha}_i\}_{i=1}^k$  are all 1. The projections of a new input  $\mathbf{x}$  would be the inner products between the above directions and  $\phi(\mathbf{x}) - \frac{1}{m} \sum_{i=1}^m \phi(\mathbf{x}_i)$ .

### 1.16.3.2 Kernel canonical correlation analysis

Canonical correlation analysis (CCA), proposed by [26], works on a paired dataset (i.e., data with two representations) to find two linear transformations each for one of the two representations such that the correlations between the transformed variables are maximized. It was later generalized to more than two sets of variables in several ways [27, 28]. Here we only focus on the situation of two sets of variables.

Suppose we have a paired dataset  $S_{\mathbf{x}, \mathbf{u}} = \{(\mathbf{x}_1, \mathbf{u}_1), \dots, (\mathbf{x}_m, \mathbf{u}_m)\}$ . For example,  $\mathbf{x}_i$  and the corresponding  $\mathbf{u}_i$  can be the representations of a same semantic content in two different languages. CCA attempts to seek the projection directions  $\mathbf{w}_x$  and  $\mathbf{w}_u$  to maximize the following empirical correlation

$$\frac{\text{cov}(\mathbf{w}_x^\top \mathbf{x}, \mathbf{w}_u^\top \mathbf{u})}{\sqrt{\text{var}(\mathbf{w}_x^\top \mathbf{x}) \text{var}(\mathbf{w}_u^\top \mathbf{u})}} = \frac{\mathbf{w}_x^\top \mathbf{C}_{xu} \mathbf{w}_u}{\sqrt{(\mathbf{w}_x^\top \mathbf{C}_{xx} \mathbf{w}_x)(\mathbf{w}_u^\top \mathbf{C}_{uu} \mathbf{w}_u)}}, \quad (16.39)$$

where covariance matrix  $\mathbf{C}_{xu}$  is defined as (definitions for  $\mathbf{C}_{xx}$  and  $\mathbf{C}_{uu}$  can be obtained analogously)

$$\mathbf{C}_{xu} = \frac{1}{m} \sum_{i=1}^m (\mathbf{x}_i - \mathbf{m}_x)(\mathbf{u}_i - \mathbf{m}_u)^\top \quad (16.40)$$

with  $\mathbf{m}_x$  and  $\mathbf{m}_u$  being the means of the two representations, respectively

$$\mathbf{m}_x = \frac{1}{m} \sum_{i=1}^m \mathbf{x}_i, \quad \mathbf{m}_u = \frac{1}{m} \sum_{i=1}^m \mathbf{u}_i. \quad (16.41)$$

Because the scales of  $\mathbf{w}_x$  and  $\mathbf{w}_u$  have no effects on the value of (16.39), we can constrain each of the two terms in the denominator to take value 1. Thus we reach another widely used objective for CCA

$$\begin{aligned} \max_{\mathbf{w}_x, \mathbf{w}_u} \quad & \rho = \mathbf{w}_x^\top \mathbf{C}_{xu} \mathbf{w}_u \\ \text{s.t.} \quad & \mathbf{w}_x^\top \mathbf{C}_{xx} \mathbf{w}_x = 1, \quad \mathbf{w}_u^\top \mathbf{C}_{uu} \mathbf{w}_u = 1. \end{aligned} \quad (16.42)$$

The solution is given by first solving the generalized eigenvalue problem [1]

$$\begin{pmatrix} \mathbf{0} & \mathbf{C}_{xu} \\ \mathbf{C}_{ux} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \mathbf{w}_x \\ \mathbf{w}_u \end{pmatrix} = \lambda \begin{pmatrix} \mathbf{C}_{xx} & \mathbf{0} \\ \mathbf{0} & \mathbf{C}_{uu} \end{pmatrix} \begin{pmatrix} \mathbf{w}_x \\ \mathbf{w}_u \end{pmatrix}, \quad (16.43)$$

and then normalizing the resulting directions to comply with the constraints of (16.42). Note that the eigenvalue  $\lambda$  for a particular eigenvector  $\begin{pmatrix} \mathbf{w}_x \\ \mathbf{w}_u \end{pmatrix}$  gives the corresponding correlation value

$$\rho = \mathbf{w}_x^\top \mathbf{C}_{xu} \mathbf{w}_u = \mathbf{w}_x^\top (\lambda \mathbf{C}_{xx} \mathbf{w}_x) = \lambda. \quad (16.44)$$

Consequently, all eigenvalues lie in the interval  $[-1, +1]$ . Interestingly, if  $\begin{pmatrix} \mathbf{w}_x \\ \mathbf{w}_u \end{pmatrix}$ ,  $\lambda$  is an eigenvector-eigenvalue pair, so is  $\begin{pmatrix} \mathbf{w}_x \\ -\mathbf{w}_u \end{pmatrix}$ ,  $-\lambda$ . Therefore, only half the spectrum, e.g., the positive eigenvalues, are necessary to be considered, and the corresponding eigenvectors constitute desirable projection directions (as with PCA, we often need more than one projection directions). The eigenvectors with largest eigenvalues identify the strongest correlations.

Now we give the dual form of CCA to facilitate the derivation of kernel CCA [29–31]. Assume that the dataset  $S_{x,u}$  is centered, that is, the mean value of each of the two representations is zero. We consider expressing  $\mathbf{w}_x$  and  $\mathbf{w}_u$  as linear combinations of training examples

$$\mathbf{w}_x = \mathbf{X}^\top \boldsymbol{\alpha}_x, \quad \mathbf{w}_u = \mathbf{U}^\top \boldsymbol{\alpha}_u, \quad (16.45)$$

where the rows of  $\mathbf{X}$  and  $\mathbf{U}$  are vectors  $\mathbf{x}_i^\top$  and  $\mathbf{u}_i^\top$  ( $i = 1, \dots, m$ ), respectively. Substituting (16.45) into (16.42) results in

$$\begin{aligned} \max_{\boldsymbol{\alpha}_x, \boldsymbol{\alpha}_u} \quad & \boldsymbol{\alpha}_x^\top \mathbf{X} \mathbf{X}^\top \mathbf{U} \mathbf{U}^\top \boldsymbol{\alpha}_u \\ \text{s.t.} \quad & \boldsymbol{\alpha}_x^\top \mathbf{X} \mathbf{X}^\top \mathbf{X} \mathbf{X}^\top \boldsymbol{\alpha}_x = 1, \quad \boldsymbol{\alpha}_u^\top \mathbf{U} \mathbf{U}^\top \mathbf{U} \mathbf{U}^\top \boldsymbol{\alpha}_u = 1. \end{aligned} \quad (16.46)$$

Since the above formulation only involves inner products among training examples, we can write down the objective for kernel CCA simply as

$$\begin{aligned} \max_{\boldsymbol{\alpha}_x, \boldsymbol{\alpha}_u} \quad & \boldsymbol{\alpha}_x^\top \mathbf{K}_x \mathbf{K}_u \boldsymbol{\alpha}_u \\ \text{s.t.} \quad & \boldsymbol{\alpha}_x^\top \mathbf{K}_x^2 \boldsymbol{\alpha}_x = 1, \quad \boldsymbol{\alpha}_u^\top \mathbf{K}_u^2 \boldsymbol{\alpha}_u = 1, \end{aligned} \quad (16.47)$$

where  $\mathbf{K}_x$  and  $\mathbf{K}_u$  are the kernel matrices for the two representations, respectively (if data are not centered in feature spaces, techniques similar to centering for kernel PCA can be adopted).

It was shown that overfitting with perfect correlations which fail to distinguish spurious features from those revealing the underlying semantics can appear using the above versions of CCA and kernel CCA

[1,27]. In other words, some kind of regularization is needed to detect meaningful patterns. Statistical stability analysis shows that controlling the norms of the two projection directions is a good way for regularization [1]. Hence, we have the regularized CCA whose objective is to maximize

$$\frac{\mathbf{w}_x^\top \mathbf{C}_{xu} \mathbf{w}_u}{\sqrt{((1 - \tau_x) \mathbf{w}_x^\top \mathbf{C}_{xx} \mathbf{w}_x + \tau_x \|\mathbf{w}_x\|^2) ((1 - \tau_u) \mathbf{w}_u^\top \mathbf{C}_{uu} \mathbf{w}_u + \tau_u \|\mathbf{w}_u\|^2)}}, \quad (16.48)$$

where regularization parameters  $\tau_x$  and  $\tau_u$  vary in the interval  $[0, 1]$ . The kernel regularized CCA corresponding to (16.47) is given by optimizing

$$\begin{aligned} & \max_{\alpha_x, \alpha_u} \alpha_x^\top \mathbf{K}_x \mathbf{K}_u \alpha_u \\ & \text{s.t. } (1 - \tau_x) \alpha_x^\top \mathbf{K}_x^2 \alpha_x + \tau_x \alpha_x^\top \mathbf{K}_x \alpha_x = 1, \\ & \quad (1 - \tau_u) \alpha_u^\top \mathbf{K}_u^2 \alpha_u + \tau_u \alpha_u^\top \mathbf{K}_u \alpha_u = 1. \end{aligned} \quad (16.49)$$

### 1.16.3.3 Kernel Fisher discriminant analysis

The Fisher discriminant is a classification function

$$f(\mathbf{x}) = \text{sign}(\mathbf{w}^\top \mathbf{x} + b), \quad (16.50)$$

where the weight vector  $\mathbf{w}$  is found through a specific optimization to well separate different classes. In particular, a direction is found which maximizes the distance between projected class means and simultaneously minimizes the projected class variances. In this article, the binary case is considered. The parameter  $b$  in the Fisher discriminant is usually determined by projecting training data to  $\mathbf{w}$  and then identifying the middle point of two class means.

Suppose examples from two different classes are given by  $S_1 = \{\mathbf{x}_1^1, \dots, \mathbf{x}_{m_1}^1\}$  and  $S_2 = \{\mathbf{x}_1^2, \dots, \mathbf{x}_{m_2}^2\}$ . Fisher discriminant analysis [32,33] finds  $\mathbf{w}$  which maximizes

$$J(\mathbf{w}) = \frac{\mathbf{w}^\top \mathbf{S}_B \mathbf{w}}{\mathbf{w}^\top \mathbf{S}_W \mathbf{w}}, \quad (16.51)$$

where

$$\begin{aligned} \mathbf{S}_B &= (\mathbf{m}_1 - \mathbf{m}_2)(\mathbf{m}_1 - \mathbf{m}_2)^\top, \\ \mathbf{S}_W &= \sum_{i=1,2} \sum_{\mathbf{x} \in S_i} (\mathbf{x} - \mathbf{m}_i)(\mathbf{x} - \mathbf{m}_i)^\top \end{aligned} \quad (16.52)$$

are respectively the between and within class scatter matrices and  $\mathbf{m}_i$  is defined by  $\mathbf{m}_i = \frac{1}{m_i} \sum_{j=1}^{m_i} \mathbf{x}_j^i$ . The solution is the eigenvector corresponding to the largest eigenvalue of the generalized eigen-decomposition

$$\mathbf{S}_B \mathbf{w} = \lambda \mathbf{S}_W \mathbf{w}. \quad (16.53)$$

Since the matrix  $\mathbf{S}_B$  has rank 1, only the leading eigenvector contains meaningful information.

Let  $\phi$  be a nonlinear map to some feature space  $F$ . Kernel Fisher discriminant analysis attempts to find a direction  $\mathbf{w} \in F$  to maximize

$$J(\mathbf{w}) = \frac{\mathbf{w}^\top \mathbf{S}_B^\phi \mathbf{w}}{\mathbf{w}^\top \mathbf{S}_W^\phi \mathbf{w}}, \quad (16.54)$$

where

$$\begin{aligned} \mathbf{S}_B^\phi &= (\mathbf{m}_1^\phi - \mathbf{m}_2^\phi)(\mathbf{m}_1^\phi - \mathbf{m}_2^\phi)^\top, \\ \mathbf{S}_W^\phi &= \sum_{i=1,2} \sum_{\mathbf{x} \in S_i} (\phi(\mathbf{x}) - \mathbf{m}_i^\phi) (\phi(\mathbf{x}) - \mathbf{m}_i^\phi)^\top \end{aligned} \quad (16.55)$$

with  $\mathbf{m}_i^\phi = \frac{1}{m_i} \sum_{j=1}^{m_i} \phi(\mathbf{x}_j^i)$ .

Define  $S = S_1 \cup S_2$  and denote its elements by  $\{\mathbf{x}_1, \dots, \mathbf{x}_m\}$  with  $m = m_1 + m_2$ . We would like to find an expansion for  $\mathbf{w}$  in the form  $\mathbf{w} = \sum_{i=1}^m \alpha_i \phi(\mathbf{x}_i)$ . It follows that

$$\mathbf{w}^\top \mathbf{m}_i^\phi = \frac{1}{m_i} \sum_{j=1}^{m_i} \sum_{k=1}^{m_i} \alpha_j \kappa(\mathbf{x}_j, \mathbf{x}_k^i) = \boldsymbol{\alpha}^\top \mathbf{M}_i, \quad (16.56)$$

where vector  $\mathbf{M}_i$  is defined as  $(\mathbf{M}_i)_j = \frac{1}{m_i} \sum_{k=1}^{m_i} \kappa(\mathbf{x}_j, \mathbf{x}_k^i)$  and the dot products are replaced with kernels [33]. Based on (16.56), the numerator of (16.54) can be rewritten as

$$\mathbf{w}^\top \mathbf{S}_B^\phi \mathbf{w} = \boldsymbol{\alpha}^\top \mathbf{M} \boldsymbol{\alpha}, \quad (16.57)$$

where  $\mathbf{M} = (\mathbf{M}_1 - \mathbf{M}_2)(\mathbf{M}_1 - \mathbf{M}_2)^\top$ . And the denominator is rewritten as

$$\mathbf{w}^\top \mathbf{S}_W^\phi \mathbf{w} = \boldsymbol{\alpha}^\top \mathbf{N} \boldsymbol{\alpha}, \quad (16.58)$$

where  $\mathbf{N} = \sum_{j=1,2} \mathbf{K}_j (\mathbf{I} - \mathbf{1}_{m_j}) \mathbf{K}_j^\top$ ,  $\mathbf{K}_j$  is an  $m \times m_j$  matrix with  $(\mathbf{K}_j)_{ik} = \kappa(\mathbf{x}_i, \mathbf{x}_k^j)$ ,  $\mathbf{I}$  is the identity matrix and  $\mathbf{1}_{m_j}$  is the matrix with all entries  $\frac{1}{m_j}$  [33].

Hence, (16.54) is reformulated as

$$J(\boldsymbol{\alpha}) = \frac{\boldsymbol{\alpha}^\top \mathbf{M} \boldsymbol{\alpha}}{\boldsymbol{\alpha}^\top \mathbf{N} \boldsymbol{\alpha}}. \quad (16.59)$$

The problem can be solved similarly to (16.51). To enhance numerical stability and perform capacity control in the feature space,  $\mathbf{N}$  in the above formulation is usually replace by  $\mathbf{N} + \mu \mathbf{I}$  with positive  $\mu$ . An alternative regularization is penalizing  $\|\mathbf{w}\|^2$  as in kernel CCA instead of the current  $\|\boldsymbol{\alpha}\|^2$  which corresponds to the term  $\mu \mathbf{I}$ .

#### 1.16.3.4 SVMs for classification and regression

Given the training set  $S = \{(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_m, y_m)\}$  of points  $\mathbf{x}_i \in \mathbb{R}^n$  with corresponding labels  $y_i \in \{1, -1\}$ , SVM classifiers attempt to find a classification hyperplane induced from the maximum

margin principle [7,8]. In real applications data are usually not linearly separable. Thus a loss on the violation of the linearly separable constraints has to be introduced. A common choice is the hinge loss

$$\max \left( 0, 1 - y_i (\mathbf{w}^\top \mathbf{x}_i + b) \right), \quad (16.60)$$

which can be represented by a slack variable  $\xi_i$ .

The optimization problem for SVM classification is formulated as

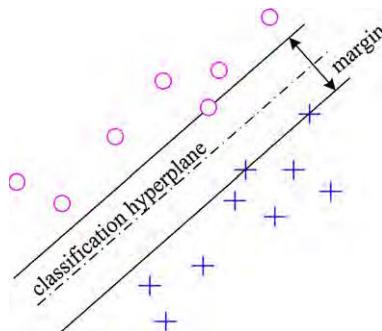

$$\begin{aligned} \min_{\mathbf{w}, b, \xi} \quad & \frac{1}{2} \|\mathbf{w}\|^2 + C \sum_{i=1}^m \xi_i \\ \text{s.t.} \quad & y_i (\mathbf{w}^\top \mathbf{x}_i + b) \geq 1 - \xi_i, \quad i = 1, \dots, m, \\ & \xi_i \geq 0, \quad i = 1, \dots, m, \end{aligned} \quad (16.61)$$

where the scalar  $C$  controls the balance between the margin and empirical loss, and  $\xi = [\xi_1, \dots, \xi_m]^\top$ . The large margin principle is reflected by minimizing  $\frac{1}{2} \|\mathbf{w}\|^2$  with  $2/\|\mathbf{w}\|$  being the margin between two hyperplanes  $\mathbf{w}^\top \mathbf{x} + b = 1$  and  $\mathbf{w}^\top \mathbf{x} + b = -1$  (For the linearly separable case, the concepts of the margin and classification hyperplane are illustrated in Figure 16.2). The SVM classifier would be

$$c_{\mathbf{w}, b}(\mathbf{x}) = \text{sign}(\mathbf{w}^\top \mathbf{x} + b). \quad (16.62)$$

The Lagrangian of problem (16.61) is

$$\begin{aligned} L(\mathbf{w}, b, \xi, \lambda, \gamma) = & \frac{1}{2} \|\mathbf{w}\|^2 + C \sum_{i=1}^m \xi_i - \sum_{i=1}^m \lambda_i \left[ y_i (\mathbf{w}^\top \mathbf{x}_i + b) - 1 + \xi_i \right] \\ & - \sum_{i=1}^m \gamma_i \xi_i, \quad \lambda_i \geq 0, \quad \gamma_i \geq 0, \end{aligned} \quad (16.63)$$

**FIGURE 16.2**

An illustration of the margin and classification hyperplane for the linearly separable binary case.

where  $\lambda = [\lambda_1, \dots, \lambda_m]^\top$  and  $\gamma = [\gamma_1, \dots, \gamma_m]^\top$  are the associated Lagrange multipliers. Using the superscript star to denote the solutions of the optimization problem, according to the KKT (Karush-Kuhn-Tucker) conditions [34, 35], we obtain

$$\partial_w L(\mathbf{w}^*, b^*, \xi^*, \lambda^*, \gamma^*) = \mathbf{w}^* - \sum_{i=1}^m \lambda_i^* y_i \mathbf{x}_i = 0, \quad (16.64)$$

$$\partial_b L(\mathbf{w}^*, b^*, \xi^*, \lambda^*, \gamma^*) = - \sum_{i=1}^m \lambda_i^* y_i = 0, \quad (16.65)$$

$$\partial_{\xi_i} L(\mathbf{w}^*, b^*, \xi^*, \lambda^*, \gamma^*) = C - \lambda_i^* - \gamma_i^* = 0, \quad i = 1, \dots, m. \quad (16.66)$$

From (16.64), the solution  $\mathbf{w}^*$  has the form

$$\mathbf{w}^* = \sum_{i=1}^m \lambda_i^* y_i \mathbf{x}_i. \quad (16.67)$$

Since examples with  $\lambda_i^* = 0$  can be omitted from the expression, the training examples for which  $\lambda_i^* > 0$  are called support vectors.

By substituting (16.64)–(16.66) into the Lagrangian, we can finally get the dual optimization problem [35]

$$\begin{aligned} \max_{\lambda} \quad & \lambda^\top \mathbf{j} - \frac{1}{2} \lambda^\top D \lambda \\ \text{s.t.} \quad & \lambda^\top \mathbf{y} = 0, \\ & \lambda \succeq \mathbf{0}, \\ & \lambda \leq C \mathbf{j}, \end{aligned} \quad (16.68)$$

where  $\mathbf{j}$  is the vector with all entries being 1,  $\mathbf{y} = [y_1, \dots, y_m]^\top$  and  $D$  is a symmetric  $m \times m$  matrix with entries  $D_{ij} = y_i y_j \mathbf{x}_i^\top \mathbf{x}_j$  [1, 36].

The complementary slackness condition (also called the zero KKT-gap requirement) [6] implies

$$\begin{aligned} \lambda_i^* \left[ y_i (\mathbf{x}_i^\top \mathbf{w}^* + b^*) - 1 + \xi_i^* \right] &= 0, \quad i = 1, \dots, m, \\ \gamma_i^* \xi_i^* &= 0, \quad i = 1, \dots, m. \end{aligned} \quad (16.69)$$

Combining (16.66) and (16.69), we can solve  $b^* = y_i - \mathbf{x}_i^\top \mathbf{w}^*$  for any support vector  $\mathbf{x}_i$  with  $0 < \lambda_i^* < C$ . The existence of  $0 < \lambda_i^* < C$  is a reasonable assumption, though there lacks a rigorous justification [36]. Once  $\lambda^*$  and  $b^*$  are solved, the SVM classifier is given by

$$c^*(\mathbf{x}) = \text{sign} \left( \sum_{i=1}^m y_i \lambda_i^* \mathbf{x}_i^\top \mathbf{x} + b^* \right). \quad (16.70)$$

Using the kernel trick, the optimization problem (16.68) for SVMs becomes

$$\max_{\lambda} \quad \lambda^\top \mathbf{j} - \frac{1}{2} \lambda^\top D \lambda$$

$$\begin{aligned} \text{s.t. } & \lambda^\top \mathbf{y} = 0, \\ & \lambda \succeq \mathbf{0}, \\ & \lambda \leq C\mathbf{j}, \end{aligned} \quad (16.71)$$

where the entries of  $D$  are  $D_{ij} = y_i y_j \kappa(\mathbf{x}_i, \mathbf{x}_j)$ . The solution for the corresponding SVM classifier is formulated as

$$c^*(\mathbf{x}) = \text{sign} \left( \sum_{i=1}^m y_i \lambda_i^* \kappa(\mathbf{x}_i, \mathbf{x}) + b^* \right). \quad (16.72)$$

For regression problems, the labels in the training set  $S$  are real numbers, that is  $y_i \in \mathbb{R}$  ( $i = 1, \dots, m$ ). In order to induce a sparse representation for the decision function (i.e., some training examples can be ignored), [8] devised the following  $\epsilon$ -insensitive function and applied it to support vector regression

$$|y - f(\mathbf{x})|_\epsilon = \max\{0, |y - f(\mathbf{x})| - \epsilon\}, \quad \epsilon \geq 0. \quad (16.73)$$

The standard form of support vector regression is to minimize

$$\frac{1}{2} \|\mathbf{w}\|^2 + C \sum_{i=1}^m |y_i - f(\mathbf{x}_i)|_\epsilon, \quad (16.74)$$

where the positive scalar  $C$  reflects the trade-off between the margin and the empirical loss. An equivalent optimization that is commonly used is

$$\begin{aligned} \min_{\mathbf{w}, b, \xi, \xi^*} & \frac{1}{2} \|\mathbf{w}\|^2 + C \sum_{i=1}^m \xi_i + C \sum_{i=1}^m \xi_i^* \\ \text{s.t. } & \langle \mathbf{w}, \phi(\mathbf{x}_i) \rangle + b - y_i \leq \epsilon + \xi_i, \\ & y_i - \langle \mathbf{w}, \phi(\mathbf{x}_i) \rangle - b \leq \epsilon + \xi_i^*, \\ & \xi_i, \xi_i^* \geq 0, \quad i = 1, \dots, m, \end{aligned} \quad (16.75)$$

where  $\phi(\mathbf{x}_i)$  is the image of  $\mathbf{x}_i$  in the feature space, and  $\xi, \xi^*$  are defined similarly as before. The prediction output of support vector regression is

$$c^*(\mathbf{x}) = \langle \mathbf{w}^*, \phi(\mathbf{x}) \rangle + b^*, \quad (16.76)$$

where  $\mathbf{w}^*$  and  $b^*$  are the solution of (16.75). For support vector regression, the derivation for the dual representation of solutions and the dual optimization problem can consult the counterpart for classification, and thus is omitted here.

### 1.16.3.5 Bayesian kernel methods: Gaussian processes

All the previous methods introduced in this section can be summarized into the framework of risk minimization. The Bayesian learning approach differs from them in several aspects. The key distinction is that the Bayesian approach intuitively incorporates prior knowledge into the process of estimation [6]. Another benefit of the Bayesian framework is the possibility of measuring the confidence of the estimation in a straightforward manner. However, algorithms designed by the Bayesian approach (e.g., with maximum a posterior estimation) can have similar counterparts originating from the risk minimization

framework. Below we focus on the Gaussian process approach for regression, which is a classical Bayesian kernel method.

The Gaussian process models have two kinds of equivalent representations, namely the function-space view and the weight-space view [37]. We will start with the weight-space view to illustrate the explicit roles of kernels using the Bayesian treatment of linear regression, followed by a very brief introduction of the function-space view.

Suppose the training set  $S$  is  $\{(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_m, y_m)\}$  as defined in Section 1.16.2.1. The standard linear regression model with Gaussian noise is

$$f(\mathbf{x}) = \mathbf{w}^\top \mathbf{x}, \quad y = f(\mathbf{x}) + \varepsilon, \quad (16.77)$$

where  $f$  is the function value,  $y$  is the noisy observed value, and the noise obeys an independent, identically distributed Gaussian distribution with mean zero and variance  $\sigma_n^2$

$$\varepsilon \sim \mathcal{N}(0, \sigma_n^2). \quad (16.78)$$

This gives rise to the likelihood of the independent observations in the training set

$$\begin{aligned} p(\mathbf{y}|\mathbf{X}, \mathbf{w}) &= \prod_{i=1}^m p(y_i|\mathbf{x}_i, \mathbf{w}) = \prod_{i=1}^m \frac{1}{\sqrt{2\pi}\sigma_n} \exp\left(-\frac{(y_i - \mathbf{w}^\top \mathbf{x}_i)^2}{2\sigma_n^2}\right) \\ &= \frac{1}{(2\pi\sigma_n^2)^{m/2}} \exp\left(-\frac{\|\mathbf{y} - \mathbf{X}\mathbf{w}\|^2}{2\sigma_n^2}\right) = \mathcal{N}(\mathbf{X}\mathbf{w}, \sigma_n^2 \mathbf{I}), \end{aligned} \quad (16.79)$$

where  $\mathbf{y} = [y_1, \dots, y_m]^\top$  and  $\mathbf{X}^\top = [\mathbf{x}_1, \dots, \mathbf{x}_m]$ . Suppose we specify a Gaussian prior on the parameters with mean zero and covariance matrix  $\Sigma_p$  [37]

$$\mathbf{w} \sim \mathcal{N}(\mathbf{0}, \Sigma_p). \quad (16.80)$$

According to Bayes' rule, the posterior of the parameters is proportional to the product of the prior and likelihood

$$\begin{aligned} p(\mathbf{w}|\mathbf{X}, \mathbf{y}) &\propto \exp\left(-\frac{1}{2}\mathbf{w}^\top \Sigma_p^{-1} \mathbf{w}\right) \exp\left(-\frac{1}{2\sigma_n^2}(\mathbf{y} - \mathbf{X}\mathbf{w})^\top (\mathbf{y} - \mathbf{X}\mathbf{w})\right) \\ &\propto \exp\left(-\frac{1}{2}(\mathbf{w} - \bar{\mathbf{w}})^\top A(\mathbf{w} - \bar{\mathbf{w}})\right), \end{aligned} \quad (16.81)$$

where  $A = \frac{1}{\sigma_n^2} \mathbf{X}^\top \mathbf{X} + \Sigma_p^{-1}$ , and  $\bar{\mathbf{w}} = \frac{1}{\sigma_n^2} A^{-1} \mathbf{X}^\top \mathbf{y}$ . It turns out that the posterior is a Gaussian distribution with mean  $\bar{\mathbf{w}}$  and covariance  $A^{-1}$ .

The predictive distribution for a test example  $\mathbf{x}$  is given by averaging the outputs of all possible linear models from the above Gaussian posterior

$$\begin{aligned} p(f(\mathbf{x})|\mathbf{x}, \mathbf{X}, \mathbf{y}) &= \int p(f(\mathbf{x})|\mathbf{x}, \mathbf{w}) p(\mathbf{w}|\mathbf{X}, \mathbf{y}) d\mathbf{w} \\ &= \mathcal{N}\left(\frac{1}{\sigma_n^2} \mathbf{x}^\top A^{-1} \mathbf{X}^\top \mathbf{y}, \mathbf{x}^\top A^{-1} \mathbf{x}\right). \end{aligned} \quad (16.82)$$

Now suppose we use a function  $\phi(\cdot)$  to map the inputs in the original space to a feature space, and perform linear regression there. The predictive distribution would be

$$p(f(\mathbf{x})|\mathbf{x}, \mathbf{X}, \mathbf{y}) = \mathcal{N}\left(\frac{1}{\sigma_n^2} \phi(\mathbf{x})^\top A^{-1} \Phi^\top \mathbf{y}, \phi(\mathbf{x})^\top A^{-1} \phi(\mathbf{x})\right), \quad (16.83)$$

where  $\Phi^\top = [\phi(\mathbf{x}_1), \dots, \phi(\mathbf{x}_m)]$ , and  $A = \frac{1}{\sigma_n^2} \Phi^\top \Phi + \Sigma_p^{-1}$ . Using matrix transformations such as the matrix inversion lemma, we can rewrite (16.83) as

$$\begin{aligned} p(f(\mathbf{x})|\mathbf{x}, \mathbf{X}, \mathbf{y}) &= \mathcal{N}\left(\phi(\mathbf{x})^\top \Sigma_p \Phi^\top (K + \sigma_n^2 \mathbf{I})^{-1} \mathbf{y}, \right. \\ &\quad \left. \phi(\mathbf{x})^\top \Sigma_p \phi(\mathbf{x}) - \phi(\mathbf{x})^\top \Sigma_p \Phi^\top (K + \sigma_n^2 \mathbf{I})^{-1} \Phi \Sigma_p \phi(\mathbf{x})\right), \end{aligned} \quad (16.84)$$

where  $K = \Phi \Sigma_p \Phi^\top$  [37]. Notice that in the above formulation the terms related to the images in the feature space can be represented in the form of  $\phi(\mathbf{x})^\top \Sigma_p \phi(\mathbf{x}')$  with  $\mathbf{x}$  and  $\mathbf{x}'$  in either the training or test sets [37]. Define  $\kappa(\mathbf{x}, \mathbf{x}') = \phi(\mathbf{x})^\top \Sigma_p \phi(\mathbf{x}')$ . By Theorem 7, we know that  $\kappa(\mathbf{x}, \mathbf{x}')$  is a valid kernel function. In the Gaussian process literature, it is often called the covariance function.

The function-space view of the Gaussian processes is given by the following definition which describes a distribution over functions [37].

**Definition 8 (Gaussian processes).** A Gaussian process is a collection of random variables, any finite number of which have a joint Gaussian distribution.

A Gaussian process is specified by its mean function and covariance function. If we define the mean function  $m(\mathbf{x})$  and the covariance function  $k(\mathbf{x}, \mathbf{x}')$  of a real process  $f(\mathbf{x})$  as

$$\begin{aligned} m(\mathbf{x}) &= \mathbb{E}[f(\mathbf{x})], \\ k(\mathbf{x}, \mathbf{x}') &= \mathbb{E}[(f(\mathbf{x}) - m(\mathbf{x})) (f(\mathbf{x}') - m(\mathbf{x}'))], \end{aligned} \quad (16.85)$$

the Gaussian process can be written as

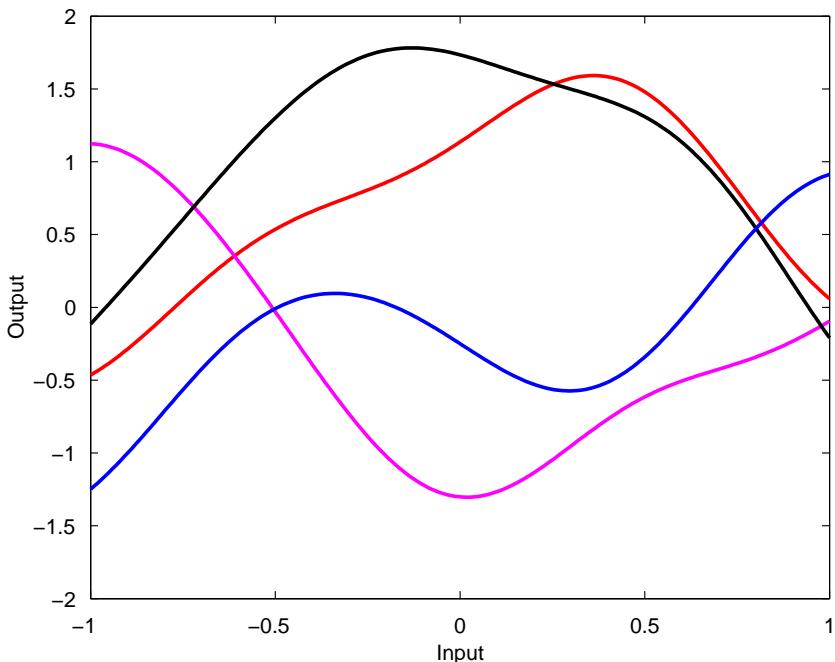

$$f(\mathbf{x}) \sim \mathcal{GP}(m(\mathbf{x}), k(\mathbf{x}, \mathbf{x}')). \quad (16.86)$$

Figure 16.3 shows samples of functions drawn from a specific Gaussian process.

The Bayesian linear regression model  $f(\mathbf{x}) = \mathbf{w}^\top \phi(\mathbf{x})$  with parameter prior  $\mathbf{w} \sim \mathcal{N}(\mathbf{0}, \Sigma_p)$  can be cast into the above function-space view. It is simple to see that the function values  $f(\mathbf{x}_1), \dots, f(\mathbf{x}_q)$  corresponding to any number of inputs  $q$  are jointly Gaussian, and the mean and covariance are given by

$$\begin{aligned} \mathbb{E}[f(\mathbf{x})] &= \mathbb{E}[\mathbf{w}^\top] \phi(\mathbf{x}) = 0, \\ \mathbb{E}[f(\mathbf{x}) f(\mathbf{x}')] &= \phi(\mathbf{x})^\top \mathbb{E}[\mathbf{w} \mathbf{w}^\top] \phi(\mathbf{x}') = \phi(\mathbf{x})^\top \Sigma_p \phi(\mathbf{x}'), \end{aligned} \quad (16.87)$$

where the second equation recovers our definition of the kernel function for the weight-space view. In other words, now  $m(\mathbf{x}) = 0$  and  $k(\mathbf{x}, \mathbf{x}') = \kappa(\mathbf{x}, \mathbf{x}') = \phi(\mathbf{x})^\top \Sigma_p \phi(\mathbf{x}')$ .

**FIGURE 16.3**

Samples from a Gaussian process with zero mean and a Gaussian kernel as the covariance function.

## 1.16.4 Computational issues of kernel methods

Implementation of kernel methods often involve eigen-decomposition of kernel matrices or inversion of the sum of a kernel matrix and a scaled identity matrix. The computational complexity of this operation is typically  $O(m^3)$  with  $m$  being the number of training examples. This can be very demanding for large training sets, and therefore approximation algorithms are desirable.

Good low-rank approximations of kernel matrices are usually enough to deal with the above problems. For example, the matrix inversion lemma can use the low-rank decomposition to invert the sum of the kernel matrix and a scaled identity matrix efficiently. Eigen-decomposition of kernel matrices can also be converted to do the same operation on much smaller matrices. Here we just give a pointer to some of the approximation methods. Interested readers can refer to the corresponding literature for detailed implementation techniques.

Partial Gram-Schmidt orthogonalization [38] and incomplete Cholesky decomposition [27] are good approaches for finding low-rank approximations of kernel matrices. These two approaches are essentially equivalent, since performing a Cholesky decomposition of the kernel matrix is equivalent to performing

Gram-Schmidt orthogonalization in the feature space [1]. In other words, incomplete Cholesky decomposition can be viewed as the dual implementation of the partial Gram-Schmidt orthogonalization.

The sparse greedy matrix approximation [39] and the Nyström approximation [40] are two alternative approaches. The idea of the former is to select a collection of basis functions to obtain an approximate kernel matrix  $\tilde{K}$  whose distance to the original kernel matrix  $K$  is small. The Nyström approximation is much simpler, which randomly chooses  $r$  rows/columns of  $K$  without replacement, and then sets  $\tilde{K} = K_{m,r} K_{r,r}^{-1} K_{r,m}$ , where  $K_{m,r}$  is the  $m \times r$  block of  $K$  and similar definitions apply to the other blocks. For a given  $r$ , the sparse greedy matrix approximation produces a better approximation to  $K$ , but computationally more demanding [40].

### 1.16.5 Multiple kernel learning

In practical problems, for a given decision-making task, there can be multiple different data sources. These data can be heterogeneous, which means that they represent different properties (e.g., visual features or lingual features) or have different forms (e.g., continuous value or discrete value). Consequently, using a different kernel to account for each of the data sources and then combining them is sensible. In other cases, even if the data are homogeneous, we may still want to adopt multiple kernels to capture more information. This problem of learning a combination of multiple kernels is termed multiple kernel learning [17] and now is an active research topic [41–47]. Here we review some multiple kernel learning methods, several of which have sparsity regularizations [48, 49], to provide a brief outline of the research progress.

The kernel learning approach proposed by [17] is to add to the original optimization problems some extra constraints on the symmetric kernel matrix  $K$ , e.g., by

$$\begin{aligned} K &= \sum_{i=1}^t \mu_i K_i, \\ \mu_i &\in \mathbb{R}, \quad i = 1, \dots, t, \\ K &\succeq 0, \\ \text{trace}(K) &\leq c, \end{aligned} \tag{16.88}$$

or

$$\begin{aligned} K &= \sum_{i=1}^t \mu_i K_i, \\ \mu_i &\geq 0, \quad i = 1, \dots, t, \\ K &\succeq 0, \\ \text{trace}(K) &\leq c, \end{aligned} \tag{16.89}$$

where  $t$  is the number of individual kernels, and then formulate the problem in terms of semidefinite programming (SDP) [34, 35]. The advantages of the second set of constraints over the first include reducing computational burden and facilitating the study of some statistical properties of kernel matrices [17].

However, the learning problem would become intractable when the number of training examples or kernels grow large.

[48] reformulated the problem and proposed a sequential minimal optimization (SMO) algorithm to improve the efficiency. They used second-order cone programming (SOCP) and Moreau-Yosida regularization to derive the SMO algorithm and made multiple kernel learning applicable for medium-scale problems. The corresponding KKT conditions not only lead to support vectors, but also to “support kernels” which means a sparse combination of candidate kernels can be expected. [50] adopted semi-infinite liner programming (SILP) to formulate the multiple kernel learning problem, based on which they iteratively solved a standard SVM problem with a single kernel and a linear program whose constraints increase with iterations. This approach makes multiple kernel learning applicable to large-scale problems. Later, [49] further improved the efficiency by using a formulation of a weighted 2-norm regularization with sparsity considerations imposed on the weights. Evidence show that it is globally faster than the mentioned SILP approach but with more kernels selected.

[41] considered multiple kernel learning with infinite number of basic kernels. In particular, kernels are selected from the convex hull of continuously parameterized kernels. Making use of the conjugate function and von Neumann minimax theorem [44], they adopted a greedy algorithm to solve the optimization problem, where the DC (difference of convex functions) programming techniques that attempt to optimize a non-convex function by the difference of two convex functions [51] were used to optimize a subroutine of the algorithm. Experimental results indicated the advantage of working with a continuous parameterization over a predesignated finite number of basic kernels.

For Bayesian multiple kernel learning, recently, [52] proposed a new variational approximation for infinite mixtures of Gaussian processes. The mixtures of Gaussian processes have the advantages of characterizing varying covariances or multimodal data and reducing the cubic computational complexity of the single Gaussian process model [53–55]. They used mean field variational inference and a truncated stick-breaking representation of the Dirichlet process to approximate the posterior of latent variables, and applied the approach to traffic prediction problems.

## 1.16.6 Applications

The applications of kernel methods and SVMs are rather broad. Here we just list some of its typical applications.

Biometrics refers to the identification of humans based on their physical or behavioral traits, which can be used for access control. Typical methods for biometrics include face recognition, signature recognition and EEG-based biometrics [56]. Over the past years, kernel methods and SVMs have been successfully applied to this field [57,58].

Intelligent transportation systems are an important application platform for machine learning techniques. Representative applications include pedestrian recognition, traffic flow forecasting, and traffic bottleneck identification. Kernel methods including Gaussian processes have achieved very good performance in this area [52,59].

Research on brain-computer interfaces which aim to enable severely disabled people to drive communication or control devices, arouses many interests recently. The discrimination of different brain

signals is essentially a pattern classification problem, where SVMs have been shown to be a very useful tool [60,61].

Natural language processing, e.g., text classification and retrieval, is an active research field which has used a lot of machine learning methods. Kernel techniques applied to this task include kernel design, supervised classification and semi-supervised classification [14,62,63].

### 1.16.7 Open issues and problems

In this article, we have presented some key techniques for using kernel methods, such as how to derive the dual formulation of an original method, what are essential conditions for valid kernels, typical kernel functions, and how to construct new kernels. This constitutes the foundations of kernel methods. Then, we introduced some fundamental kernel methods which are well-known and now used widely for unsupervised or supervised learning. In particular, as a representative of Bayesian kernel methods, Gaussian processes were introduced.

The computational complexity of kernel methods is usually cubic with respect to the number of training examples. Therefore, reducing the computational costs has been an important research topic. For this problem, we briefly pointed out four methods—partial Gram-Schmidt orthogonalization, incomplete Cholesky decomposition, sparse greedy matrix approximation and the Nyström approximation, and explained the idea on why they can be used to alleviate the computational burden.

In addition, we have introduced the recent developments on multiple kernel learning which has shown its merit over single kernel learning in the past few years. However, for multiple kernel learning, we have to learn both the combination coefficients for candidate kernels and other parameters inherited from traditional single kernel learning. Therefore, there are various efforts to reformulate the optimization problem to accelerate learning, and indeed people have achieved some encouraging results.

Studies on kernel methods can be further deepened in different aspects, e.g., the above mentioned multiple kernel learning, and combining kernel techniques with other machine learning mechanisms. Another line of important open problems would be performing theoretical analysis on the generalization errors of newly emerging kernel methods, such as the multitask SVMs and multitask multiclass SVMs. We hope this article is helpful to promote the applications and theoretical developments of kernel methods in the future.

---

## Glossary

Canonical correlation analysis	A method to find two linear transformations respectively for two representations such that the correlations between the transformed variables are maximized
Fisher discriminant analysis	A method for classification which seeks a direction to maximize the distance between projected class means and simultaneously minimize the projected class variances
Gaussian process	A collection of random variables, any finite number of which have a joint Gaussian distribution

Kernel trick	A method to extend any algorithm only involving computations of inner products from the original space to a feature space with kernel functions
Multiple kernel learning	A learning mechanism which aims to learn a combination of multiple kernels to capture more information or reduce the computational complexity
Principal component analysis	A method to find a set of orthogonal directions which forms a subspace to maximize data variances along the directions in this subspace
Reproducing kernel Hilbert space	A function space which is a Hilbert space possessing a reproducing kernel
Support vector machine	A method to learn a hyperplane induced from the maximum margin principle, which has wide applications including classification and regression

## Nomenclature

Training Data	A set of input-output measurements that are used to train a specific learning machine
Online Learning	A learning task, where the data points arrive sequentially and used only once
Batch Learning	A learning task, where the training data are known beforehand
Regression Task	A learning task that estimates a parametric input-output relationship that best fits the available data
Classification Task	A learning task that classifies the data into one or more classes
Overfitting	A common notion in the Machine Learning literature. If the adopted model is too complex then the learning algorithm tends to fit to the training data as much as possible (e.g., it fits even the noisy data) and cannot perform well when new data arrive
Regularization	A technique that biases the solution towards a smoother result. This is usually achieved by adding the norm of the solution to the cost function of the minimization task
Sparsification	A method that biases the solution towards a result, that the least significant components are pushed to zero
Reproducing Kernel Hilbert Spaces (RKHS)	An inner product space of functions that is complete and has a special structure
Kernel	A positive definite function of two variables that is associated to a specific RKHS

Fréchet Differentiation	A mathematical framework that generalizes the notion of the standard derivative, to more general function spaces
Least Mean Squares	This is a class of stochastic online learning tasks, which aim to find the parameters of an input-output relation by minimizing the least mean squares of the error at each iteration (difference between the desired and the actual output), using a gradient descent rationale
Recursive Least Squares	A class of deterministic online learning tasks, which aim to find the parameters of an input-output relation by minimizing the least mean squares of the total error (the sum of differences between the desired and the actual output up to the current iteration) using a recursive Newton-like method
Adaptive Projected Subgradient Method (APSM)	A convex analytic framework for online learning. Based on set theoretic estimation arguments, and fixed point theory, the APSM is tailored to attack online learning problems related to general, convexly constrained, non-smooth optimization tasks
Wirtinger's Calculus	A methodology for computing gradients of real valued functions that are defined on complex domains, using the standard rules of differentiation

### 1.17.1 Introduction

A large class of Machine Learning tasks becomes equivalent with estimating an unknown functional dependence that relates the so called input (cause) to the output (effect) variables. Most often, this function is chosen to be of a specific type, e.g., linear, quadratic, etc., and it is described by a set of unknown parameters. There are two major paths in dealing with this set of parameters.

The first one, known as *Bayesian Inference*, treats the parameters as random variables, [1]. According to this approach, the dependence between the input and output variables is expressed via a set of pdfs. The task of learning is to obtain estimates of the pdf that relates the input-output variables as well as the pdf that describes the random nature of the parameters. However, the main concern of the Bayesian Inference approach is not in obtaining specific values for the parameters. Bayesian Inference can live without this information. In contrast, the alternative path, which will be our focus in this paper, considers the unknown parameters to be deterministic and its major concern is to obtain specific estimates for their values.

Both trends share a common trait; they dig out the required information, in order to build up their estimates, from an available set of input-output measurements known as the *training set*. The stage

of estimating the pdfs/parameters is known as training and this philosophy of learning is known as *supervised learning*. This is not the only approach which Machine Learning embraces in order to “learn” from data. *Unsupervised* and *semi-supervised* learning are also major learning directions, [2]. In the former, no measurements of the output variable(s) are available in the training data set. In the latter, there are only a few. In this paper, we will focus on the supervised learning of a set of deterministically treated parameters. We will refer to this task as *parameter estimation*.

In the parameter estimation task, depending on the adopted functional dependence, different models result. At this point, it has to be emphasized that the only “truth” that the designer has at his/her disposal is the set of training data. The model that the designer attempts to “fit” in the data is just a concept in an effort to be able to exploit and use the available measurements for his/her own benefit; that is, to be able to make useful predictions of the output values in the future, when new measurements of the inputs, outside the training set, become available. The ultimate goal of the obtained predictions is to assist the designer to make decisions, once the input measurements are disclosed to him/her. In nature, one can never know if there is a “true” model associated with the data. Our confidence in “true” models only concerns simulated data. In real life, one is obliged to adopt a model and a training method to learn its parameters so that the resulting predictions can be useful in practice. The designed Machine Learning system can be used till it is substituted by another, which will be based on a new model and/or a new training method, that leads to improved predictions and which can be computed with affordable computational resources.

In this paper, we are concerned with the more general case of nonlinear models. Obviously, different nonlinearities provide different models. Our approach will be in treating a large class of nonlinearities, which are usually met in practice, in a unifying way by mobilizing the powerful tool of Reproducing Kernel Hilbert Spaces (RKHS). This is an old concept, that was gradually developed within the functional analysis discipline [3] and it was, more recently, popularized in Machine Learning in the context of *Support Vector Machines*. This methodology allows one to treat a wide class of different nonlinearities in a unifying way, by solving an equivalent linear task in a space different than the one where the original measurements lie. This is done by adopting an implicit mapping from the input space to the so called *feature* space. In the realm of RKHSs, one needs not to bother about the specific nature of this space, not even about its dimensionality. Once the parametric training has been completed, the designer can “try” different implicit mappings, which correspond to different nonlinearities and keep the one that fits best his/her needs. This is achieved during the so-called *validation* stage. Ideally, this can be done by testing the performance of the resulting estimator using a data set that is independent of the one used for training. In case this is not possible, then various techniques are available in order to exploit a single data set, both for training and validation, [2].

Concerning the estimation process, once a parametric modeling has been adopted, the parameter estimation task relies on adopting, also, a criterion that measures the quality of fit between the predicted values and the measured ones, over the training set. Different criteria result in different estimates and it is up to the designer to finally adopt the one that better fits his/her needs. In the final step of parameter estimation, an algorithm has to be chosen to optimize the criterion. There are two major philosophies that one has to comply with. The more classical one is the so-called *batch processing* approach. The training data are available in “one go.” The designer has access to all of them simultaneously, which are then used for the optimization. In some scenarios, algorithms are developed so that to consider one

training point at a time and consider all of them sequentially, and this process goes on till the algorithm converges. Sometimes, such schemes are referred to as online; however, these schemes retain their batch processing flavor, in the sense that the training data set is *fixed* and the number of the points in it is known before the training starts. Hence, we will refer to these as batch techniques and keep the term online for something different.

All batch schemes suffer from a major disadvantage. Once a new measurement becomes available, after the training has been completed, the whole training process has to start from scratch, with a new training set that has been enriched by the extra measurement. No doubt, this is an inefficient way to attack the task. The most efficient way is to have methods that perform the optimization recursively, in the sense of updating the current estimate every time a new measurement is received, by considering *only* this newly received information and the currently available estimate of the parameters. The previously used training data will *never be needed again*. They have become part of the history; all information that they had to contribute to the training process now resides in the current estimate. We will refer to such schemes as *online* or *adaptive*, although many authors call them *time-recursive* or *sequential*. The term Adaptive Learning is mainly used in Signal Processing and such schemes have also been used extensively in Communications, System Theory and Automatic Control from the early sixties, in the context of the LMS, RLS and Kalman Filtering, e.g., [4–6]. The driving force behind the need for such schemes was the need for the training mechanism to be able to accommodate slow time variations of the learning environment and slowly forget the past. As a matter of fact, such a philosophy imitates better the way that human brain learns and tries to adapt to new situations. Online learning mechanisms have recently become very popular in applications such as Data Mining and Bioinformatics and more general in cases where data reside in large data bases, with massive number of training points, which cannot be stored in the memory and have to be considered one at a time. It is this path of online parameter estimation learning that we will pursue in this paper. As we will see, it turns out that very efficient schemes, of even linear complexity per iteration with respect to the number of the unknown parameters, are now available.

Our goal in this overview is to make an effort to collect a number of online/adaptive algorithms, which have been proposed over a number of decades, in a systematic way under a common umbrella; they are schemes that basically stem from only a few generic recurrences. It is interesting to note that some of these algorithms have been discovered and used under different names in different research communities, without one being referring to the other.

In an overview paper, there is always the dilemma how deep one can go in proofs. Sometimes proofs are completely omitted. We decided to keep some proofs, associated with the generic schemes; those which do not become too technical. Proofs give the newcomer to the field the flavor of the required mathematical tools and also give him/her the feeling of what is behind the performance of an algorithm; in simple words, why the algorithm works. For those who are not interested in proofs, simply, they can bypass them. It was for the less mathematically inclined readers, that we decided to describe first two structurally simple algorithms, the LMS and the RLS. We left the rest, which are derived via convex analytic arguments, for the later stage. As we move on, the treatment may look more mathematically demanding, although we made an effort to simplify things as much as we could. After all, talking about algorithms one cannot just use “words” and a “picture” of an algorithm. Although sometimes this is a line that is followed, the authors of this paper belong to a different school. Thus, this paper may not address the needs of a black-box user of the algorithms.

## 1.17.2 Parameter estimation: The regression and classification tasks

In the sequel,  $\mathcal{R}$ ,  $\mathcal{N}$ , and  $\mathcal{N}_*$  will stand for the set of all real numbers, non-negative and positive integers, respectively.

Two of the major pillars in parametric modeling in Machine Learning are the *regression* and *classification* tasks. These are two closely related, yet different tasks.

In regression, given a set of training points,  $(y_n, \mathbf{x}_n), n = 1, 2, \dots, y_n \in \mathcal{R}, \mathbf{x}_n \in \mathcal{R}^l$ <sup>1</sup>, the goal is to establish the input-output relationship via a model of the form

$$y_n = f(\mathbf{x}_n) + \eta_n, \quad n = 1, 2, \dots, \quad (17.1)$$

where  $\eta_n$  is a noise, unobservable, sequence and the nonlinear function is modeled in the form

$$f(\mathbf{x}) = \theta_0 + \sum_{k=1}^{K-1} \theta_k \phi_k(\mathbf{x}), \quad (17.2)$$

where  $\theta_k, k = 0, 1, \dots, K - 1$ , comprise the set of the unknown parameters, and  $\phi_k(\mathbf{x})$  are preselected nonlinear functions

$$\phi_k(\cdot) : \mathcal{R}^l \rightarrow \mathcal{R}, \quad k = 1, 2, \dots, K - 1.$$

The input vectors are also known as *regressors*. Combining (17.1) and (17.2) we obtain

$$y_n = \theta_0 + \sum_{k=1}^{K-1} \theta_k \phi_k(\mathbf{x}_n) + \eta_n := \boldsymbol{\theta}^T \boldsymbol{\phi}(\mathbf{x}_n) + \eta_n, \quad (17.3)$$

where

$$\boldsymbol{\phi}(\cdot) = [\phi_1(\cdot), \phi_2(\cdot), \dots, \phi_{K-1}(\cdot), 1]^T, \text{ and } \boldsymbol{\theta} = [\theta_1, \theta_2, \dots, \theta_{K-1}, \theta_0]^T.$$

$\theta_0$  is known as the *bias* or the *intercept* and it has been absorbed in  $\boldsymbol{\theta}$  by simultaneously adding 1 as the last element in  $\boldsymbol{\phi}$ . The goal of the parameter estimation task is to obtain estimates  $\hat{\boldsymbol{\theta}}$  of  $\boldsymbol{\theta}$  using the available training set. Once  $\hat{\boldsymbol{\theta}}$  has been obtained and given a value of  $\mathbf{x}$ , the prediction of the corresponding output value is computed according to the model

$$\hat{y} = \hat{\boldsymbol{\theta}}^T \boldsymbol{\phi}(\mathbf{x}). \quad (17.4)$$

Figure 17.1 shows the graphs of (17.4) for two different cases of training data,  $(y_n, \mathbf{x}_n)$ . In Figure 17.1a, the fitted model is

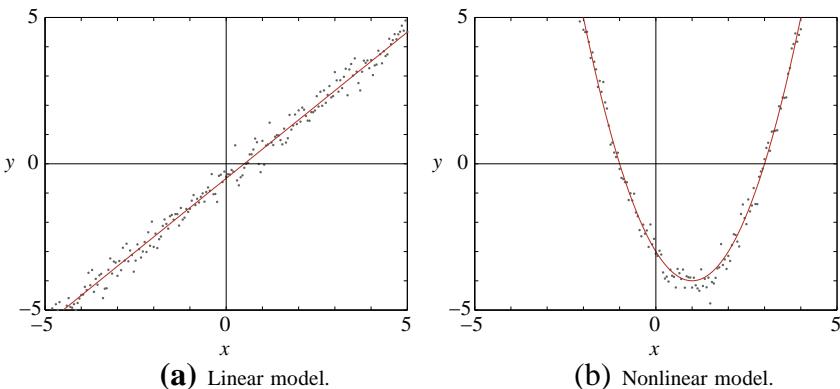

$$\hat{y} = -0.5 + x,$$

and for the case of Figure 17.1b, the model is

$$\hat{y} = -3 - 2\phi_1(x) + \phi_2(x),$$

---

<sup>1</sup>In general,  $y \in \mathcal{R}^m$ . Unless otherwise stated, we will consider  $y$  to be a real value for simplicity. Generalizations to Euclidean spaces are also possible.

## FIGURE 17.1

Fitting sets of training data  $(y_n, \mathbf{x}_n)_{n=1}^N$  by a linear and a quadratic function.

where

$$\phi_1(x) = x, \quad \phi_2(x) = x^2.$$

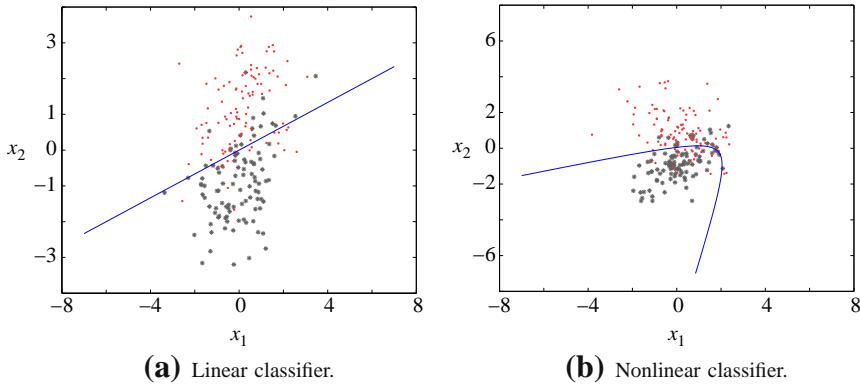

The figures also reveal the main goal of regression, which is to “explain” the generation mechanism of the data, and the graph of the curve defined in (17.4) should be designed so that to follow the spread of the data in the  $(y, x)$  space as close as possible.

In classification, the task is slightly different. The output variables are of a discrete/qualitative nature. That is,  $y_n \in D$ , where  $D$  is a finite set of discrete values. For example, for the simple case of a two-class classification problem, one may select  $D = \{1, -1\}$  or  $D = \{1, 0\}$ . The output values are also known as *class labels*. The input vectors,  $\mathbf{x}$ , are known as *feature vectors*, and they are chosen so that the respective components to encapsulate as much class-discriminatory information as possible. The goal of a classification task is to design a function (or in the more general case a set of functions), known as the classifier, so that the corresponding (hyper)surface  $f(\mathbf{x}) = 0$ , in the  $\mathbf{x}$  space, to separate the points that belong to different classes as much as possible. That is, the purpose of a classifier is to divide the input space into regions, where each one of the regions is associated with one and only one of the classes. The surface (and let us stay here in the simple case of the two-class problem with a single function) that is realized in the input space is known as decision surface. In this paper, we will consider functions of the same form as in (17.2). Hence, once more, designing a classifier is cast as a parameter estimation task. Once estimates of the unknown parameters are computed, say,  $\hat{\theta}$ , given a feature vector  $\mathbf{x}$ , which results from a pattern whose class label,  $y$ , is unknown, the predicted label is obtained as

$$\hat{y} = g(f(\mathbf{x})), \quad (17.5)$$

where  $g(\cdot)$  is a nonlinear indicator function, which indicates on which side of  $f(x) = 0$  the pattern  $x$  lies; typically  $g(\cdot) = \text{sign}(\cdot)$ , that is, the sign function. Figure 17.2a shows examples of two classifiers. In Figure 17.2 the classifier is linear, i.e.,

$$f(\mathbf{x}) = x_1 - 3x_2 = 0,$$

**FIGURE 17.2**

Two examples of classifiers.

and in Figure 17.2b is a nonlinear one

$$f(\mathbf{x}) = -0.23 + \phi_1(\mathbf{x}) + \phi_2(\mathbf{x}) = 0,$$

where

$$\phi_1(\mathbf{x}) = \mathbf{x}^T \begin{bmatrix} 0.61 \\ -4.64 \end{bmatrix}, \quad \phi_2(\mathbf{x}) = \mathbf{x}^T \begin{bmatrix} -0.45 & 0.93 \\ 0.93 & -0.45 \end{bmatrix} \mathbf{x}.$$

Note that, as it is apparent from both examples, the classes cannot, in general, be completely separated by the classifiers and errors in predicting the class labels are unavoidable. Tasks with separable classes are possible to occur, yet this is rather the exception than the rule.

Regression and Classification are two typical Machine Learning tasks, and a wide range of learning applications can be formulated as either one of the two. Moreover, we discussed that both tasks can be cast as parameter estimations problems, which comprise the focus of the current paper. Needless to say that both problems can also be attacked via alternative paths. For example, the  $k$ -nearest neighbor method is another possibility, which does not involve any parameter estimation phase; the only involved parameter,  $k$ , is determined via cross validation, e.g., [2].

Let us now put our parameter estimation task in a more formal setting. We are given a set of training points  $(y_n, \mathbf{x}_n) \in \mathcal{R} \times \mathcal{R}^l$ . For classification tasks, we replace  $\mathcal{R}$  with  $D$ . We adopt a parametric class of functions,

$$\mathcal{F} = \left\{ f_{\boldsymbol{\theta}}(\cdot) : \boldsymbol{\theta} \in \mathcal{A} \subseteq \mathcal{R}^K \right\}. \quad (17.6)$$

Our goal is to find a function in  $\mathcal{F}$ , denoted as  $f_{\boldsymbol{\theta}_*}(\cdot)$ , such that, given a measured value of  $\mathbf{x}$  and an adopted prediction model (e.g., (17.4) for regression or (17.5) for classification), it approximates the respective output value,  $\hat{y}$ , in an optimal way. Obviously, the word optimal paves the way to look for an optimizing criterion. To this end, a *loss function* is selected, from an available palette of non-negative functions,

$$\mathcal{L} : \mathcal{R} \times \mathcal{R} \rightarrow [0, \infty), \quad (17.7)$$

and compute  $\boldsymbol{\theta}_*$  so that to minimize the total loss over all the training data points, i.e.,

$$f_{\boldsymbol{\theta}_*}(\cdot) : \boldsymbol{\theta}_* \in \underset{\boldsymbol{\theta} \in \mathcal{A}}{\operatorname{argmin}} J(\boldsymbol{\theta}), \quad (17.8)$$

where

$$J(\boldsymbol{\theta}) := \sum_{n=1}^N \mathcal{L}(y_n, f_{\boldsymbol{\theta}}(\mathbf{x}_n)), \quad (17.9)$$

assuming that a minimum exists. In an adaptive setting, minimizing the cost function takes place iteratively in the form

$$\boldsymbol{\theta}_n = \boldsymbol{\theta}_{n-1} + \text{error correction term}, \quad (17.10)$$

as  $n$  increases. Different class of functions  $\mathcal{F}$  and different loss functions result in different estimators. In practice, for fixed number of training points, one uses cross validation to determine the “best” choice. Of course, in practice, when adaptive techniques are used and  $n$  is left to vary, cross validation techniques loose their meaning, especially when the statistical properties of the environment are slowly time varying. In such cases, the choice of the class of functions as well as the loss functions, which now has to be minimized adaptively, are empirically chosen. The critical factors, as we will see, for such choices are (a) *computational complexity*, (b) *convergence speed*, (c) *tracking agility*, (d) *robustness to noise and to numerical error accumulation*. In this paper, a number of different class functions as well as loss functions will be considered and discussed.

### 1.17.3 Overfitting and regularization

A problem of major importance in any Machine Learning task is that of *overfitting*. This is related to the complexity of the adopted model. If the model is too complex, with respect to the number of training points,  $N$ , then it tends to learn too much from the specific training set on which it is trained. For example, in regression, it tries to learn not only the useful information associated with the input data but also the contribution of the noise. So, if the model is too complex, it tends to fit very well the data points of the training set, but it does not cope well with data outside the training set; as we say, it cannot *generalize* well. In classification, the source of overfitting lies in the class overlap. A complex classifier will attempt to classify correctly all the points of the training set, and this is quite common in practice when very complex classifiers are employed. However, most of the class discriminatory information lies in the points lying in the “non-overlapping” regions. This is the information that a classifier has to learn in order to be able to generalize well, when faced with data outside the training set. A classifier which is designed to give very low error rates on the training set, usually results in large errors when faced with unseen data.

On the other hand, if our model is too simple it does not have the ability to learn even the useful information, which is contributed by the input data themselves, hence leading to very poor predictions. In practice, one seeks for a tradeoff, see, e.g., [2]. Figure 17.3 shows three cases of fitting by a very simple, a very complex and the correct model (that corresponds to the model which generated the data points). The first one is a linear model, the second one corresponds to a polynomial of high degree, i.e., 80, and the third one to a quadratic polynomial. Note that for the case of Figure 17.3b, the resulting

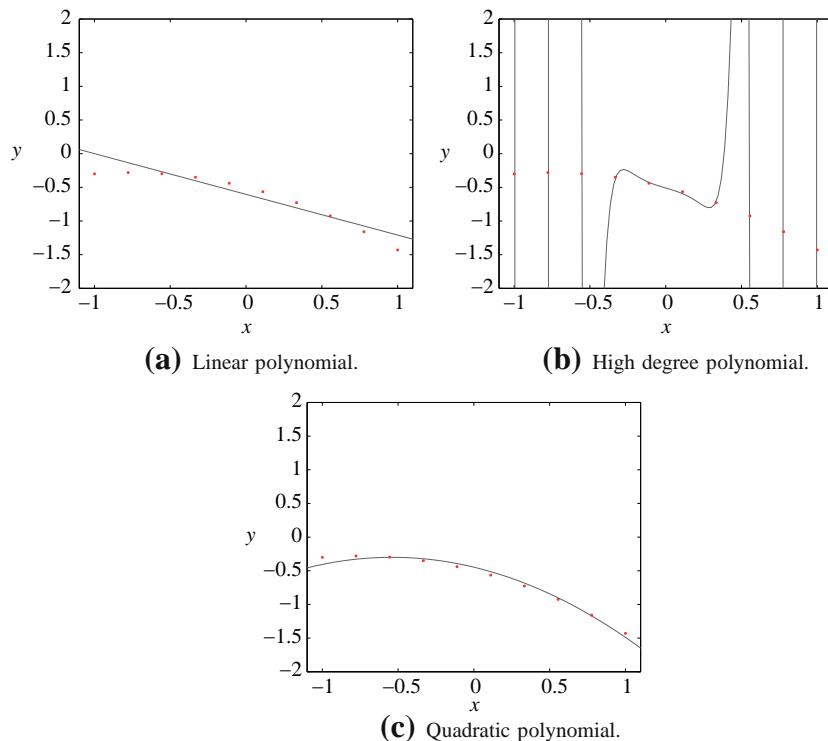

FIGURE 17.3

## Fitting noisy data by polynomials of various degrees.

curve passes through all the points. However, this is not what we want, since the points we have are the result of a noisy process, and the curve “follows” a path which is the combined result of the useful as well as the noise-contributed information. In practice, the performance of the resulting estimator is measured as the misfit, using a loss criterion (e.g., mean squared error, probability of error) between the predicted values and the true ones, over an independent set of data or using cross-validation techniques; for example, the resulting misfit is expected to be larger for the case of fitting the high order polynomial compared to the one corresponding to the quadratic polynomial of Figure 17.3c.

The reader may have noticed that we have avoided to define the term “complex” and we used it in a rather vague context. Complexity is often directly related to the number of the unknown parameters. However, this is not always the case. Complexity is a more general property and sometimes we may have classifiers in, even, infinite dimensional spaces, trained with a finite number of points, which generalize very well, [7].

A way to cope with the overfitting problem is to employ the *regularization* method. This is an elegant mathematical tool, that simultaneously cares to serve both desires; to keep the contribution of the loss function term as small as possible, since this accounts for the accuracy of the estimator, but at the same time to retain the fitted model as less complex as possible. This is achieved by adding a second term in

the cost function in (17.9), whose goal is to keep the norm of the parameters as small as possible, i.e.,

$$J(\boldsymbol{\theta}) := \sum_{n=1}^N \mathcal{L}(y_n, f_{\boldsymbol{\theta}}(\mathbf{x}_n)) + \lambda \Omega(\|\boldsymbol{\theta}\|), \quad (17.11)$$

where  $\Omega(\cdot)$  is a strictly increasing monotonic non-negative function and  $\|\cdot\|$  is a norm, e.g., the Euclidean ( $l_2$ ) or the  $l_1$  norms. The parameter  $\lambda$  is known as the regularization parameter and it controls the relative significance of the two terms in the cost function. For fixed  $N$ ,  $\lambda$  is usually determined via cross-validation. In a time varying adaptive mode of operation, when cross-validation is not possible, then empirical experience comes to assist or some adhoc techniques can be mobilized, to make  $\lambda = \lambda_N$ , i.e., time varying. Take as an example the case where the environment does not change and the only reason that we use an adaptive algorithm is due to complexity reasons. Then, as  $N \rightarrow \infty$ , the value of  $\lambda$  should go to zero. For very large values of  $N$ , overfitting is no problem, since the complexity remains a small portion of the data and only the loss-related term in the cost function is sufficient. As a matter of fact, the regularization term, in this case, will only do harm by biasing the solution away from the optimum, this time without reason.

Very often,  $\Omega$  is chosen so that

$$\Omega(\|\boldsymbol{\theta}\|) = \sum_{k=0}^{K-1} |\theta_k|^2, \text{ or } \Omega(\|\boldsymbol{\theta}\|) = \sum_{k=0}^{K-1} |\theta_k|,$$

the latter being the  $l_1$  norm, which has been popularized in the context of sparsity-aware learning/compressed sensing. Note that, usually, the bias term is not included in the norm, since it can make the solution sensitive to the shifts of the origin. This can easily be checked out for the case of the Least Squares loss function

$$\mathcal{L}(y, f_{\boldsymbol{\theta}}(\mathbf{x})) = (y - \boldsymbol{\theta}^T \boldsymbol{\phi}(\mathbf{x}))^2.$$

In practice, very often, if the mean values are not zero, we use centered data by subtracting from  $\mathbf{x}$  its sample mean, and then we can neglect  $\theta_0$ . Besides the norm, other functions have also been used as regularizers, e.g., [8].

Using (17.2) and plugging it in the loss function-related term (17.11), then after minimization and due to the presence of the norm-related term, some of the components of  $\boldsymbol{\theta}$  are pushed towards zero. This pushing towards zero is more aggressive when the  $l_1$  norm is used, see, e.g., [9]. Obviously, the terms which are pushed to zero are those whose elimination affects the least the loss function term, which implicitly results in less complex models.

*Sparsification* is another term used to indicate that the adopted estimation method has the ability to push the least significant, from the accuracy point of view (as this is measured my the loss function-related term in the regularized cost function) to zero. This is a way to guard against overfitting. Regularization techniques gain in importance and become unavoidable within a certain class of nonlinear modeling.

Consider the following modeling,

$$\phi_k(\mathbf{x}) = \kappa(\mathbf{x}, \mathbf{x}_k), \quad k = 1, 2, \dots, N, \quad (17.12)$$

where

$$\kappa(\cdot, \cdot) : \mathcal{R}^l \times \mathcal{R}^l \rightarrow \mathcal{R}, \quad (17.13)$$

which, dressed with some properties, as we will soon see, is known as kernel. In other words, the expansion of our nonlinear function in (17.2) involves as many terms as our training data points, and each term in the expansion is related with one point from the training set, that is,

$$f(\cdot) = \sum_{k=1}^N \theta_k \kappa(\cdot, \mathbf{x}_k) + \theta_0. \quad (17.14)$$

Such models are met in the context of Support Vector Machines as well as in Relevance Vector Machines, [1, 2, 7]. As we will soon see, this class of models has a strong theoretical justification. In any case, such models demand drastic sparsification, otherwise they will suffer for strong overfitting. Moreover, besides overfitting, in the adaptive case, where  $N$  keeps increasing, such a model would soon become unmanageable. This paper will discuss a number of related sparsification techniques.

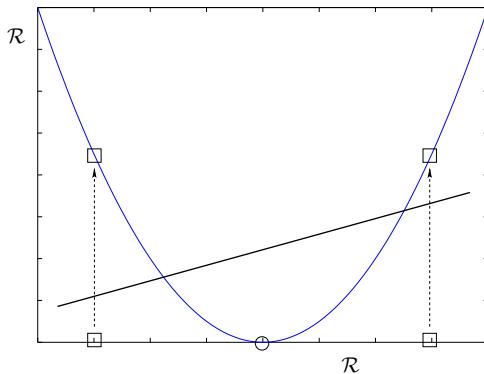

#### 1.17.4 Mapping a nonlinear to a linear task

Let us now look at the expansion in (17.2) in conjunction with our prediction models given in (17.4) for the regression and (17.5) for the classification tasks. Basically, all that such a modeling says is that if we map our original input  $l$ -dimensional space into a new  $K$ -dimensional space,

$$\mathcal{R}^l \ni \mathbf{x} \mapsto \phi(\mathbf{x}) \in \mathcal{R}^K, \quad (17.15)$$

we expect our task to be sufficiently well modeled by adopting a linear model in this new space. It is only up to us to choose the proper functions,  $\phi_k(\cdot)$ , as well as the appropriate dimensionality of the new space,  $K$ . For the classification task, such a procedure has a strong theoretical support from *Cover's theorem*, which states that: Consider  $N$  randomly located points in an  $l$ -dimensional space and use a mapping to map these points into a higher dimensional space. Then the probability of locating them, in the new space, in linearly separable groupings tends to one as the dimensionality,  $K$ , of the new space tends to infinity. Figure 17.4 illustrates how an appropriate mapping can transform a nonlinearly separable task to a linearly separable one. Notice that nature cannot be fooled. After the mapping in the higher 2-dimensional space, the points continue to live in an  $l$ -dimensional manifold [10] (paraboloid in this case). The mapping gives the opportunity to our  $l$ -dimensional points to take advantage of the freedom, which a higher dimensional space provides, so that to move around and be placed in linearly separable positions, while retaining their original  $l$ -dimensional (true degrees of freedom) nature; a paraboloid in the 2-dimensional space can be fully described in terms of one free parameter.

Although such a method sounds great, it has its practical drawbacks. To transform a problem into a linear one, we may have to map the original space to a very high dimensional one, and this can lead to a huge number of unknown parameters to be estimated. However, the mathematicians have, once more, offered to us an escape route that has been developed many years ago. The magic name is *Reproducing Kernel Hilbert Spaces*. Choosing to map to such spaces, and some of them can even be of

**FIGURE 17.4**

Transforming linearly non-separable learning tasks to separable ones by using nonlinear mappings to higher dimensional spaces. The original data, i.e., two “squares” and a “circle,” are placed on the 1-dimensional space,  $\mathcal{R}$ , rendering thus the linear classification task intractable. However, by using the polynomial function  $\Phi(x) := x^2, \forall x \in \mathcal{R}$ , we are able to map the original data to a manifold which lies in the 2-dimensional space  $\mathcal{R}^2$ . The mapped data can be now easily linearly separated, as this can be readily verified by the linear classifier which is illustrated by the straight, black, solid line of the figure.

infinite dimension, makes computations much easier; moreover, there is an associated strong theorem that justifies the expansion in (17.14). Assume that we have selected a mapping

$$\mathcal{R}^l \ni \mathbf{x} \mapsto \phi(\mathbf{x}) \in \mathcal{H}, \quad (17.16)$$

where  $\mathcal{H}$  is RKHS. Then, the following statements are valid:

- *The Kernel Trick:* Let  $\mathbf{x}_1, \mathbf{x}_2$  be two points in our original  $l$ -dimensional space and  $\phi(\mathbf{x}_1), \phi(\mathbf{x}_2)$  their respective images in an RKHS,  $\mathcal{H}$ . Since  $\mathcal{H}$  is a Hilbert space, an inner product,  $\langle \cdot, \cdot \rangle_{\mathcal{H}}$ , is associated with it, by the definition of Hilbert spaces. As we will more formally see in the next section, the inner product of any RKHS is uniquely defined in terms of the so called kernel function,  $\kappa(\cdot, \cdot)$  and the following holds true

$$\langle \phi(\mathbf{x}_1), \phi(\mathbf{x}_2) \rangle_{\mathcal{H}} = \kappa(\mathbf{x}_1, \mathbf{x}_2). \quad (17.17)$$

This is a remarkable property, since it allows to compute inner products in a (high dimensional) RKHS as a function operating in the lower dimensional input space. Also, this property allows the following “black box” approach, that has extensively been exploited in Machine Learning:

- Design an algorithm, which operates in the input space and computes the estimates of the parameters of a linear modeling.
- Cast this algorithm, if of course this is possible, in terms of inner product operations *only*.
- Replace each inner product with a kernel operation.

Then the resulting algorithm is equivalent with solving the (linear modeling) estimation task in an RKHS, which is defined by the selected kernel. Different kernel functions correspond to different RKHSs and, consequently, to different nonlinearities; each inner product in the RKHS is a nonlinear function operation in the input space. The kernel trick was first used in [11, 12].

- *Representer Theorem:* Consider the cost function in (17.11), and constrain the solutions to lie within an RKHS space, defined by a kernel function  $\kappa(\cdot, \cdot)$ . Then the minimizer of (17.11) is of the form

$$f(\cdot) = \sum_{n=1}^N \theta_n \kappa(\cdot, \mathbf{x}_n) + \theta_0. \quad (17.18)$$

This makes crystal clear the reason for the specific modeling in (17.14). In other words, if we choose to attack a nonlinear modeling by “transforming” it to a linear one, after performing a mapping of our data into a RKHS in order to exploit the advantage of efficient inner product operations, then the (linear with respect to the parameters) modeling in (17.14) results naturally from the theory. Our only concern now is to use an appropriate regularization, in order to cope with overfitting problems.

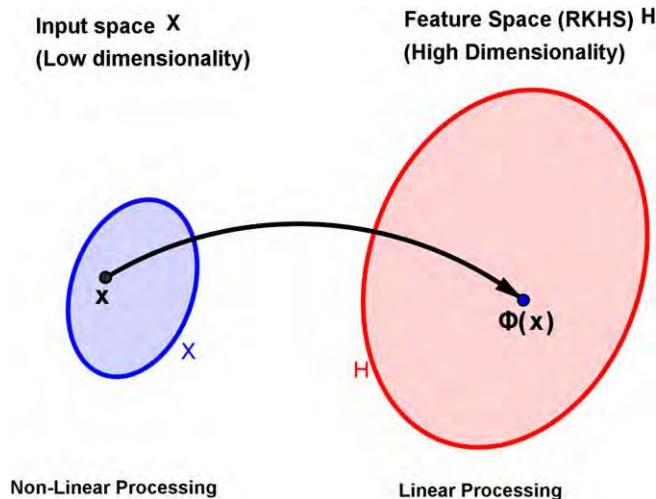

All the previously presented issues will be discussed in more detail in the sections to come. Our goal, so far, was to try to give the big picture of the paper in simple terms and focus more on the notions than on mathematics. We will become more formal in the sections to come. The reader, however, may bypass some of the sections, if his/her current focus is not on the mathematical details but on the algorithms. As said already before, we have made an effort to write the paper in such a way, so that to serve both needs: mathematical rigor and practical flavor, as much as we could.

## 1.17.5 Reproducing kernel Hilbert spaces

In kernel-based methods, the notion of the Reproducing Kernel Hilbert Space (RKHS) plays a crucial role. A RKHS is a rich construct (roughly, a space of functions with an inner product), which has been proven to be a very powerful tool. Kernel-based methods are utilized in an increasingly large number of scientific areas, especially where nonlinear models are required. For example, in pattern analysis, a classification task of a set  $X \subset \mathcal{R}^l$  is usually reformed by mapping the data into a higher dimensional space (possibly of infinite dimension)  $\mathcal{H}$ , which is a Reproducing Kernel Hilbert Space (RKHS). The advantage of such a mapping is to make the task more tractable, by employing a linear classifier in the feature space  $\mathcal{H}$ , exploiting Cover’s theorem (see [2, 13]). This is equivalent with solving a nonlinear problem in the original space.

Similar approaches have been used in principal components analysis, in Fisher’s linear discriminant analysis, in clustering, regression, image processing and in many other subdisciplines. Recently, processing in RKHS is gaining in popularity within the Signal Processing community in the context of adaptive learning.

Although the kernel trick works well for most applications, it may conceal the basic mathematical steps that underlie the procedure, which are essential if one seeks a deeper understanding of the problem. These steps are: 1) Map the finite dimensionality input data from the input space  $X$  (usually  $X \subset \mathcal{R}^l$ ) into a higher dimensionality (possibly infinite) RKHS  $\mathcal{H}$  (feature space) and 2) Perform a linear processing (e.g., adaptive filtering) on the mapped data in  $\mathcal{H}$ . The procedure is equivalent with a nonlinear processing

**FIGURE 17.5**

Mapping from input space  $X$  to feature space  $H$ .

(nonlinear filtering) in  $X$  (see Figure 17.5). The specific choice of the kernel  $\kappa$  defines, implicitly, an RKHS with an appropriate inner product. Moreover, the specific choice of the kernel defines the type of nonlinearity that underlies the model to be used.

### 1.17.5.1 A historical overview

In the past, there have been two trends in the study of these spaces by the mathematicians. The first one originated in the theory of integral equations by Mercer [14, 15]. He used the term “positive definite kernel” to characterize a function of two points  $\kappa(\mathbf{x}, \mathbf{y})$  defined on  $X^2$ , which satisfies Mercer’s theorem:

$$\sum_{n,m=1}^N a_n a_m \kappa(\mathbf{x}_n, \mathbf{x}_m) \geq 0, \quad (17.19)$$

for any numbers  $a_n, a_m$ , any points  $\mathbf{x}_n, \mathbf{x}_m, n = 1, \dots, N$ , and for all  $N \in \mathcal{N}_*$ . Later on, Moore [16–18] found that to such a kernel there corresponds a well determined class of functions,  $\mathcal{H}$ , equipped with a specific inner product  $\langle \cdot, \cdot \rangle_{\mathcal{H}}$ , in respect to which the kernel  $\kappa$  possesses the so called reproducing property:

$$f(\mathbf{x}) = \langle f, \kappa(\cdot, \mathbf{x}) \rangle_{\mathcal{H}}, \quad (17.20)$$

for all functions  $f \in \mathcal{H}$  and  $\mathbf{x} \in X$ . Those that followed this trend used to consider a specific given positive definite kernel  $\kappa$  and studied it in itself, or eventually applied it in various domains (such as integral equations, theory of groups, general metric theory, interpolation, etc.). The class  $\mathcal{H}$  corresponding to  $\kappa$  was mainly used as a tool of research and it was usually introduced a posteriori. The work of Bochner

[19, 20], which introduced the notion of the “positive definite function” in order to apply it in the theory of Fourier transforms, also belongs to the same path as the one followed by Mercer and Moore.

On the other hand, those who followed the second trend were primarily interested in the class of functions  $\mathcal{H}$ , while the associated kernel was employed essentially as a tool in the study of the functions of this class. This trend is traced back to the works of Zaremba [21, 22] during the first decade of the 20th century. He was the first to introduce the notion of a kernel, which corresponds to a specific class of functions and to state its reproducing property. However, he did not develop any general theory, nor did he give any particular name to the kernels he introduced. In this, second trend, the mathematicians were primarily interested in the study of the class of functions  $\mathcal{H}$  and the corresponding kernel  $\kappa$ , which satisfies the reproducing property, was used as a tool in this study. To the same trend belong also the works of Bergman [23] and Aronszajn [3]. Those two trends evolved separately during the first decades of the 20th century, but soon the links between them were noticed. After the second world war, it was known that the two concepts of defining a kernel, either as a positive definite kernel, or as a reproducing kernel, are equivalent. Furthermore, it was proved that there is a one to one correspondence between the space of positive definite kernels and the space of reproducing kernel Hilbert spaces.

It has to be emphasized that examples of such kernels have been known for a long time prior to the works of Mercer and Zaremba; for example, all the Green’s functions of self-adjoint ordinary differential equations belong to this type of kernels. However, some of the important properties that these kernels possess have only been realized and used in the beginning of the 20th century and since then have been the focus of research. In the following, we will give a more detailed description of these spaces and establish their main properties, focusing on the essentials that elevate them to such a powerful tool in the context of machine learning. Most of the material presented here can also be found in more detail in several other papers and textbooks, such as the celebrated paper of Aronszajn [3], the excellent introductory text of Paulsen [24] and the popular books of Schölkopf and Smola [13] and Shawe-Taylor and Cristianini [25]. Here, we attempt to portray both trends and to highlight the important links between them. Although the general theory applies to complex spaces, to keep the presentation as simple as possible, we will mainly focus on real spaces.

### 1.17.5.2 Definition

We begin our study with the classic definitions on positive definite matrices and kernels as they were introduced by Mercer. Given a function  $\kappa : X \times X \rightarrow \mathcal{R}$  and  $\mathbf{x}_1, \dots, \mathbf{x}_N \in X$  (typically  $X$  is a compact subset of  $\mathcal{R}^l$ ,  $l > 0$ ), the square matrix  $\mathbf{K} = (K_{n,m})$  with elements  $K_{n,m} = \kappa(\mathbf{x}_n, \mathbf{x}_m)$ , for  $n, m = 1, \dots, N$ , is called the *Gram matrix* (or *kernel matrix*) of  $\kappa$  with respect to  $\mathbf{x}_1, \dots, \mathbf{x}_N$ . A symmetric matrix  $\mathbf{K} = (K_{n,m})$  satisfying

$$\mathbf{c}^T \cdot \mathbf{K} \cdot \mathbf{c} = \sum_{n=1, m=1}^N c_n c_m K_{n,m} \geq 0,$$

for all  $\mathbf{c} \in \mathcal{R}^N$ ,  $n = 1, \dots, N$ , where the notation  $(\cdot)^T$  denotes transposition, is called *positive definite*. In matrix analysis literature, this is the definition of a positive semidefinite matrix. However, as positive definite matrices were originally introduced by Mercer and others in this context, we employ the term positive definite, as it was already defined. If the inequality is strict, for all non-zero vectors  $\mathbf{c} \in \mathcal{R}^N$ , the

matrix will be called *strictly positive definite*. A function  $\kappa : X \times X \rightarrow \mathcal{R}$ , which for all  $N \in \mathcal{N}_*$  and all  $\mathbf{x}_1, \dots, \mathbf{x}_N \in X$  gives rise to a positive definite Gram matrix  $K$ , is called a *positive definite kernel*. In the following, we will frequently refer to a positive definite kernel simply as *kernel*. We conclude that a positive definite kernel is symmetric and satisfies

$$\sum_{n=1, m=1}^N c_n c_m \kappa(\mathbf{x}_n, \mathbf{x}_m) \geq 0,$$

for all  $c \in \mathcal{R}^N$ ,  $n = 1, \dots, N$ ,  $\mathbf{x}_1, \dots, \mathbf{x}_N \in X$ , and for all  $N \in \mathcal{N}_*$ . Formally, a Reproducing Kernel Hilbert space is defined as follows:

**Definition 1 (Reproducing Kernel Hilbert Space (RKHS)).** Consider a linear space  $\mathcal{H}$  of real valued functions,  $f$ , defined on a set  $X$ . Suppose, further, that in  $\mathcal{H}$  we can define an inner product  $\langle \cdot, \cdot \rangle_{\mathcal{H}}$  with corresponding norm  $\|\cdot\|_{\mathcal{H}}$  and that  $\mathcal{H}$  is complete with respect to that norm, i.e.,  $\mathcal{H}$  is a Hilbert space. We call  $\mathcal{H}$  a *Reproducing Kernel Hilbert Space (RKHS)*, if there exists a function  $\kappa : X \times X \rightarrow \mathcal{R}$  with the following two important properties:

1. For every  $\mathbf{x} \in X$ ,  $\kappa(\cdot, \mathbf{x})$  belongs to  $\mathcal{H}$  (or equivalently  $\kappa$  spans  $\mathcal{H}$ , i.e.,  $\mathcal{H} = \overline{\text{span}\{\kappa(\cdot, \mathbf{x}), \mathbf{x} \in X\}}$ , where the overline stands for the closure of a set).
2.  $\kappa$  has the so called *reproducing property*, i.e.,

$$f(\mathbf{x}) = \langle f, \kappa(\cdot, \mathbf{x}) \rangle_{\mathcal{H}}, \text{ for all } f \in \mathcal{H}, \mathbf{x} \in X, \quad (17.21)$$

in particular  $\kappa(\mathbf{x}, \mathbf{y}) = \langle \kappa(\cdot, \mathbf{y}), \kappa(\cdot, \mathbf{x}) \rangle_{\mathcal{H}}$ . Furthermore,  $\kappa$  is a positive definite kernel and the mapping  $\Phi : X \rightarrow \mathcal{H}$ , with  $\Phi(\mathbf{x}) = \kappa(\cdot, \mathbf{x})$ , for all  $\mathbf{x} \in X$  is called the feature map of  $\mathcal{H}$ .  $\diamond$

To denote the RKHS associated with a specific kernel  $\kappa$ , we will also use the notation  $\mathcal{H}(\kappa)$ . Furthermore, under the aforementioned notations  $\kappa(\mathbf{x}, \mathbf{y}) = \langle \Phi(\mathbf{y}), \Phi(\mathbf{x}) \rangle_{\mathcal{H}}$ , i.e.,  $\kappa(\mathbf{x}, \mathbf{y})$  is the inner product of  $\Phi(\mathbf{y})$  and  $\Phi(\mathbf{x})$  in the feature space. This is the essence of the kernel trick mentioned in Section 1.17.4. The feature map  $\Phi$  transforms the data from the low dimensionality space  $X$  to the higher dimensionality feature space  $\mathcal{H}$ . Linear processing in  $\mathcal{H}$  involves inner products in  $\mathcal{H}$ , which can be calculated via the kernel  $\kappa$  disregarding the actual structure of  $\mathcal{H}$ .

### 1.17.5.3 Some basic theorems

In the following, we consider the definition of a RKHS as a class of functions with specific properties (following the second trend) and show the key ideas that underlie Definition 1. To that end, consider a linear class  $\mathcal{H}$  of real valued functions,  $f$ , defined on a set  $X$ . Suppose, further, that in  $\mathcal{H}$  we can define an inner product  $\langle \cdot, \cdot \rangle_{\mathcal{H}}$  with corresponding norm  $\|\cdot\|_{\mathcal{H}}$  and that  $\mathcal{H}$  is complete with respect to that norm, i.e.,  $\mathcal{H}$  is a Hilbert space. Consider, also, a *linear* functional  $T$ , from  $\mathcal{H}$  into the field  $\mathcal{R}$ . An important theorem of functional analysis states that such a functional is *continuous*, if and only if it is *bounded*. The space consisting of all continuous linear functionals from  $\mathcal{H}$  into the field  $\mathcal{R}$  is called the *dual space* of  $\mathcal{H}$ . In the following, we will frequently refer to the so called *linear evaluation functional*  $T_y$ . This is a special case of a linear functional that satisfies  $T_y(f) = f(y)$ , for all  $f \in \mathcal{H}$ .

We call  $\mathcal{H}$  a *Reproducing Kernel Hilbert Space (RKHS)* on  $X$  over  $\mathcal{R}$ , if for every  $y \in X$ , the linear evaluation functional,  $T_y$ , is continuous. We will prove that such a space is related to a positive definite kernel, thus providing the first link between the two trends. Subsequently, we will prove that any positive definite kernel defines implicitly a RKHS, providing the second link and concluding the equivalent definition of RKHS (Definition 1), which is usually used in the machine learning literature. The following theorem establishes an important connection between a Hilbert space  $H$  and its dual space.

**Theorem 2 (Riesz Representation).** *Let  $\mathcal{H}$  be a general Hilbert space and let  $\mathcal{H}^*$  denote its dual space. Every element  $\Phi$  of  $\mathcal{H}^*$  can be uniquely expressed in the form:*

$$\Phi(f) = \langle f, \phi \rangle_{\mathcal{H}},$$

for some  $\phi \in \mathcal{H}$ . Moreover,  $\|\Phi\|_{\mathcal{H}^*} = \|\phi\|_{\mathcal{H}}$ .  $\diamond$

Following the Riesz representation theorem, we have that for every  $y \in X$ , there exists a *unique* element  $\kappa_y \in \mathcal{H}$ , such that for every  $f \in \mathcal{H}$ ,  $f(y) = T_y(f) = \langle f, \kappa_y \rangle_{\mathcal{H}}$ . The function  $\kappa_y$  is called the reproducing kernel for the point  $y$  and the function  $\kappa(x, y) = \kappa_y(x)$  is called the *reproducing kernel* of  $\mathcal{H}$ . In addition, note that  $\langle \kappa_y, \kappa_x \rangle_{\mathcal{H}} = \kappa_y(x) = \kappa(x, y)$  and  $\|T_y\|_{\mathcal{H}^*}^2 = \|\kappa_y\|_{\mathcal{H}}^2 = \langle \kappa_y, \kappa_y \rangle_{\mathcal{H}} = \kappa(y, y)$ .

**Proposition 3.** *The reproducing kernel of  $\mathcal{H}$  is symmetric, i.e.,  $\kappa(x, y) = \kappa(y, x)$ .*  $\diamond$

**Proof.** Observe that  $\langle \kappa_y, \kappa_x \rangle_{\mathcal{H}} = \kappa_y(x) = \kappa(x, y)$  and  $\langle \kappa_x, \kappa_y \rangle_{\mathcal{H}} = \kappa_x(y) = \kappa(y, x)$ . As the inner product of  $\mathcal{H}$  is symmetric (i.e.,  $\langle \kappa_y, \kappa_x \rangle_{\mathcal{H}} = \langle \kappa_x, \kappa_y \rangle_{\mathcal{H}}$ ) the result follows.  $\square$

In the following, we will frequently identify the function  $\kappa_y$  with the notation  $\kappa(\cdot, y)$ . Thus, we write the reproducing property of  $\mathcal{H}$  as:

$$f(y) = \langle f, \kappa(\cdot, y) \rangle_{\mathcal{H}}, \quad (17.22)$$

for any  $f \in \mathcal{H}$ ,  $y \in X$ . Note that due to the uniqueness provided by the Riesz representation theorem,  $\kappa$  is the unique function that satisfies the reproducing property. The following proposition establishes the first link between the positive definite kernels and the reproducing kernels.

**Proposition 4.** *The reproducing kernel of  $\mathcal{H}$  is a positive definite kernel.*  $\diamond$

**Proof.** Consider  $N > 0$ , the real numbers  $a_1, a_2, \dots, a_N$  and the elements,  $x_1, x_2, \dots, x_N \in X$ . Then

$$\begin{aligned} \sum_{n=1}^N \sum_{m=1}^N a_n a_m \kappa(x_n, x_m) &= \sum_{n=1}^N \sum_{m=1}^N a_n a_m \langle \kappa(\cdot, x_m), \kappa(\cdot, x_n) \rangle_{\mathcal{H}} = \sum_{n=1}^N a_n \left\langle \sum_{m=1}^N a_m \kappa(\cdot, x_m), \kappa(\cdot, x_n) \right\rangle_{\mathcal{H}} \\ &= \left\langle \sum_{m=1}^N a_m \kappa(\cdot, x_m), \sum_{n=1}^N a_n \kappa(\cdot, x_n) \right\rangle_{\mathcal{H}} = \left\| \sum_{n=1}^N a_n \kappa(\cdot, x_n) \right\|_{\mathcal{H}}^2 \geq 0. \end{aligned}$$

Combining Proposition 3 and the previous result, we complete the proof.  $\square$

**Remark 5.** In general, the respective Gram matrix associated with a reproducing kernel is strictly positive definite. For if not, then there must exist at least one non zero vector  $a$  such that

$\left\| \sum_{n=1}^N a_n \kappa(\cdot, \mathbf{x}_n) \right\|_{\mathcal{H}}^2 = 0$ , for some finite set of points  $x_1, x_2, \dots, x_N$ . Hence, for every  $f \in \mathcal{H}$ , we have that  $\sum_n a_n f(\mathbf{x}_n) = \langle f, \sum_n a_n \kappa(\cdot, \mathbf{x}_n) \rangle_{\mathcal{H}} = 0$ . Thus, in this case there exists a linear dependence between the values of *every* function in  $\mathcal{H}$  at some finite set of points. Such examples do exist (e.g., Sobolev spaces), but in most cases the reproducing kernels define Gram matrices that are always strictly positive and invertible.

The following proposition establishes a very important fact; any RKHS,  $\mathcal{H}$ , can be generated by the respective reproducing kernel  $\kappa$ . Note that the overline denotes the closure of a set (i.e., if  $A$  is a subset of  $\mathcal{H}$ ,  $\overline{A}$  is the closure of  $A$ ).

**Proposition 6.** *Let  $\mathcal{H}$  be a RKHS on the set  $X$  with reproducing kernel  $\kappa$ . Then the linear span of the functions  $\kappa(\cdot, \mathbf{x})$ ,  $\mathbf{x} \in X$ , is dense in  $\mathcal{H}$ , i.e.,  $\mathcal{H} = \overline{\text{span}\{\kappa(\cdot, \mathbf{x}), \mathbf{x} \in X\}}$ .*  $\diamond$

**Proof.** We will prove that the only function of  $\mathcal{H}$  orthogonal to  $A = \text{span}\{\kappa(\cdot, \mathbf{x}), \mathbf{x} \in X\}$  is the zero function. Let  $f$  be such a function. Then, as  $f$  is orthogonal to  $A$ , we have that  $f(\mathbf{x}) = \langle f, \kappa(\cdot, \mathbf{x}) \rangle_{\mathcal{H}} = 0$ , for every  $\mathbf{x} \in X$ . This holds true if and only if  $f = 0$ . Thus  $A^\perp = \overline{A^\perp} = \{0\}$ . Suppose that there is  $f \in \mathcal{H}$  such that  $f \notin \overline{A}$ . As  $\overline{A}$  is a closed (convex) subspace of  $\mathcal{H}$ , there is a  $g \in \overline{A}$  which minimizes the distance between  $f$  and points in  $\overline{A}$  (theorem of best approximation). For the same  $g$  we have that  $f - g \perp \overline{A}$ . Thus, the non-zero function  $h = f - g$  is orthogonal to  $\overline{A}$ . However, we proved that there isn't any non-zero vector orthogonal to  $A$ . This leads us to conclude that  $\overline{A} = \mathcal{H}$ .  $\square$

In the following we give some important properties of the specific spaces.

**Proposition 7 (Norm convergence implies point-wise convergence).** *Let  $\mathcal{H}$  be a RKHS on  $X$  and let  $\{f_n\}_{n \in \mathcal{N}_*} \subseteq \mathcal{H}$ . If  $\lim_n \|f_n - f\|_{\mathcal{H}} = 0$ , then  $f(\mathbf{x}) = \lim_n f_n(\mathbf{x})$ , for every  $\mathbf{x} \in X$ . Conversely, if for any sequence  $\{f_n\}_{n \in \mathcal{N}_*}$  of a Hilbert space  $\mathcal{H}$ , such that  $\lim_n \|f_n - f\|_{\mathcal{H}} = 0$ , we have also that  $f(\mathbf{x}) = \lim_n f_n(\mathbf{x})$ , then  $\mathcal{H}$  is a RKHS.*  $\diamond$

**Proof.** For every  $\mathbf{x} \in X$  we have that

$$|f_n(\mathbf{x}) - f(\mathbf{x})|_{\mathcal{H}} = |\langle f_n, \kappa(\cdot, \mathbf{x}) \rangle_{\mathcal{H}} - \langle f, \kappa(\cdot, \mathbf{x}) \rangle_{\mathcal{H}}| = |\langle f_n - f, \kappa(\cdot, \mathbf{x}) \rangle_{\mathcal{H}}| \leq \|f_n - f\|_{\mathcal{H}} \cdot \|\kappa(\cdot, \mathbf{x})\|_{\mathcal{H}}.$$

As  $\lim_n \|f_n - f\| = 0$ , we have that  $\lim_n |f_n(\mathbf{x}) - f(\mathbf{x})| = 0$ , for every  $\mathbf{x} \in X$ . Hence  $f(\mathbf{x}) = \lim_n f_n(\mathbf{x})$ , for every  $\mathbf{x} \in X$ .

For the converse, consider the evaluation functional  $T_y : \mathcal{H} \rightarrow \mathcal{R}$ ,  $T_y(f) = f(y)$  for some  $y \in \mathcal{H}$ . We will prove that  $T_y$  is continuous for all  $y \in \mathcal{H}$ . To this end, consider a sequence  $\{f_n\}_{n \in \mathcal{N}_*}$  of  $\mathcal{H}$ , with the property  $\lim_n \|f_n - f\|_{\mathcal{H}} = 0$ , i.e.,  $f_n$  converges to  $f$  in the norm. Then  $|T_y(f_n) - T_y(f)| = |f_n(y) - f(y)| \rightarrow 0$ , as  $f(\mathbf{x}) = \lim_n f(\mathbf{x}) = \lim_n f_n(\mathbf{x})$ . Thus  $T_y(f) = \lim_n T_y(f_n)$  for all  $y \in X$  and all converging sequences  $\{f_n\}_{n \in \mathcal{N}_*}$  of  $\mathcal{H}$ .  $\square$

**Proposition 8 (Different RKHS's cannot have the same reproducing kernel).** *Let  $\mathcal{H}_1, \mathcal{H}_2$  be RKHS's on  $X$  with reproducing kernels  $\kappa_1, \kappa_2$ . If  $\kappa_1(\mathbf{x}, \mathbf{y}) = \kappa_2(\mathbf{x}, \mathbf{y})$ , for all  $\mathbf{x}, \mathbf{y} \in X$ , then  $\mathcal{H}_1 = \mathcal{H}_2$  and  $\|f\|_{\mathcal{H}_1} = \|f\|_{\mathcal{H}_2}$  for every  $f$ .*  $\diamond$

**Proof.** Let  $\kappa(\mathbf{x}, \mathbf{y}) = \kappa_1(\mathbf{x}, \mathbf{y}) = \kappa_2(\mathbf{x}, \mathbf{y})$  and  $A_i = \text{span}\{\kappa_i(\cdot, \mathbf{x}), \mathbf{x} \in X\}$ ,  $i = 1, 2$ . As shown in Proposition 6,  $\mathcal{H}_i = \overline{A_i}$ ,  $i = 1, 2$ . Note that for any  $f \in A_i$ ,  $i = 1, 2$ , we have that  $f(\mathbf{x}) = \sum_n a_n \kappa_i(\cdot, \mathbf{x}_n)$ , for some real numbers  $a_n$  and thus the values of the function are independent of whether we regard it as in  $A_1$  or  $A_2$ . Furthermore, for any  $f \in A_i$ ,  $i = 1, 2$ , as the two kernels are identical, we have that  $\|f\|_{\mathcal{H}_1}^2 = \sum_{n,m} a_n a_m \kappa(\mathbf{x}_m, \mathbf{x}_n) = \|f\|_{\mathcal{H}_2}^2$ . Thus,  $\|f\|_{\mathcal{H}_1} = \|f\|_{\mathcal{H}_2}$ , for all  $f \in A_1 = A_2$ .

Finally, we turn our attention to the limit points of  $A_1$  and  $A_2$ . If  $f \in \mathcal{H}_1$ , then there exists a sequence of functions,  $\{f_n\}_{n \in \mathcal{N}} \subseteq A_1$  such that  $\lim_n \|f - f_n\|_{\mathcal{H}_1} = 0$ . Since  $\{f_n\}_{n \in \mathcal{N}}$  is a converging sequence, it is Cauchy in  $A_1$  and thus it is also Cauchy in  $A_2$ . Therefore, there exists  $g \in \mathcal{H}_2$  such that  $\lim_n \|g - f_n\|_{\mathcal{H}_2} = 0$ . Employing proposition 7, we take that  $f(\mathbf{x}) = \lim_n f_n(\mathbf{x}) = g(\mathbf{x})$ . Thus, every  $f$  in  $\mathcal{H}_1$  is also in  $\mathcal{H}_2$  and by analogous argument we can prove that every  $g \in \mathcal{H}_2$  is also in  $\mathcal{H}_1$ . Hence,  $\mathcal{H}_1 = \mathcal{H}_2$  and as  $\|f\|_{\mathcal{H}_1} = \|f\|_{\mathcal{H}_2}$  for all  $f$  in a dense subset (i.e.,  $A_1$ ), we have that the norms are equal for every  $f$ . To prove the latter, we use the relation  $\lim_n \|f_n\|_{\mathcal{H}_i} = \|f\|_{\mathcal{H}_i}, i = 1, 2$ .  $\square$

The following theorem is the converse of Proposition 4. It was proved by Moore and it gives us a characterization of reproducing kernel functions. Also, it provides the second link between the two trends that have been mentioned in Section 1.17.5.1. Moore's theorem, together with Proposition 4, Proposition 8 and the uniqueness property of the reproducing kernel of a RKHS, establishes a one-to-one correspondence between RKHS's on a set and positive definite functions on the set.

**Theorem 9 (Moore [16]).** *Let  $X$  be a set and let  $\kappa : X \times X \rightarrow \mathcal{R}$  be a positive definite kernel. Then there exists a RKHS of functions on  $X$ , such that  $\kappa$  is the reproducing kernel of  $\mathcal{H}$ .*  $\diamond$

**Proof.** We will give only a sketch of the proof. The interested reader is referred to [24]. The first step is to define  $A = \text{span}\{\kappa(\cdot, \mathbf{x}), \mathbf{x} \in X\}$  and the linear map  $P : A \times A \rightarrow \mathcal{R}$  such that

$$P \left( \sum_m a_m \kappa(\cdot, \mathbf{y}_m), \sum_n b_n \kappa(\cdot, \mathbf{y}_n) \right) = \sum_{n,m} a_m b_n \kappa(\mathbf{y}_n, \mathbf{y}_m).$$

We prove that  $P$  is well defined and that it satisfies the properties of the inner product. Then, given the vector space  $A$  and the inner product  $P$ , one may complete the space by taking equivalence classes of Cauchy sequences from  $A$  to obtain the Hilbert space  $\mathcal{A}$ . Finally, the reproducing property of the kernel  $\kappa$  with respect to the inner product  $P$  is proved.  $\square$

In view of the aforementioned theorems, the Definition 1 of the RKHS given in 1.17.5.2, which is usually used in the machine learning literature, follows naturally.

We conclude this section with a short description of the most important points of the theory developed by Mercer in the context of integral operators. Mercer considered integral operators  $T_\kappa$  generated by a kernel  $\kappa$ , i.e.,  $T_\kappa : L_2(X) \rightarrow L_2(X)$ , such that  $(T_\kappa f)(\mathbf{x}) := \int_X \kappa(\mathbf{x}, \mathbf{y}) f(\mathbf{y}) d\mathbf{y}$ . He concluded the following theorem [14]:

**Theorem 10 (Mercer kernels are positive definite [14]).** *Let  $X \subseteq \mathcal{R}^l$  be a nonempty set and let  $\kappa : X \times X \rightarrow \mathcal{R}$  be continuous. Then  $\kappa$  is a positive definite kernel, if and only if,*

$$\int_{X^2} f(\mathbf{x}) \kappa(\mathbf{x}, \mathbf{y}) f(\mathbf{y}) d\mathbf{x} d\mathbf{y} \geq 0,$$

for all functions  $f \in L_2(X)$ . Moreover, if  $\kappa$  is positive definite, the integral operator  $T_\kappa : L_2(X) \rightarrow L_2(X) : (T_\kappa f)(\mathbf{x}) := \int_X \kappa(\mathbf{x}, \mathbf{y}) f(\mathbf{y}) d\mathbf{y}$  is positive definite, that is,

$$\langle T_\kappa f, f \rangle = \int_X f(\mathbf{y}) (T_\kappa f)(\mathbf{x}) d\mathbf{y} = \int_{X^2} \kappa(\mathbf{x}, \mathbf{y}) f(\mathbf{x}) f(\mathbf{y}) d\mathbf{x} d\mathbf{y} \geq 0,$$

for all  $f \in L_2(X)$ , and if  $\psi_i \in L_2(X)$  are the normalized orthogonal eigenfunctions of  $T_\kappa$  associated with the eigenvalues  $\sigma_i > 0$  then:

$$\kappa(\mathbf{x}, \mathbf{y}) = \sum_i \sigma_i \psi_i(\mathbf{x}) \psi_i(\mathbf{y}).$$

◇

Note that the original form of above theorem is more general, involving  $\sigma$ -algebras and probability measures. However, as in the applications concerning this manuscript such general terms are of no importance, we decided to include this simpler form. The previous theorems established that Mercer's kernels, as they are positive definite kernels, are also reproducing kernels. Furthermore, the first part of Theorem 10 provides a useful tool of determining whether a specific function is actually a reproducing kernel.

#### 1.17.5.4 Examples of kernels

Before proceeding to some more advanced topics in the theory of RKHS, it is important to give some examples of kernels that appear more often in the literature and are used in various applications. Perhaps the most widely used reproducing kernel is the Gaussian radial basis function defined on  $X \times X$ , where  $X \subseteq \mathcal{R}^l$ , as:

$$\kappa_\sigma(\mathbf{x}, \mathbf{y}) = \exp\left(-\frac{\|\mathbf{x} - \mathbf{y}\|^2}{2\sigma^2}\right), \quad (17.23)$$

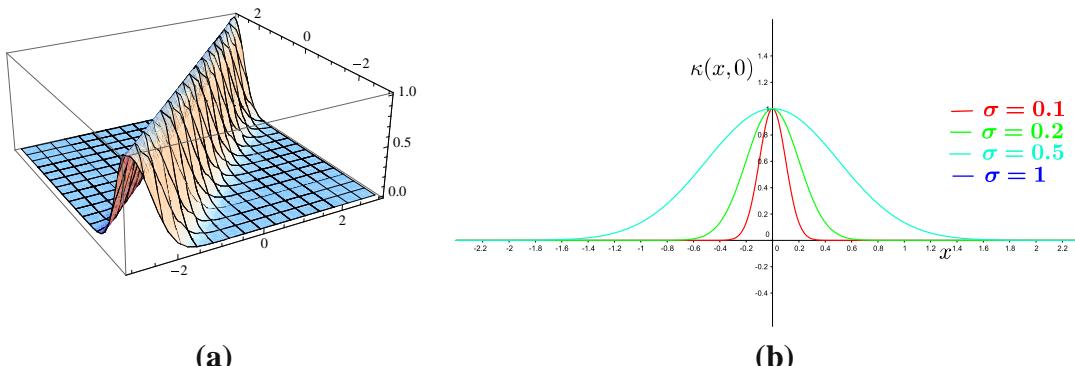

where  $\sigma > 0$ . Equivalently the Gaussian RBF function can be defined as:

$$\kappa_t(\mathbf{x}, \mathbf{y}) = \exp\left(-t\|\mathbf{x} - \mathbf{y}\|^2\right), \quad (17.24)$$

for  $t > 0$ .

Other well-known kernels defined in  $X \times X$ ,  $X \subseteq \mathcal{R}^l$  are:

- The homogeneous polynomial kernel:  $\kappa_d(\mathbf{x}, \mathbf{y}) = \langle \mathbf{x}, \mathbf{y} \rangle^d$ .
- The inhomogeneous polynomial kernel:  $\kappa_d(\mathbf{x}, \mathbf{y}) = (\langle \mathbf{x}, \mathbf{y} \rangle + c)^d$ , where  $c \geq 0$  a constant.

**FIGURE 17.6**

(a) The Gaussian kernel for the case  $X = \mathcal{R}$ ,  $\sigma = 0.5$ . (b) The element  $\Phi(0) = \kappa(\cdot, 0)$  of the feature space induced by the Gaussian kernel for various values of the parameter  $\sigma$ .

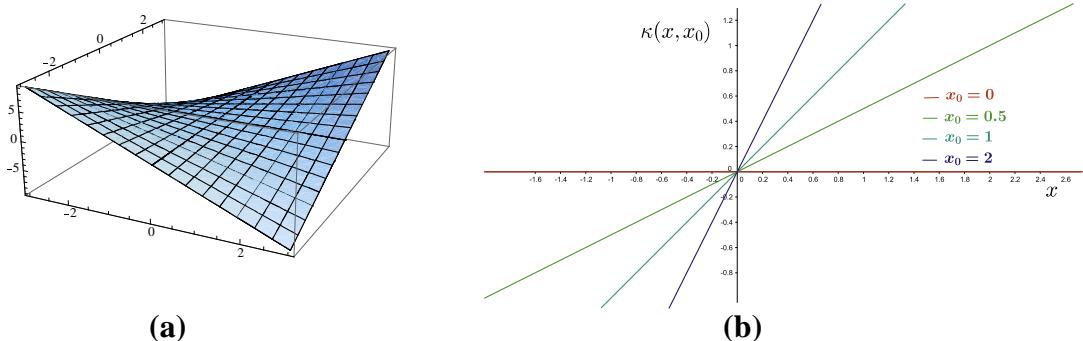

FIGURE 17.7

(a) The homogeneous polynomial kernel for the case  $X = \mathcal{R}$ ,  $d = 1$ . (b) The element  $\Phi(x_0) = \kappa(\cdot, x_0)$  of the feature space induced by the homogeneous polynomial kernel ( $d = 1$ ) for various values of  $x_0$ .

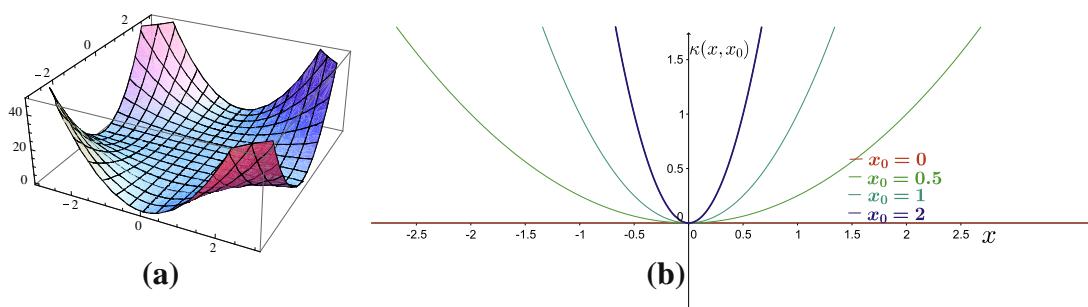

FIGURE 17.8

(a) The homogeneous polynomial kernel for the case  $X = \mathcal{R}$ ,  $d = 2$ . (b) The element  $\Phi(x_0) = \kappa(\cdot, x_0)$  of the feature space induced by the homogeneous polynomial kernel ( $d = 2$ ) for various values of  $x_0$ .

- The spline kernel:  $\kappa_p(\mathbf{x}, \mathbf{y}) = B_{2p+1}(\|\mathbf{x} - \mathbf{y}\|^2)$ , where  $B_n = \bigoplus_{i=1}^n I_{[-\frac{i}{2}, \frac{i}{2}]}$ .
- The cosine kernel:  $\kappa(\mathbf{x}, \mathbf{y}) = \cos(\angle(\mathbf{x}, \mathbf{y}))$ .
- The Laplacian kernel:  $\kappa_t(\mathbf{x}, \mathbf{y}) = \exp(-t\|\mathbf{x} - \mathbf{y}\|)$ .

Note that the RKHS associated to the Gaussian RBF kernel and the Laplacian kernel are infinite dimensional, while the RKHS associated to the polynomial kernels have finite dimension [13]. Figures 17.6–17.10, show some of the aforementioned kernels together with a sample of the elements  $\kappa(\cdot, \mathbf{x})$  that span the respective RKHS's for the case  $X = \mathcal{R}$ . Figures 17.11–17.13, show some of the elements  $\kappa(\cdot, \mathbf{x})$  that span the respective RKHS's for the case  $X = \mathcal{R}^2$ . Interactive figures regarding the aforementioned examples can be found in <http://bouboulis.mysch.gr/kernels.html>. Moreover, Appendix A highlights several properties of the popular Gaussian kernel.

### 1.17.5.5 Some properties of the RKHS

In this section, we will refer to some more advanced topics on the theory of RKHS, which are useful for a deeper understanding of the underlying theory and show why RKHS's constitute such a powerful tool. We begin our study with some properties of RKHS's and conclude with the basic theorems that enable us to generate new kernels. As we work in Hilbert spaces, the two *Parseval's identities* are an extremely helpful tool. When  $\{e_s : s \in S\}$  (where  $S$  is an arbitrary set) is an orthonormal basis for a

**FIGURE 17.11**

The element  $\Phi(0) = \kappa(\cdot, 0)$  of the feature space induced by the Gaussian kernel ( $X = \mathcal{R}^2$ ) for various values of the parameter  $\sigma$ .

Hilbert space  $\mathcal{H}$ , then for any  $h \in \mathcal{H}$  we have that:

$$h = \sum_{s \in S} \langle h, e_s \rangle e_s, \quad (17.25)$$

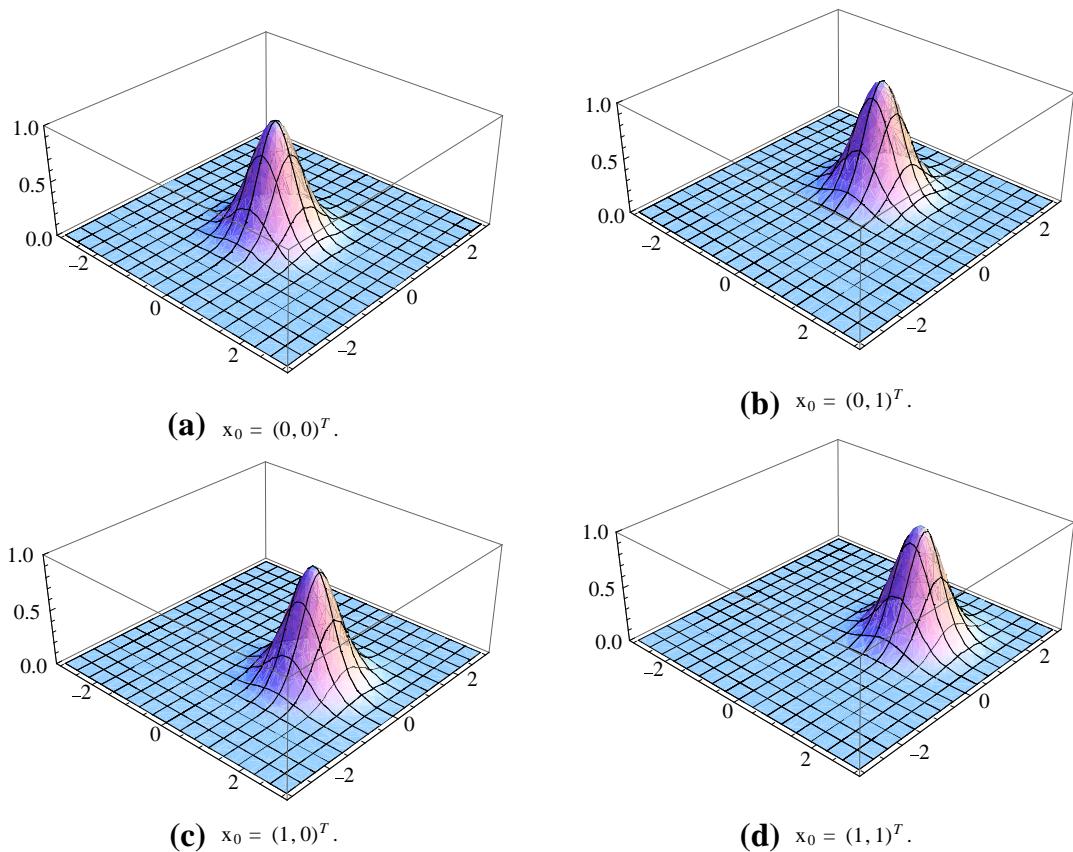

$$\|h\|^2 = \sum_{s \in S} |\langle h, e_s \rangle|^2. \quad (17.26)$$

Note that these two identities hold for a general arbitrary set  $S$  (not necessarily ordered). The convergence in this case is defined somewhat differently. We say that  $h = \sum_{s \in S} h_s$ , if for any  $\epsilon > 0$ , there exists a finite subset  $F_0 \subseteq S$ , such that for any finite set  $F : F_0 \subseteq F \subseteq S$ , we have that  $\|h - \sum_{s \in F} h_s\| < \epsilon$ .

**Proposition 11 (Cauchy-Schwarz Inequality).** *If  $\kappa$  is a reproducing kernel on  $X$  then*

$$\|\kappa(x, y)\|^2 \leq \kappa(x, x) \cdot \kappa(y, y).$$

◇

**FIGURE 17.12**

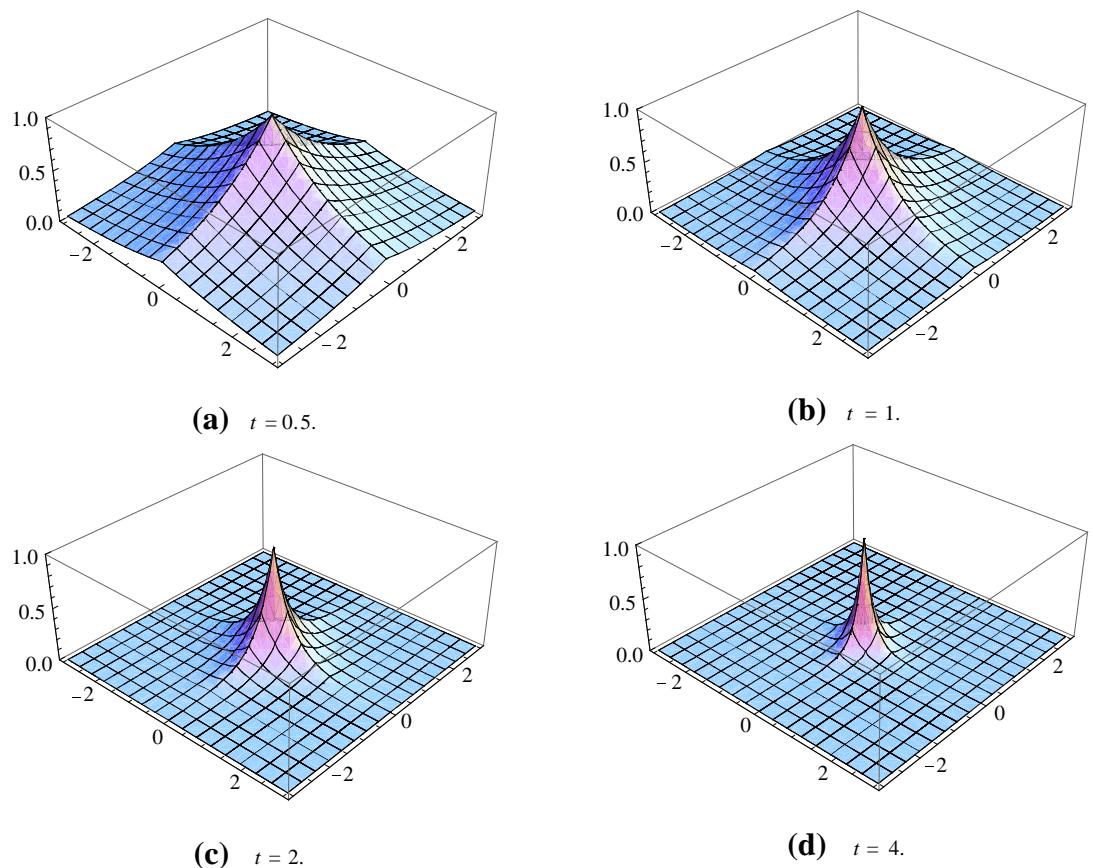

The element  $\Phi(x_0) = \kappa(\cdot, x_0)$  of the feature space induced by the Gaussian kernel ( $X = \mathcal{R}^2$ ) with  $\sigma = 0.5$ .

**Proof.** The proof is straightforward, as  $\kappa(x, y)$  is the inner product  $\langle \Phi(y), \Phi(x) \rangle_{\mathcal{H}}$  of the space  $\mathcal{H}(\kappa)$ .  $\square$

**Theorem 12.** Every finite dimensional class of functions defined on  $X$ , equipped with an inner product, is an RKHS. Let  $h_1, \dots, h_N$  constitute a basis of the space and the inner product is defined as follows

$$\langle f, g \rangle = \sum_{n,m=1}^N \alpha_{n,m} \gamma_n \zeta_m,$$

for  $f = \sum_{n=1}^N \gamma_n h_n$  and  $g = \sum_{n=1}^N \zeta_n h_n$ , where the  $N \times N$  real matrix  $A = (\alpha_{n,m})^N$  is strictly positive definite. Let  $B = (\beta_{n,m})^N$  be the inverse of  $A$ , then the kernel of the RKHS is given by

**FIGURE 17.13**

The element  $\Phi(0) = \kappa(\cdot, 0)$  of the feature space induced by the Laplacian kernel ( $X = \mathcal{R}^2$ ) for various values of the parameter  $t$ .

$$\kappa(\mathbf{x}, \mathbf{y}) = \sum_{n,m=1}^N \beta_{n,m} h_n(\mathbf{x}) h_m(\mathbf{y}). \quad (17.27)$$

◇

**Proof.** The reproducing property is immediately verified by Eq. (17.27):

$$\langle f, \kappa(\cdot, \mathbf{x}) \rangle_{\mathcal{H}} = \left\langle \sum_{n=1}^N \gamma_n h_n, \sum_{n,m=1}^N \beta_{n,m} h_m(\mathbf{x}) \cdot h_m \right\rangle_{\mathcal{H}} = \sum_{n,m=1}^N \alpha_{n,m} \gamma_n \sum_{k=1}^N \beta_{m,k} h_k(\mathbf{x})$$

$$\begin{aligned}
&= \sum_{n,k=1}^N \left( \sum_{m=1}^N \alpha_{n,m} \beta_{m,k} \right) \gamma_n h_k(\mathbf{x}) = \sum_{n=1}^N \gamma_n h_n(\mathbf{x}) \\
&= f(\mathbf{x}). \quad \square
\end{aligned}$$

The following theorem gives the kernel of a RKHS (of finite or infinite dimension) in terms of the elements of an orthonormal basis.

**Theorem 13.** *Let  $\mathcal{H}$  be a RKHS on  $X$  with reproducing kernel  $\kappa$ . If  $\{e_s : s \in S \subset \mathcal{N}_*\}$  is an orthonormal basis for  $\mathcal{H}$ , then  $\kappa(\mathbf{x}, \mathbf{y}) = \sum_{s \in S} e_s(\mathbf{y}) e_s(\mathbf{x})$ , where this series converges pointwise.*  $\diamond$

**Proof.** For any  $\mathbf{y} \in X$  we have that  $\langle \kappa(\cdot, \mathbf{y}), e_s \rangle_{\mathcal{H}} = \langle e_s, \kappa(\cdot, \mathbf{y}) \rangle_{\mathcal{H}} = e_s(\mathbf{y})$ . Hence, employing Parseval's identity (17.25), we have that  $\kappa(\cdot, \mathbf{y}) = \sum_{s \in S} e_s(\mathbf{y}) e_s(\cdot)$ , where these sums converge in the norm on  $\mathcal{H}$ . Since the sums converge in the norm, they converge at every point. Hence,  $\kappa(\mathbf{x}, \mathbf{y}) = \sum_{s \in S} e_s(\mathbf{y}) e_s(\mathbf{x})$ .  $\square$

**Proposition 14.** *If  $\mathcal{H}$  is a RKHS on  $X$  with respective kernel  $\kappa$ , then every closed subspace  $\mathcal{F} \subseteq \mathcal{H}$  is also a RKHS. In addition, if  $\mathcal{F}_1(\kappa_1)$  and  $\mathcal{F}_2(\kappa_2)$  are complementary subspaces in  $\mathcal{H}$  then  $\kappa = \kappa_1 + \kappa_2$ .*  $\diamond$

**Proposition 15.** *Let  $\mathcal{H}$  be a RKHS on  $X$  with kernel  $\kappa$  and  $\{g_n\}$  is an orthonormal system in  $\mathcal{H}$ . Then for any sequence of numbers  $\{a_n\}$  such that  $\sum_n a_n^2 < \infty$  (i.e.,  $\{a_n\} \in \ell_2$ ) we have*

$$\sum_n |a_n| |g_n(\mathbf{x})| \leq \kappa(\mathbf{x}, \mathbf{x})^{\frac{1}{2}} \left( \sum_n |a_n|^2 \right)^{\frac{1}{2}}. \quad \diamond$$

**Proof.** We have seen that  $g_n(\mathbf{y}) = \langle g_n, \kappa(\cdot, \mathbf{y}) \rangle$  and that  $\|\kappa(\cdot, \mathbf{y})\|_{\mathcal{H}}^2 = \kappa(\mathbf{y}, \mathbf{y})$ . Thus, considering that  $g_n$ 's are orthonormal and taking the Parseval's identity (17.26) for  $\kappa(\cdot, \mathbf{y})$  with respect to the orthonormal basis, we have:

$$\sum_n |g_n(\mathbf{y})|^2 = \sum_n |\langle g_n, \kappa(\cdot, \mathbf{y}) \rangle_{\mathcal{H}}|^2 \leq \|\kappa(\cdot, \mathbf{y})\|_{\mathcal{H}}^2 = \kappa(\mathbf{y}, \mathbf{y}).$$

Therefore, applying the Cauchy-Schwartz inequality we take

$$\sum_n |a_n| |g_n(\mathbf{x})| \leq \left( \sum_n |a_n|^2 \right)^{\frac{1}{2}} \left( \sum_n |g_n(\mathbf{x})|^2 \right)^{\frac{1}{2}} \leq \kappa(\mathbf{x}, \mathbf{x})^{\frac{1}{2}} \left( \sum_n |a_n|^2 \right)^{\frac{1}{2}}. \quad \square$$

**Theorem 16 (Representer Theorem [26]).** *Denote by  $\Omega : [0, +\infty) \rightarrow \mathcal{R}$  a strictly monotonic increasing function, by  $X$  a nonempty set and by  $\mathcal{L} : X \times \mathcal{R}^2 \rightarrow \mathcal{R} \cup \{\infty\}$  an arbitrary loss function. Then each minimizer  $f \in \mathcal{H}$  of the regularized minimization problem:*

$$\min_f \mathcal{L}((\mathbf{x}_1, y_1, f(\mathbf{x}_1)), \dots, (\mathbf{x}_N, y_N, f(\mathbf{x}_N)) + \Omega(\|f\|_{\mathcal{H}}^2),$$

admits a representation of the form

$$f = \sum_{n=1}^N \theta_n \kappa(\cdot, \mathbf{x}_n), \quad (17.28)$$

where  $\theta_n \in \mathbb{R}$ , for  $n = 1, 2, \dots, N$ .  $\diamond$

**Proof.** We may decompose each  $f \in \mathcal{H}$  into a part contained in the span of the kernels centered at the training points, i.e.,  $\kappa(\cdot, \mathbf{x}_1), \dots, \kappa(\cdot, \mathbf{x}_N)$ , (which is a closed linear subspace) and a part in the orthogonal complement of the previous span. Thus each  $f$  can be written as:

$$f = \sum_{n=1}^N \theta_n \kappa(\cdot, \mathbf{x}_n) + f_{\perp}.$$

Applying the reproducing property and considering that  $\langle f_{\perp}, \kappa(\cdot, \mathbf{x}_n) \rangle_{\mathcal{H}} = 0$ , for  $n = 1, \dots, N$ , we take:

$$f(\mathbf{x}_n) = \langle f, \kappa(\cdot, \mathbf{x}_n) \rangle_{\mathcal{H}} = \sum_{i=1}^N \theta_i \kappa(\mathbf{x}_n, \mathbf{x}_i) + \langle f_{\perp}, \kappa(\cdot, \mathbf{x}_n) \rangle_{\mathcal{H}} = \sum_{i=1}^N \theta_i \kappa(\mathbf{x}_n, \mathbf{x}_i).$$

Thus, the value of the loss function  $\mathcal{L}$  depends only on the part contained in the span of the kernels centered at the training points, i.e., on  $a_1, \dots, a_N$ . Furthermore, for all  $f_{\perp}$  we have:

$$\Omega(\|f\|^2) = \Omega\left(\left\|\sum_{n=1}^N \theta_n \kappa(\cdot, \mathbf{x}_n)\right\|^2 + \|f_{\perp}\|_{\mathcal{H}}^2\right) \geq \Omega\left(\left\|\sum_{n=1}^N \theta_n \kappa(\cdot, \mathbf{x}_n)\right\|^2\right).$$

Thus, for any fixed  $\theta_1, \dots, \theta_n$  the value of the cost function is minimized for  $f_{\perp} = 0$ . Hence, the solution of the minimization task will have to obey this property too.  $\square$

Examples of loss functions  $\mathcal{L}$  as the ones mentioned in Theorem 16 are for example the total squared error:

$$\mathcal{L}((\mathbf{x}_1, y_1, f(\mathbf{x}_1)), \dots, (\mathbf{x}_N, y_N, f(\mathbf{x}_N))) = \sum_{n=1}^N (f(\mathbf{x}_n) - y_n)^2,$$

and the  $l_1$  norm measured error

$$\mathcal{L}((\mathbf{x}_1, y_1, f(\mathbf{x}_1)), \dots, (\mathbf{x}_N, y_N, f(\mathbf{x}_N))) = \sum_{n=1}^N |f(\mathbf{x}_n) - y_n|.$$

The aforementioned theorem is of great importance to practical applications. Although one might be trying to solve an optimization task in an infinite dimensional RKHS  $\mathcal{H}$  (such as the one that generated by the Gaussian kernel), the Representer Theorem states that the solution of the problem lies in the span of  $N$  particular kernels, those centered on the training points.

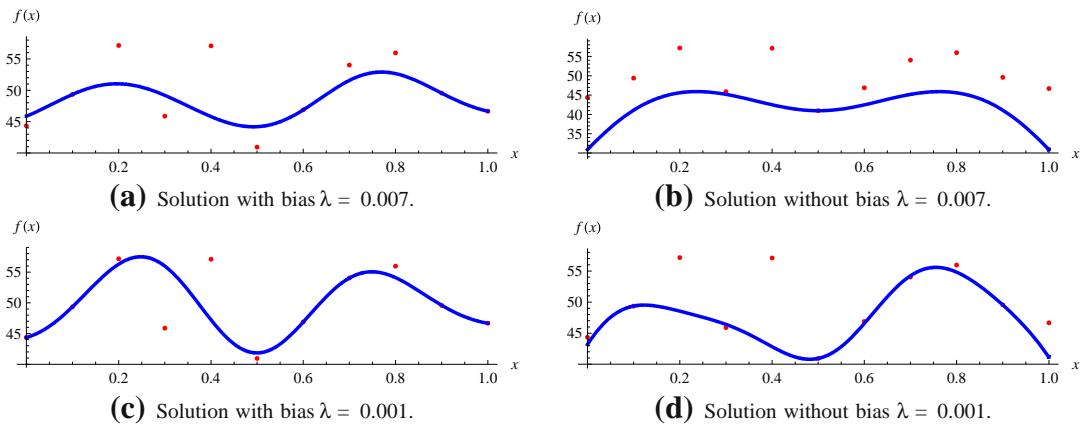

FIGURE 17.14

Solving the regression problem  $\min_f \frac{1}{N} \sum_{n=1}^N (y_n - f(x_n))^2 + \lambda \|f\|_{\mathcal{H}}^2$ , on a set of 11 points (a), (c) with a bias, i.e.,  $f$  admits the form of (17.29) and (b), (d) without a bias, i.e.,  $f$  admits the form of (17.28). In all the examples the Gaussian kernel function was employed. In (a) and (b) we set  $\sigma = 0.15$ ,  $\lambda = 0.007$ . In (c) and (d) we set  $\sigma = 0.15$ ,  $\lambda = 0.001$ . Observe that for  $\lambda = 0.007$ , the unbiased solution takes values significantly lower compared to the values of the training points. For the smaller  $\lambda = 0.001$ , the difference between (c) and (d) is reduced (compared to the case  $\lambda = 0.007$ ). Moreover, one may observe that for the larger value,  $\lambda = 0.007$ , the resulting curves are smoother compared to the curves that correspond to  $\lambda = 0.001$ .

In practice, we often include a bias factor to the solution of kernel-based regularized minimization tasks, that is, we assume that  $f$  admits a representation of the form

$$f = \sum_{n=1}^N \theta_n \kappa(\cdot, x_n) + b, \quad (17.29)$$

where  $b \in \mathcal{R}$ . This has been shown to improve the performance of the respective algorithms [2, 13, 27], for two main reasons. Firstly, the introduction of the bias,  $b$ , enlarges the family of functions in which we search for a solution, thus leading to potentially better estimations. Moreover, as the regularization factor  $\Omega(\|f\|_{\mathcal{H}}^2)$  penalizes the values of  $f$  at the training points, the resulting solution tends to take values as close to zero as possible, for large values of  $\lambda$  (compare Figures 17.14b and 17.14d). At this point, another comment is of interest also. Note that it turns out that the regularization factor  $\|f\|_{\mathcal{H}}^2$  for certain types of kernel functions (e.g., Gaussian) involves the derivatives of  $f$  of all orders [13, 28]. As a consequence the larger the  $\lambda$  is, the smoother the resulting curve becomes (compare Figures 17.14a with 17.14c and Figures 17.14b with 17.14d). The use of the bias factor is theoretically justified by the semi-parametric Representer theorem.

**Theorem 17 (Semi-parametric Representer Theorem [13]).** Suppose that in addition to the assumptions of theorem 16, we are given a set of  $M$  real valued functions  $\{\psi_m\}_{m=1}^M : X \rightarrow \mathcal{R}$ , with the property that the  $N \times M$  matrix  $(\psi_m(x_n))_{n,m}$  has rank  $M$ . Then any  $\tilde{f} := f + h$ , with  $f \in \mathcal{H}$  and

$h \in \text{span}\{\psi_m; m = 1, \dots, M\}$ , solving

$$\min_{\tilde{f}} \mathcal{L}((\mathbf{x}_1, y_1, \tilde{f}(\mathbf{x}_1)), \dots, (\mathbf{x}_N, y_N, \tilde{f}(\mathbf{x}_N)) + \Omega(\|f\|_{\mathcal{H}}^2),$$

admits a representation of the form

$$\tilde{f} = \sum_{n=1}^N \theta_n \kappa(\cdot, \mathbf{x}_n) + \sum_{m=1}^M b_m \psi_m(\cdot), \quad (17.30)$$

with  $\theta_n \in \mathcal{R}, b_m \in \mathcal{R}$ , for all  $n = 1, \dots, N, m = 1, \dots, M$ .  $\diamond$

The following results can be used for the construction of new kernels.

**Proposition 18 (Conformal Transformations).** *If  $f : X \rightarrow \mathcal{R}$  is any function, then  $\kappa_1(\mathbf{x}, \mathbf{y}) = f(\mathbf{x})f(\mathbf{y})$  is a reproducing kernel. Moreover, if  $\kappa$  is any other reproducing kernel then  $\kappa_2(\mathbf{x}, \mathbf{y}) = f(\mathbf{x})\kappa(\mathbf{x}, \mathbf{y})f(\mathbf{y})$  is also a reproducing kernel.*  $\diamond$

**Proof.** The first part is a direct consequence of theorem 12. For the second part, consider  $\mathbf{x}_1, \dots, \mathbf{x}_N \in X$  and  $a_1, \dots, a_N \in \mathcal{R}$ . Then

$$\begin{aligned} \sum_{n,m=1}^N a_n a_m f(\mathbf{x}_n) \kappa(\mathbf{x}_n, \mathbf{x}_m) f(\mathbf{x}_m) &= \sum_{n,m=1}^N a_n a_m f(\mathbf{x}_n) f(\mathbf{x}_m) \langle \Phi(\mathbf{x}_m), \Phi(\mathbf{x}_n) \rangle_{\mathcal{H}} \\ &= \left\langle \sum_m^N a_m f(\mathbf{x}_m) \Phi(\mathbf{x}_m), \sum_n^N a_n f(\mathbf{x}_n) \Phi(\mathbf{x}_n) \right\rangle_{\mathcal{H}} \\ &= \left\| \sum_n^N a_n f(\mathbf{x}_n) \Phi(\mathbf{x}_n) \right\|^2 \geq 0. \end{aligned}$$

Moreover, as

$$\begin{aligned} \cos(\angle(\Phi_2(\mathbf{x}), \Phi_2(\mathbf{y}))) &= \frac{f(\mathbf{x})\kappa(\mathbf{x}, \mathbf{y})f(\mathbf{y})}{\sqrt{f(\mathbf{x})\kappa(\mathbf{x}, \mathbf{x})f(\mathbf{x})}\sqrt{f(\mathbf{y})\kappa(\mathbf{y}, \mathbf{y})f(\mathbf{y})}} \\ &= \frac{\kappa(\mathbf{x}, \mathbf{y})}{\sqrt{\kappa(\mathbf{x}, \mathbf{x})}\sqrt{\kappa(\mathbf{y}, \mathbf{y})}} = \cos(\angle(\Phi(\mathbf{x}), \Phi(\mathbf{y}))), \end{aligned}$$

this transformation of the original kernel, preserves angles in the feature space.  $\square$

**Theorem 19 (Restriction of a kernel).** *Let  $\mathcal{H}$  be a RKHS on  $X$  with respective kernel  $\kappa$ . Then  $\kappa$  restricted to the set  $X_1 \subset X$  is the reproducing kernel of the class  $\mathcal{H}_1$  of all restrictions of functions of  $\mathcal{H}$  to the subset  $X_1$ . The respective norm of any such restricted function  $f_1 \in \mathcal{H}_1$  (originating from  $f \in \mathcal{H}$ ) has norm  $\|f_1\|_{\mathcal{H}_1} = \min\{\|f\|_{\mathcal{H}} : f \in \mathcal{H}, f|_{X_1} = f_1\}$ .*  $\diamond$

**Proposition 20 (Normalization of a kernel).** *Let  $\mathcal{H}$  be a RKHS on  $X$  with respective kernel  $\kappa$ . Then*

$$\hat{\kappa}(\mathbf{x}, \mathbf{y}) = \frac{\kappa(\mathbf{x}, \mathbf{y})}{\sqrt{\kappa(\mathbf{x}, \mathbf{x})\kappa(\mathbf{y}, \mathbf{y})}}, \quad (17.31)$$

*is also a positive definite kernel on  $X$ . Note that  $|\hat{\kappa}(\mathbf{x}, \mathbf{y})| \leq 1$ , for all  $\mathbf{x}, \mathbf{y} \in X$ .*  $\diamond$

**Proof.** Let  $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N \in X$  and  $c_1, \dots, c_N$  be real numbers. Then

$$\begin{aligned} \sum_{n,m=1}^N c_n c_m \hat{\kappa}(\mathbf{x}_n, \mathbf{x}_m) &= \sum_{n,m=1}^N c_n c_m \frac{\kappa(\mathbf{x}_n, \mathbf{x}_m)}{\sqrt{\kappa(\mathbf{x}_n, \mathbf{x}_n)\kappa(\mathbf{x}_m, \mathbf{x}_m)}} \\ &= \sum_{n,m=1}^N \frac{c_n}{\sqrt{\kappa(\mathbf{x}_n, \mathbf{x}_n)}} \frac{c_m}{\sqrt{\kappa(\mathbf{x}_m, \mathbf{x}_m)}} \kappa(\mathbf{x}_n, \mathbf{x}_m) \geq 0, \end{aligned}$$

as  $\kappa$  is a positive definite kernel.  $\square$

**Theorem 21 (Sum of kernels [3]).** Let  $\mathcal{H}_1, \mathcal{H}_2$  be two RKHS's on  $X$  with respective kernels  $\kappa_1, \kappa_2$ . Then  $\kappa = \kappa_1 + \kappa_2$  is also a reproducing kernel. The corresponding RKHS,  $\mathcal{H}$ , contains the functions  $f = f_1 + f_2$ , where  $f_i \in \mathcal{H}_i$ ,  $i = 1, 2$ . The respective norm is defined by

$$\|f\|_{\mathcal{H}} = \min\{\|f_1\| + \|f_2\| : f = f_1 + f_2, f_i \in \mathcal{H}_i, i = 1, 2\}. \quad \diamond$$

**Proof.** It is trivial to show that  $\kappa_1 + \kappa_2$  is a positive definite kernel. The difficult part is to associate this kernel with the specific RKHS  $\mathcal{H}$ . Consider the Hilbert space  $F = \mathcal{H}_1 \times \mathcal{H}_2$ . The respective inner product and the corresponding norm are defined as

$$\begin{aligned} \langle (f_1, f_2), (g_1, g_2) \rangle_F &= \langle f_1, g_1 \rangle_{\mathcal{H}_1} + \langle f_2, g_2 \rangle_{\mathcal{H}_2}, \\ \|(f_1, f_2)\|_F^2 &= \|f_1\|_{\mathcal{H}_1}^2 + \|f_2\|_{\mathcal{H}_2}^2, \end{aligned}$$

for  $f_1, g_1 \in \mathcal{H}_1$  and  $f_2, g_2 \in \mathcal{H}_2$ . If  $\mathcal{H}_1$  and  $\mathcal{H}_2$  have only 0 in common, it is easy to show that there is a one-to-one correspondence between  $F$  and  $\mathcal{H} = \mathcal{H}_1 + \mathcal{H}_2$ , as each  $f \in \mathcal{H}$  can be decomposed into two parts (one belonging to  $\mathcal{H}_1$  and the other in  $\mathcal{H}_2$ ) uniquely. The difficult part is to discover such a relation, if  $\mathcal{H}_0 = \mathcal{H}_1 \cap \mathcal{H}_2$  is larger than  $\{0\}$ . To make this fact clear, consider this simple example: Let  $\mathcal{H}_1$  and  $\mathcal{H}_2$  be the linear classes of polynomials of orders up to 1 and up to 2 respectively. Obviously,  $\mathcal{H} = \mathcal{H}_1 + \mathcal{H}_2 = \mathcal{H}_2$ , as  $\mathcal{H}_1 \subset \mathcal{H}_2$ . Let  $f(x) = x^2 + 5x$ ,  $f \in \mathcal{H}$ . Then  $f$  can be decomposed into two parts (one belonging to  $\mathcal{H}_1$  and the other in  $\mathcal{H}_2$ ) in more than one ways. For example  $f(x) = (x^2) + (5x)$ , or  $f(x) = (x^2 + 4x) + (x)$ , or  $f(x) = (x^2 + 2x) + (3x)$ , e.t.c. Thus, the mapping between  $f = f_1 + f_2 \in \mathcal{H}$  and  $(f_1, f_2) \in F$  is not one-to-one. However, in such cases, we can still find a smaller subspace of  $F$ , which can be identified to  $\mathcal{H}$ .

To this end, define  $F_0 = \{(f, -f) : f \in \mathcal{H}_0\}$ . It is clear that  $F_0$  is a linear subspace of  $F$ . We will show that it is a closed one. Consider the converging sequence in  $F_0$ :  $(f_n, -f_n) \rightarrow (\tilde{f}_1, \tilde{f}_2)$ . Then  $f_n \rightarrow \tilde{f}_1$  and  $-f_n \rightarrow \tilde{f}_2$ . Thus  $\tilde{f}_1 = -\tilde{f}_2$  and  $(\tilde{f}_1, \tilde{f}_2)$  is in  $F_0$ . As  $F_0$  is a closed linear subspace of  $F$ , we may consider its complementary subspace  $F_0^\perp : F = F_0 \oplus F_0^\perp$ .

As a next step, consider the linear transformation  $T : F \rightarrow \mathcal{H} : T(f_1, f_2) = f_1 + f_2$ . The kernel of this transformation is the subspace  $F_0$ . Hence, there is a one-to-one correspondence between  $F_0^\perp$  and  $\mathcal{H}$ . Consider the inverse transformation  $(T|_{F_0^\perp})^{-1}$  and let  $(T|_{F_0^\perp})^{-1}(f) = (f', f'')$ , for  $f \in \mathcal{H}$ , where  $f' \in \mathcal{H}_1$  and  $f'' \in \mathcal{H}_2$ , i.e., through  $(T|_{F_0^\perp})^{-1}$  we decompose  $f$  uniquely into two components, one in  $\mathcal{H}_1$  and the other in  $\mathcal{H}_2$ . This decomposition enables us to define an inner product in  $\mathcal{H}$ , i.e.,

$$\langle f, g \rangle_{\mathcal{H}} = \langle f' + f'', g' + g'' \rangle_{\mathcal{H}} = \langle f', g' \rangle_{\mathcal{H}_1} + \langle f'', g'' \rangle_{\mathcal{H}_2} = \langle (f', f''), (g', g'') \rangle_F,$$

for  $f, g \in \mathcal{H}$ . To prove that to this  $\mathcal{H}$  there corresponds the kernel  $\kappa = \kappa_1 + \kappa_2$ , we make the following remarks:

1. For every  $y \in X$ ,  $\kappa(\cdot, y) = \kappa_1(\cdot, y) + \kappa_2(\cdot, y) \in \mathcal{H}$ .
2. For every  $y \in X$ , let  $T^{-1}(\kappa(\cdot, y)) = (\kappa'(\cdot, y), \kappa''(\cdot, y))$ . Thus

$$\kappa(x, y) = \kappa'(x, y) + \kappa''(x, y) = \kappa_1(x, y) + \kappa_2(x, y),$$

and consequently  $\kappa_1(x, y) - \kappa'(x, y) = -(\kappa_2(x, y) - \kappa''(x, y))$ . This means that  $(\kappa_1(x, y) - \kappa'(x, y), \kappa_2(x, y) - \kappa''(x, y)) \in F_0$ . Hence, for every  $y \in X$  we have

$$\begin{aligned} f(y) &= f'(y) + f''(y) = \langle f', \kappa_1(\cdot, y) \rangle_{\mathcal{H}_1} + \langle f'', \kappa_2(\cdot, y) \rangle_{\mathcal{H}_2} \\ &= \langle (f', f''), (\kappa_1(\cdot, y), \kappa_2(\cdot, y)) \rangle_F \\ &= \langle (f', f''), (\kappa'(\cdot, y), \kappa''(\cdot, y)) \rangle_F + \langle (f', f''), (\kappa_1(\cdot, y) - \kappa'(\cdot, y), \kappa_2(\cdot, y) - \kappa''(\cdot, y)) \rangle_F. \end{aligned}$$

As  $(\kappa_1(x, y) - \kappa'(x, y), \kappa_2(x, y) - \kappa''(x, y)) \in F_0$  and  $(f', f'') \in F_0^\perp$ , we conclude that

$$f(y) = \langle (f', f''), (\kappa'(\cdot, y), \kappa''(\cdot, y)) \rangle_F = \langle f' + f'', \kappa'(\cdot, y) + \kappa''(\cdot, y) \rangle_{\mathcal{H}} = \langle f, \kappa(\cdot, y) \rangle_{\mathcal{H}}.$$

This is the reproducing property.

Finally, to prove the last part of the theorem, consider again  $f \in \mathcal{H}$  and let  $f_i \in \mathcal{H}_i$ ,  $i = 1, 2$ , such that  $f = f_1 + f_2$  and let  $f' \in \mathcal{H}_1$  and  $f'' \in \mathcal{H}_2$  be the unique decomposition of  $f$  through  $T^{-1}$ . As  $f_1 + f_2 = f' + f''$  we obtain that  $f' - f_1 = -(f'' - f_2)$ , which implies that  $(f' - f_1, f'' - f_2) \in F_0$ . Thus, we take:

$$\begin{aligned} \|f_1\|_{\mathcal{H}_1}^2 + \|f_2\|_{\mathcal{H}_2}^2 &= \|(f_1, f_2)\|_F^2 = \|(f', f'')\|_F^2 + \|(f_1 - f', f_2 - f'')\|_F^2 \\ &= \|f'\|_{\mathcal{H}_1}^2 + \|f''\|_{\mathcal{H}_2}^2 + \|(f_1 - f', f_2 - f'')\|_F^2 \\ &= \|f\|_{\mathcal{H}}^2 + \|(f_1 - f', f_2 - f'')\|_F^2. \end{aligned}$$

From the last relation we conclude that  $\|f\|_{\mathcal{H}}^2 = \|f_1\|_{\mathcal{H}_1}^2 + \|f_2\|_{\mathcal{H}_2}^2$ , if and only if  $f_1 = f'$  and  $f_2 = f''$ . In this case we take the minimum value of  $\|f_1\|_{\mathcal{H}_1}^2 + \|f_2\|_{\mathcal{H}_2}^2$ , for all possible decompositions  $f = f_1 + f_2$ . This completes the proof.  $\square$

Despite the sum of kernels, other operations preserve reproducing kernels as well. Below, we give an extensive list of such operations. For a description of the induced RKHS and a formal proof (in the cases that are not considered here) the interested reader may refer to [3, 13].

1. If  $\kappa(x, y)$  is a positive definite kernel on  $X$ , then  $\lambda\kappa(x, y)$  is also a positive definite kernel for any  $\lambda \geq 0$ . It is obvious that in this case  $\mathcal{H}(\lambda\kappa) = \mathcal{H}(\kappa)$ , if  $\lambda > 0$ . If  $\lambda = 0$ , then  $\mathcal{H}(0) = \{0\}$ .
2. If  $\kappa_1(x, y)$  and  $\kappa_2(x, y)$  are positive definite kernels on  $X$ , then  $\kappa_1(x, y) + \kappa_2(x, y)$  is also a positive definite kernel, as Theorem 21 established.
3. If  $\kappa_1(x, y)$  and  $\kappa_2(x, y)$  are positive definite kernels on  $X$ , then  $\kappa_1(x, y) \cdot \kappa_2(x, y)$  is also a positive definite kernel.

4. If  $\kappa_n(\mathbf{x}, \mathbf{y})$  are positive definite kernels on  $X$ , such that  $\lim_n \kappa_n(\mathbf{x}, \mathbf{y}) = \kappa(\mathbf{x}, \mathbf{y})$ , for all  $\mathbf{x}, \mathbf{y} \in X$ , then  $\kappa(\mathbf{x}, \mathbf{y})$  is also a positive definite kernel.
5. If  $\kappa(\mathbf{x}, \mathbf{y})$  is a positive definite kernel on  $X$  and  $p(z)$  is a polynomial with non-negative coefficients, then  $p(\kappa(\mathbf{x}, \mathbf{y}))$  is also a positive definite kernel.
6. If  $\kappa(\mathbf{x}, \mathbf{y})$  is a positive definite kernel on  $X$ , then  $e^{\kappa(\mathbf{x}, \mathbf{y})}$  is also a positive definite kernel. To prove this, consider the Taylor expansion formula of  $e^z$ , which may be considered as a limit of polynomials with non-negative coefficients.
7. If  $\kappa(\mathbf{x}, \mathbf{y})$  is a positive definite kernel on  $X$  and  $\Psi : X' \rightarrow X$  is a function, then  $\kappa(\Psi(\mathbf{x}), \Psi(\mathbf{y}))$  is a positive definite kernel on  $X'$ .
8. If  $\kappa_1(\mathbf{x}, \mathbf{y})$  and  $\kappa_2(\mathbf{x}', \mathbf{y}')$  are positive definite kernels on  $X$  and  $X'$  respectively, then their tensor product  $(\kappa_1 \otimes \kappa_2)(\mathbf{x}, \mathbf{y}, \mathbf{x}', \mathbf{y}') = \kappa_1(\mathbf{x}, \mathbf{y})\kappa_2(\mathbf{x}', \mathbf{y}')$ , is a kernel on  $X \times X'$ .
9. If  $\kappa_1(\mathbf{x}, \mathbf{y})$  and  $\kappa_2(\mathbf{x}', \mathbf{y}')$  are positive definite kernels on  $X$  and  $X'$  respectively, then their direct sum  $(\kappa_1 \oplus \kappa_2)(\mathbf{x}, \mathbf{y}, \mathbf{x}', \mathbf{y}') = \kappa_1(\mathbf{x}, \mathbf{y}) + \kappa_2(\mathbf{x}', \mathbf{y}')$ , is a kernel on  $X \times X'$ .

### 1.17.5.6 Dot product and translation invariant kernels

There are two important classes of kernels that follow certain rules and are widely used in practice. The first one includes the *dot product kernels*, which are functions defined as  $\kappa(\mathbf{x}, \mathbf{y}) = f(\langle \mathbf{x}, \mathbf{y} \rangle)$ , for some real function  $f$ . The second class are the *translation invariant kernels*, which are defined as  $\kappa(\mathbf{x}, \mathbf{y}) = f(\mathbf{x} - \mathbf{y})$ , for some real function  $f$  defined on  $X$ . The following theorems establish necessary and sufficient conditions for such functions to be reproducing kernels.

**Theorem 22 (Power Series of dot product kernels [29]).** *Let  $f : \mathcal{R} \rightarrow \mathcal{R}$ . A function  $\kappa(\mathbf{x}, \mathbf{y}) = f(\langle \mathbf{x}, \mathbf{y} \rangle)$  defined on  $X$ , such that  $f$  has the power series expansion  $f(t) = \sum_n a_n t^n$ , is a positive definite kernel, if and only if we have  $a_n \geq 0$  for all  $n$ .* ◇

**Theorem 23 (Bochner's-Fourier Criterion for translation invariant kernels [20]).** *Let  $f : X \rightarrow \mathcal{R}$ . A function  $\kappa(\mathbf{x}, \mathbf{y}) = f(\mathbf{x} - \mathbf{y})$  defined on  $X \subseteq \mathcal{R}^l$ , is a positive definite kernel, if the Fourier transform*

$$F[\kappa](\omega) = (2\pi)^{-\frac{N}{2}} \int_X e^{-i\langle \omega, \mathbf{x} \rangle} f(\mathbf{x}) d\mathbf{x},$$

*is non-negative.* ◇

**Remark 24.** Bochner's theorem is more general, involving Borel measures and topological spaces. For the sake of simplicity we give only this simple form.

Employing the tools provided in this section, one can readily prove the positivity of some of the kernels given in Section 1.17.5.4. For example:

- *Homogeneous polynomial kernel:* As  $\langle \mathbf{x}, \mathbf{y} \rangle$  is a positive definite kernel and  $p(z) = z^d$  is a polynomial with non-negative coefficients,  $p(\langle \mathbf{x}, \mathbf{y} \rangle) = (\langle \mathbf{x}, \mathbf{y} \rangle)^d$  is a positive definite kernel.
- *Inhomogeneous polynomial kernel:* As  $\langle \mathbf{x}, \mathbf{y} \rangle$  is a positive definite kernel, and  $p(z) = (z + c)^d$  is a polynomial with non-negative coefficients (for positive  $c$ ),  $p(\langle \mathbf{x}, \mathbf{y} \rangle) = (c + \langle \mathbf{x}, \mathbf{y} \rangle)^d$  is a positive definite kernel.
- *The cosine kernel:* Note that  $\cos(\angle(\mathbf{x}, \mathbf{y})) = \frac{\langle \mathbf{x}, \mathbf{y} \rangle}{\|\mathbf{x}\| \|\mathbf{y}\|}$ . Thus the cosine kernel is the normalization of the simple kernel  $\langle \mathbf{x}, \mathbf{y} \rangle$ .

To prove that the Gaussian and the Laplacian are positive kernels we need another set of tools. This is the topic of Appendix A.

### 1.17.5.7 Differentiation in Hilbert spaces

#### 1.17.5.7.1 Fréchet's differentiation

In the following sections, we will develop cost functions defined on RKHS, that are suitable for minimization tasks related with adaptive filtering problems. As most minimization procedures involve computation of gradients or subgradients, we devote this section to study differentiation on Hilbert spaces. The notion of Fréchet's Differentiability, which generalizes differentiability to general Hilbert spaces, lies at the core of this analysis.

**Definition 25 (Fréchet's Differential).** Let  $\mathcal{H}$  be a real Hilbert space,  $\mathcal{L} : \mathcal{H} \rightarrow \mathcal{R}$  a function, and  $f \in \mathcal{H}$ . The function  $\mathcal{L}$  is said to be Fréchet differentiable at  $f$ , if there exists a  $g \in \mathcal{H}$  such that

$$\lim_{\|h\|_{\mathcal{H}} \rightarrow 0} \frac{\mathcal{L}(f + h) - \mathcal{L}(f) - \langle h, g \rangle_{\mathcal{H}}}{\|h\|_{\mathcal{H}}} = 0, \quad (17.32)$$

where  $\langle \cdot, \cdot \rangle_{\mathcal{H}}$  is the inner product of the Hilbert space  $\mathcal{H}$  and  $\|\cdot\|_{\mathcal{H}} = \sqrt{\langle \cdot, \cdot \rangle_{\mathcal{H}}}$  is the induced norm.  $\diamond$

The element  $g \in \mathcal{H}$  is called the gradient of the operator at  $f$ , and is usually denoted as  $\nabla \mathcal{L}(f)$ . This relates to the standard gradient operator known by Calculus in Euclidean spaces. The Fréchet's Differential is also known as Strong Differential. There is also a weaker definition of Differentiability, named Gâteaux's Differential (or Weak Differential), which is a generalization of the directional derivative. The Gâteaux differential  $d\mathcal{L}(f, h)$  of  $\mathcal{L}$  at  $f \in \mathcal{H}$  in the direction  $h \in \mathcal{H}$  is defined as

$$d\mathcal{L}(f, h) = \lim_{\epsilon \rightarrow 0} \frac{\mathcal{L}(f + \epsilon h) - \mathcal{L}(f)}{\epsilon}. \quad (17.33)$$

In the following, whenever we are referring to a derivative or a gradient we will mean the one produced by Fréchet's notion of differentiability. The interested reader is addressed to [30–35], (amongst others) for a more detailed discussion on the subject. The well known properties of the derivative of a real valued function of one variable, which are known from elementary Calculus, like the product and chain rules, apply to the Fréchet's derivatives as well.

The following simple examples demonstrate the differentiation procedure in arbitrary spaces.

**Example 26.** Consider the real Hilbert space  $\mathcal{H}$ , with inner product  $\langle \cdot, \cdot \rangle_{\mathcal{H}}$ , and  $\mathcal{L} : \mathcal{H} \rightarrow \mathcal{R} : \mathcal{L}(f) = \langle f, g \rangle_{\mathcal{H}}$ , where  $g \in \mathcal{H}$  fixed. We can easily show (using Fréchet's definition) that  $\mathcal{L}$  is differentiable at any  $f \in \mathcal{H}$  and that  $\nabla \mathcal{L}(f) = g$ . In the case where  $\mathcal{L} : \mathcal{H} \rightarrow \mathcal{R} : \mathcal{L}(f) = \|f\|_{\mathcal{H}}^2$ , we can easily show (using Fréchet's definition) that  $\mathcal{L}$  is differentiable at any  $f \in \mathcal{H}$  and that  $\nabla \mathcal{L}(f) = 2f$ .

---

## 1.17.6 Least squares learning algorithms

Having discussed the basic definitions and properties of RKHS we now turn to our main focus of the paper to discuss online learning schemes, which can operate in such spaces. We will start with two celebrated schemes, which are built around the Least Squares criterion, namely the LMS and the RLS.

Although we can look at these algorithms as special cases of the schemes to be considered later on, in the more general setting of convex analytic tools, we chose to treat them separately. The reason is that the LMS and RLS are widely known, and the less familiar reader could follow their extension to RKHSs easier.

### 1.17.6.1 Least mean square (LMS)

Consider the sequence of examples  $\{(\mathbf{x}_n, y_n)\}_{n=1,2,\dots}$ , where  $\mathbf{x}_n \in X \subset \mathcal{R}^l$ , and  $y_n \in \mathcal{R}$  for  $n = 1, \dots, N$ , and a parametric class of functions  $\mathcal{F} = \{f_\theta(\cdot) : \theta \in \mathcal{A} \subseteq \mathcal{R}^K\}$ . The goal of a typical online/adaptive learning task is to infer an input-output relationship  $f_\theta$  from the parametric class of functions  $\mathcal{F}$ , based on the given data, so that to minimize a certain loss function,  $\mathcal{L}(\theta)$ , that measures the error between the actual output,  $y_n$ , and the estimated output,  $\hat{y}_n = f_\theta(\mathbf{x}_n)$ , at iteration  $n$ .

Least mean squares (LMS) algorithms are a popular class of adaptive learning systems that adopt the least mean squares error (i.e., the mean squared difference between the desired and the actual signal) to estimate the unknown coefficients  $\theta$ . Its most typical form was invented in the 1960s by Bernard Widrow and his Ph.D. student Ted Hoff [36]. In the standard *least mean square* (LMS) setting, one adopts the class of linear functions, i.e.,  $\mathcal{F} = \{f_\theta(\mathbf{x}) = \theta^T \mathbf{x} : \theta \in \mathcal{R}^l\}$  and employs the mean square error,  $\mathcal{L}(\theta) = E[|y_n - \theta^T \mathbf{x}_n|^2]$ , as the loss function. To this end, the gradient descent rationale, e.g., [4–6], is employed and at each time instant,  $n = 1, 2, \dots, N$ , the gradient of the mean square error, i.e.,  $\nabla \mathcal{L}(\theta) = -2E[(y_n - \theta^T \mathbf{x}_n)\mathbf{x}_n]$ , is approximated via its current measurement, i.e.,  $\nabla \mathcal{L}(\theta) = -2E[(y_n - \theta^T \mathbf{x}_n)\mathbf{x}_n] \approx -2(y_n - \theta^T \mathbf{x}_n)\mathbf{x}_n = \nabla \mathcal{L}_n(\theta)$ , where

$$\mathcal{L}_n(\theta) := (y_n - \theta^T \mathbf{x}_n)^2, \quad n = 1, 2, \dots$$

If we define  $e_n := y_n - \theta_{n-1}^T \mathbf{x}_n$  as the a-priori error, where  $\theta_{n-1}$  is the current estimate, then the previous discussion leads naturally to the step update equation

$$\begin{aligned} \theta_n &= \theta_{n-1} - \mu \nabla \mathcal{L}_n(\theta_{n-1}) \\ &= \theta_{n-1} + \mu e_n \mathbf{x}_n, \quad n = 1, 2, \dots \end{aligned} \tag{17.34}$$

Another derivation of this classical recursion, through a convex analytic path, will be given in Section 1.17.7. Such a viewpoint will set the LMS as an instant of a larger family of algorithms.

Assuming that the initial  $\theta_0 = \mathbf{0}$ , a repeated application of (17.34) gives

$$\theta_n = \mu \sum_{i=1}^n e_i \mathbf{x}_i, \quad n = 1, 2, \dots, \tag{17.35}$$

while the predicted output of the learning system at iteration  $n$  becomes

$$\hat{y}_n = f_{\theta_{n-1}}(\mathbf{x}_n) = \mu \sum_{i=1}^{n-1} e_i \mathbf{x}_i^T \mathbf{x}_n, \quad n = 1, 2, \dots \tag{17.36}$$

There are a number of convergence criteria for the LMS algorithm [5]. Among the most popular ones are:

- The *convergence of the mean* property, i.e.,  $E[\epsilon_n] \rightarrow 0$ , as  $n \rightarrow \infty$ , where  $\epsilon_n = \theta_n - \theta_*$  and  $\theta_*$  is the Wiener solution. Unfortunately, this is of little practical use, as any sequence of zero mean arbitrary random numbers converges in this sense.
- The *convergence in the mean square* property: If the true input-output relation is given by  $y_n = \theta_*^T \mathbf{x}_n + \eta_n$ , and  $\mathbf{x}_n$  is a weakly stationary process, then  $\mathcal{L}(\theta_{n-1}) = E[|e_n|^2] \rightarrow \text{constant}$ , as  $n \rightarrow \infty$ , provided that  $\mu$  satisfies the condition  $0 < \mu < \frac{2}{\sigma_{\max}}$ , where  $\sigma_{\max}$  is the largest eigenvalue of the correlation matrix  $\mathbf{R} = E[\mathbf{x}_n \mathbf{x}_n^T]$ . We will see in Example 56 that the quantity  $\frac{2}{\sigma_{\max}}$  stems also from a convex analytic point of view of the LMS-related estimation task. In practice, one usually uses  $0 < \mu < \frac{2}{\text{tr}(\mathbf{R})}$ , where  $\text{tr}(\cdot)$  denotes the trace of a matrix.
- The *Misadjustment* property: The Misadjustment ratio, i.e.,  $\rho := \frac{\mathcal{L}(\infty) - \mathcal{L}_{\min}}{\mathcal{L}_{\min}}$ , where

$$\mathcal{L}(\infty) := \lim_{n \rightarrow \infty} \mathcal{L}(\theta_{n-1}) = \lim_{n \rightarrow \infty} E[|e_n|^2],$$

and  $\mathcal{L}_{\min}$  is the minimum mean squared error associated with the optimum Wiener filter, is equal to

$$\rho = \sum_{i=1}^l \frac{\mu \sigma_i}{2 - \mu \sigma_i},$$

provided that the step update parameter  $\mu$  satisfies  $\sum_{i=1}^l \frac{2\sigma_i}{2 - \mu \sigma_i} < 1$ , where  $\sigma_1, \dots, \sigma_l$  are the eigenvalues of the correlation matrix  $\mathbf{R}$ . This is a dimensionless quantity, providing a measure of closeness of the LMS algorithm from optimality in the mean square sense. The smallest  $\rho$  is (compared to 1), the more accurate the learning system is. Usually  $\rho$  is expressed as a percentage. A misadjustment of 10% is, ordinarily, considered to be satisfactory in practice [5].

LMS is sensitive to the scaling of the inputs  $\mathbf{x}_n$ . This makes it hard to choose a learning rate  $\mu$  that guarantees the stability of the algorithm for various inputs. The Normalized LMS (NLMS) is a variant of the LMS designed to cope with this problem. It solves the problem by normalizing with the power of the input. Hence, the step update equation becomes

$$\theta_n = \theta_{n-1} + \frac{\mu e_n}{\|\mathbf{x}_n\|^2} \mathbf{x}_n, \quad n = 1, 2, \dots, \quad (17.37)$$

where  $\mu \in (0, 2)$ . It has been proved that the optimal learning rate of the NLMS is  $\mu = 1$  [5, 6]. We will also see in Section 1.17.7 that the NLMS has a clear geometrical interpretation; it is the repetition of a relaxed (metric) projection mapping onto a series of hyperplanes in the Euclidean space  $\mathcal{R}^l$ . More on the LMS family of algorithms, and more specifically, on its impact in modern signal processing, can be found in [4–6].

### 1.17.6.2 The Kernel LMS

In kernel-based algorithms, we estimate the output of the learning system by a nonlinear function  $f$  in a specific RKHS,  $\mathcal{H}$ , which is associated to a positive definite kernel  $\kappa$ . The sequence of examples are transformed via the feature map  $\Phi : X \rightarrow \mathcal{H}$ ,  $\Phi(\mathbf{x}) = \kappa(\cdot, \mathbf{x})$  and the LMS rationale is employed on

the transformed data

$$\{(\Phi(\mathbf{x}_1), y_1), (\Phi(\mathbf{x}_2), y_2), \dots, (\Phi(\mathbf{x}_n), y_n), \dots\},$$

while the estimated output at iteration  $n$  takes the form  $\hat{y}_n = \langle \Phi(\mathbf{x}_n), f \rangle_{\mathcal{H}}$ , for some  $f \in \mathcal{H}$ . Although this is a linear algorithm in the RKHS  $\mathcal{H}$ , it corresponds to a nonlinear processing in  $X$ . To calculate the gradient of the respective loss function,  $\mathcal{L}(f) = E[|y_n - \langle \Phi(\mathbf{x}_n), f \rangle_{\mathcal{H}}|^2]$ , the Fréchet's notion of differentiability is adopted, leading to:  $\nabla \mathcal{L}(f) = -2E[e_n \Phi(\mathbf{x}_n)]$ ; this, according to the LMS rationale, is approximated at each time instant by its current measurement, i.e.,  $-2e_n \Phi(\mathbf{x}_n)$ . Consequently, following a gradient descent rationale, the step update equation of the KLMS is given by

$$\begin{aligned} f_n &= f_{n-1} + \mu e_n \Phi(\mathbf{x}_n), \\ &= f_{n-1} + \mu e_n \kappa(\cdot, \mathbf{x}_n), \quad n = 1, 2, \dots \end{aligned} \quad (17.38)$$

As it was stated for (17.34), the recursion (17.38) will be re-derived through convex analytic arguments in Section 1.17.7.

Assuming that  $f_0 = 0$ , i.e., the zero function, a repeated application of (17.38) gives

$$f_n = \mu \sum_{i=1}^n e_i \Phi(\mathbf{x}_i), \quad n = 1, 2, \dots, \quad (17.39)$$

and the output of the filter at iteration  $n$  becomes

$$\hat{y}_n = \langle \Phi(\mathbf{x}_n), f_{n-1} \rangle_{\mathcal{H}} = \mu \sum_{i=1}^{n-1} e_i \langle \Phi(\mathbf{x}_n), \Phi(\mathbf{x}_i) \rangle_{\mathcal{H}} = \mu \sum_{i=1}^{n-1} e_i \kappa(\mathbf{x}_i, \mathbf{x}_n). \quad (17.40)$$

Equation (17.39) provides the KLMS estimate at time  $n$ . This is an expansion (in the RKHS  $\mathcal{H}$ ) in terms of the feature map function computed at each training point up to time  $n$ . Observe that, alternatively, one could derive Eq. (17.40), simply by applying the kernel trick to (17.36). It is important to emphasize that, in contrast to the standard LMS, where the solution is a vector of fixed dimension, which is updated at each time instant, in KLMS the solution is a function of  $\mathcal{H}$  and thus it cannot be represented by a machine. Nevertheless, as it is common in kernel-based methods, one needs not to compute the actual solution (17.39), but only the estimated output of the learning system,  $\hat{y}_n$ , which is given in terms of the kernel function centered at the points,  $\mathbf{x}_i$ ,  $i = 1, \dots, n-1$ , of the given sequence (Eq. (17.40)). Under this setting, the algorithm needs to store into memory two pieces of information: a) the centers (training input points),  $\mathbf{x}_i$ , of the expansion (17.39), which are stored into a dictionary  $\mathcal{D}$  and b) the coefficients of (17.39), i.e.,  $\mu e_i$ , which are represented by a growing vector  $\theta$ . Observe that (17.39) is inline with what we know by the Representer theorem given in Section 1.17.5 (Theorem 16). Algorithm 27 summarizes this procedure.

If in place of (17.38), we use its normalized version, i.e.,

$$\begin{aligned} f_n &= f_{n-1} + \frac{\mu}{\kappa(\mathbf{x}_n, \mathbf{x}_n)} e_n \Phi(\mathbf{x}_n) \\ &= f_{n-1} + \frac{\mu}{\kappa(\mathbf{x}_n, \mathbf{x}_n)} e_n \kappa(\cdot, \mathbf{x}_n), \end{aligned} \quad (17.41)$$

**Algorithm 27.** Kernel LMS (KLMS)

---

**Require:**  $(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n), \dots$

- 1: Set  $\boldsymbol{\theta} = 0$ ,  $\mathcal{D} = \emptyset$ . Select the step parameter  $\mu$  and the parameters of the kernel.
- 2: **for**  $n = 1, 2, \dots$ , **do**
- 3:   **if**  $n = 1$  **then**
- 4:      $\hat{y}_n = 0$ .
- 5:   **else**
- 6:     Compute the learning system's output:  $\hat{y}_n = \sum_{i=1}^{n-1} \theta_i \kappa(\mathbf{u}_i, \mathbf{x}_n)$ .
- 7:   **end if**
- 8:     Compute the error:  $e_n = y_n - \hat{y}_n$ .
- 9:      $\theta_n = \mu e_n$ .
- 10:   Add the new center  $\mathbf{u}_n = \mathbf{x}_n$  to the list of centers, i.e.,  $\mathcal{D} = \mathcal{D} \cup \{\mathbf{x}_n\}$ ,  $\boldsymbol{\theta} = (\boldsymbol{\theta}^T, \theta_n)^T$ .
- 11: **end for**

---

where  $\mu \in (0, 2)$ , the normalized KLMS counterpart (KNLMS) results. This comprises replacing in Algorithm 27 the step  $\theta_n = \mu e_n$  by  $\theta_n = \mu e_n / \gamma$ , where  $\gamma = \kappa(\mathbf{x}_n, \mathbf{x}_n)$ . The convergence and stability properties of KLMS is, still, a hot topic for research. One may consider that, as the KLMS is the LMS in a RKHS  $\mathcal{H}$ , the properties of the LMS are directly transferred to the KLMS [37]. However, we should note that the properties of the LMS have been proved for Euclidean spaces, while very often the RKHS used in practice are of infinite dimension.

### 1.17.6.2.1 Sparsifying the solution

The main drawback of the KLMS algorithm is that a growing number of training points,  $\mathbf{x}_n$ , is involved in the estimation of the learning system's output (17.40). The set of these points can be thought of as a “dictionary,”  $\mathcal{D}$ , which is stored into the memory, as in Algorithm 27. This is a typical situation that arises in any kernel-based online learning scheme. As a consequence, increasing memory and computational resources are needed, as time evolves (the complexity of KLMS, as presented in Section 1.17.6.2 is  $O(n)$  at each iteration). Furthermore, it is impossible to use the KLMS in real world's applications, since the dictionary grows unbounded. In such a case, after a significant amount of iterations the expansion (17.40) will become so large that it will fill up the memory of the machine. In addition, it will require a huge amount of time to be computed, rendering the application useless. Hence, it is important to find a way to limit the size of this expansion. Several strategies have been proposed to cope with this problem. According to these strategies, the dictionary of points is created at the beginning of the algorithm and new points are inserted into it, only if they satisfy a specific rule, as in Algorithm 28. Adopting such a strategy, the complexity of KLMS is reduced to  $O(M_n)$ , where  $M_n$  is the size of the dictionary at time instant  $n$ .

For example, in the popular Plat's *novelty criterion* sparsification scheme [38], whenever a new data pair  $(\mathbf{x}_n, y_n)$  is considered, a decision is immediately made of whether to add the new point,  $\mathbf{x}_n$ , to  $\mathcal{D}$ . The decision is reached following two simple rules:

**Algorithm 28.** Kernel LMS (KLMS) with sparsification

---

**Require:**  $(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n), \dots$

- 1: Set  $\boldsymbol{\theta} = 0$ ,  $\mathcal{D} = \emptyset$ ,  $M = 0$ . Select the step parameter  $\mu$  and the parameters of the kernel.
- 2: **for**  $n = 1, 2, \dots$ , **do**
- 3:   **if**  $n = 1$  **then**
- 4:      $\hat{y}_n = 0$ .
- 5:   **else**
- 6:     Compute the learning system's output:  $\hat{y}_n = \sum_{i=1}^M \theta_i \kappa(\mathbf{u}_i, \mathbf{x}_n)$ .
- 7:   **end if**
- 8:     Compute the error:  $e_n = y_n - \hat{y}_n$ .
- 9:      $\theta_n = \mu e_n$ .
- 10:   Check the Sparsification Rules.
- 11:   **if** Sparsification Rules are not satisfied, **then**
- 12:      $M = M + 1$ .
- 13:     Add the new center  $\mathbf{u}_M = \mathbf{x}_n$  to the list of centers, i.e.,  $\mathcal{D} = \mathcal{D} \cup \{\mathbf{x}_n\}$ ,  $\boldsymbol{\theta} = (\boldsymbol{\theta}^T, \theta_n)^T$ .
- 14:   **end if**
- 15: **end for**

**Output:** The  $M$ -dimensional vector  $\boldsymbol{\theta}$  and the dictionary  $\mathcal{D} = \{\mathbf{u}_1, \dots, \mathbf{u}_M\}$ .  
The solution is then given as  $f_n = \sum_{i=1}^M \theta_i \kappa(\mathbf{u}_i, \cdot)$ .

---

- First, the distance of the new point,  $\mathbf{x}_n$ , from the current dictionary,  $\mathcal{D}_{n-1}$ , is evaluated:

$$d(\mathbf{x}_n, \mathcal{D}_{n-1}) = \inf_{\mathbf{u}_k \in \mathcal{D}_{n-1}} \{\|\mathbf{x}_n - \mathbf{u}_k\|\}.$$

If this distance is smaller than a given threshold  $\delta_1$  (i.e., the new input vector is close to a point, which is already in the existing dictionary), then the newly arrived point is not added to  $\mathcal{D}_{n-1}$ . Thus  $\mathcal{D}_n = \mathcal{D}_{n-1}$ .

- Otherwise, we compute the prediction error  $e_n = y_n - \hat{d}_n$ . If  $|e_n|$  is smaller than a predefined threshold,  $\delta_2$ , then the new point is discarded and we set  $\mathcal{D}_n = \mathcal{D}_{n-1}$ . Only if  $|e_n| \geq \delta_2$ , then  $\mathbf{x}_n$  is inserted into  $\mathcal{D}_{n-1}$ , forming the new dictionary  $\mathcal{D}_n = \mathcal{D}_{n-1} \cup \{\mathbf{x}_n\}$ .

Note that whenever we insert a new point into  $\mathcal{D}$ , we must also insert the respective coefficient,  $\theta_n = \mu e_n$ , to the growing vector  $\boldsymbol{\theta}$ .

Another popular scheme is the so called *coherence-based* sparsification strategy [39], where the point  $\mathbf{x}_n$  is inserted into the dictionary, if its coherence is above a given threshold  $\epsilon_0$ , i.e.

$$\max_{\mathbf{u}_i \in \mathcal{D}_n} \{|\kappa(\mathbf{x}_n, \mathbf{u}_i)|\} \leq \epsilon_0. \quad (17.42)$$

It has been proved that the dimension of the dictionary determined under rule (17.42) remains finite, as  $n$  goes to infinity [39].

A more sophisticated strategy is the so called *surprise criterion* [37], which employs ideas from information theoretic learning. The *surprise* of a new data pair  $(\mathbf{x}_n, y_n)$  with respect to a learning

system  $\mathcal{T}$  is defined as the negative log likelihood of  $(\mathbf{x}_n, y_n)$ , given the learning system's hypothesis on the data distribution, i.e.,

$$S_{\mathcal{T}}(\mathbf{x}_n, y_n) = -\ln p((\mathbf{x}_n, y_n)|\mathcal{T}).$$

According to this measure, one may classify the new data pair into the following three categories:

- *Abnormal*:  $S_{\mathcal{T}}(\mathbf{x}_n, y_n) > \delta_1$ ,
- *Learnable*:  $\delta_1 \geq S_{\mathcal{T}}(\mathbf{x}_n, y_n) \geq \delta_2$ ,
- *Redundant*:  $S_{\mathcal{T}}(\mathbf{x}_n, y_n) < \delta_2$ ,

where  $\delta_1, \delta_2$  are problem related parameters. In surprise-based sparsification, if the new data pair is classified as learnable, it is inserted into the dictionary. For the case of the KLMS with Gaussian inputs, the surprise measure is

$$S_n = \frac{1}{2} \ln(r_n) + \frac{e_n^2}{2r_n}, \quad (17.43)$$

where

$$r_n = \lambda + \kappa(\mathbf{x}_n, \mathbf{x}_n) - \max_{\mathbf{u}_i \in \mathcal{D}_n} \left\{ \frac{\kappa^2(\mathbf{x}_n, \mathbf{u}_i)}{\kappa(\mathbf{u}_i, \mathbf{u}_i)} \right\}$$

and  $\lambda$  is a user-defined regularization parameter.

A main drawback of the aforementioned sparsification techniques is that if one data point is inserted in the dictionary, it remains in it indefinitely. This may effect the tracking performance of the algorithm in time varying environments. Another technique, that one can adopt to impose sparsity on the solution of the KLMS, that, in addition, changes the coefficients of the solution's expansion, is the *quantization* of the training data in the input space, as in the Quantized KLMS [40]. While each data point  $\mathbf{x}_n$  arrives sequentially, the algorithm checks if it is a new point or a redundant point. If its distance from the current dictionary  $\mathcal{D}_n$  is greater than or equal to the quantization size  $\delta$  (i.e.,  $\mathbf{x}_n$  cannot be quantized to a point already contained in  $\mathcal{D}_n$ ) then  $\mathbf{x}_n$  is classified as a new point and it is inserted into the dictionary  $\mathcal{D}_n = \mathcal{D}_{n-1} \cup \{\mathbf{u}_n\}$ . Otherwise,  $\mathbf{x}_n$  is classified as a “redundant” point and the algorithm uses this information to update the coefficient of the closest center, say  $\mathbf{u}_{l_0} \in \mathcal{D}_n$ . Algorithm 29 summarizes this procedure.

An alternative method to impose sparsity in an adaptive setting has been considered in [41–43]. This is based on regularization and it has the additional benefit of introducing an exponential forgetting mechanism of past data. This mechanism is very natural to the projection-based philosophy of these algorithms, and sparsification only requires an extra projection onto a convex ball.

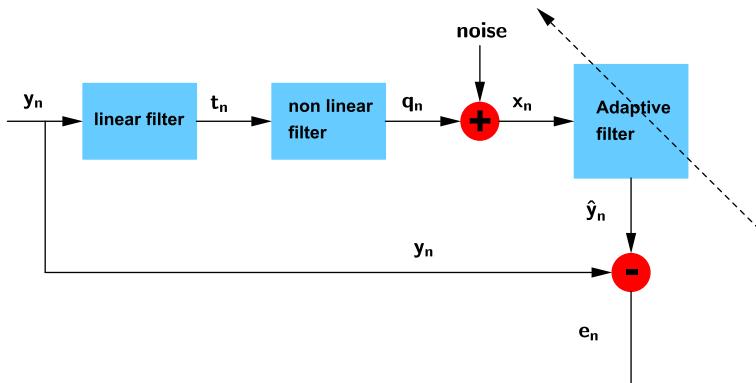

### 1.17.6.2.2 Simulation results

To demonstrate the performance of the KLMS, we consider a typical nonlinear channel equalization task (see Figure 17.15) similar to the one presented in [44,45]. The nonlinear channel consists of a linear filter:

$$t_n = -0.8 \cdot y_n + 0.7 \cdot y_{n-1},$$

and a memoryless nonlinearity

$$q_n = t_n + 0.25 \cdot t_n^2 + 0.11 \cdot t_n^3. \quad (17.44)$$

**FIGURE 17.15**

The equalization task.

**Algorithm 29.** Quantized Kernel LMS (QKLMS)

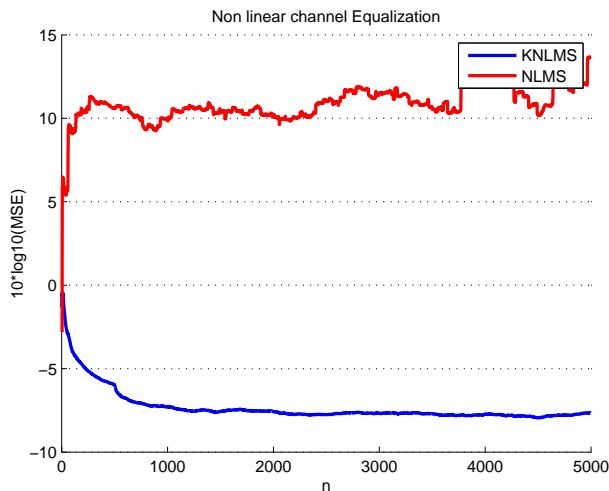

---

**Require:**  $(x_1, y_1), \dots, (x_n, y_n), \dots$

- 1: Set  $\theta = 0, \mathcal{D} = \emptyset, M = 0$ . Select the step parameter  $\mu$ , the parameters of the kernel and the quantization size  $\delta$ .
- 2: **for**  $n = 1, 2, \dots$ , **do**
- 3:   **if**  $n = 1$  **then**
- 4:      $\hat{y}_n = 0$ .
- 5:   **else**
- 6:     Compute the learning system's output:  $\hat{y}_n = \sum_{i=1}^M \theta_i \cdot \kappa(u_i, x_n)$ .
- 7:   **end if**
- 8:     Compute the error:  $e_n = y_n - \hat{y}_n$ .
- 9:      $\theta_n = \mu e_n$ .
- 10:   Compute the distance of  $x_n$  from  $\mathcal{D}$ :  $d(x_n, \mathcal{D}) = \inf_{u_i \in \mathcal{D}} \|x_n - u_i\| = \|x_n - u_{l_0}\|$ , for an  $l_0 \in \{1, \dots, M\}$ .
- 11:   **if**  $d(x_n, \mathcal{D}) > \delta$ , **then**
- 12:      $M = M + 1$ .
- 13:     Add the new center  $u_M = x_n$  to the list of centers, i.e.,  $\mathcal{D} = \mathcal{D} \cup \{u_n\}, \theta = (\theta^T, \theta_n)^T$ .
- 14:   **else**
- 15:     Keep the codebook unchanged and update the coefficient  $\theta_{l_0}$ , i.e.,  $\theta_{l_0} = \theta_{l_0} + \mu e_n$ .
- 16:   **end if**
- 17:     The  $M$ -dimensional vector  $\theta$  and the dictionary  $\mathcal{D} = \{u_1, \dots, u_M\}$ .  
The solution is then given as  $f_n = \sum_{i=1}^M \theta_i \kappa(\cdot, u_i)$ .
- 18: **end for**

---

The signal is then corrupted by additive white Gaussian noise and then it is observed as  $x_n$ . The level of the noise was set equal to 15 dB. The aim of a channel equalization task is to design an inverse filter, which acts on the output of the channel,  $x_n$ , and reproduces the original input signal,  $y_n$ , as close as

**FIGURE 17.16**

Learning curves of normalized LMS ( $\mu = 1$ ) and the normalized Gaussian Kernel LMS ( $\mu = 1/2, \sigma = 5$ ) for the equalization problem (filter length  $l = 5$ , delay  $D = 2$ ).

possible. To this end, we apply the normalized KLMS algorithm to the set of samples

$$(\mathbf{x}_n, y_{n-D}) := ((x_n, x_{n-1}, \dots, x_{n-l+1}), y_{n-D}), \quad (17.45)$$

where  $l > 0$  is the equalizer's length and  $D$  the equalization time delay, which is present to, almost, any equalization set up. In other words, the output of the equalizer at time  $n$ , provides the estimate of  $y_{n-D}$ . This is to account for the non minimum phase property of the linear filter that was used to model the channel [5].

Experiments were conducted on 50 sets of 5000 samples of the input signal (Gaussian random variable with zero mean and unit variance) comparing the standard LMS and the KLMS. Regarding the KLMS, we employed the Gaussian kernel (with  $\sigma = 5$ ) and we adopted the novelty criterion sparsification strategy ( $\delta_1 = 0.15, \delta_2 = 0.2$ ). The step update parameter,  $\mu$ , was tuned for the best possible results (in terms of the steady-state error rate). Time delay  $D$  was also set for optimality. Figure 17.16 shows the learning curves of KLMS versus the standard LMS algorithm. The superiority of the KLMS is evident and it was expected, since the standard LMS cannot cope with the nonlinearity.

Figures 17.17a and 17.17b compare the performance of the various sparsification strategies presented in Section 1.17.6.2.1, considering the same experimental set up. The user-defined parameters for the novelty detection approach were set to  $\delta_1 = 0.15, \delta_2 = 0.2$ , for the coherence-based scenario were set to  $\epsilon_0 = 0.99$  and for the surprise-based sparsification were set to  $\lambda = 0.01, \delta_1 = 2, \delta_2 = -2$ . In this experiment, one observes that although both the surprise and the coherence-based scenarios perform almost equally well in terms of sparsity, the latter gives a slightly lower steady state MSE, whereas the novelty detection approach outperforms the other two both in terms of sparsity and the steady state MSE. Moreover, we should note that the coherence-based and the surprise strategies are

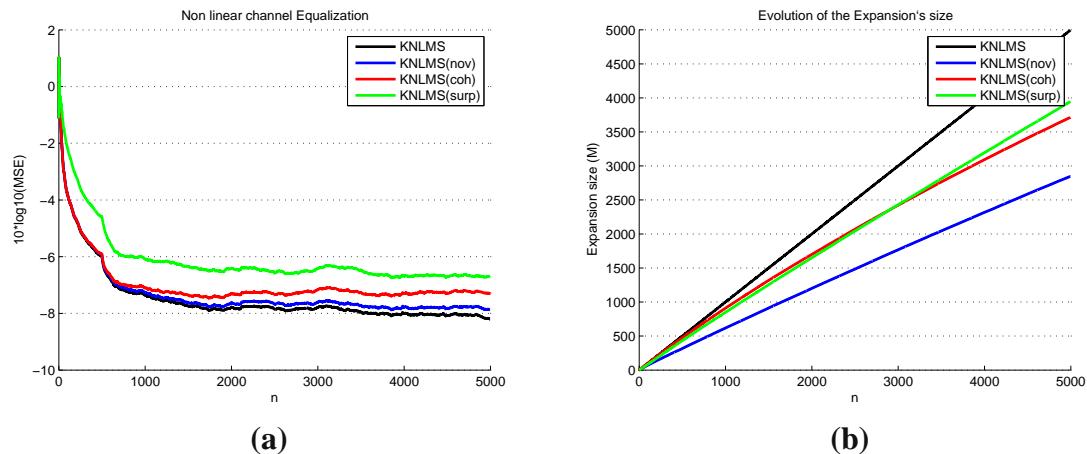

FIGURE 17.17

(a) Learning curves of the normalized Kernel LMS (KNLMS) with  $\mu = 1/2$ , using the Gaussian kernel ( $\sigma = 5$ ), under various sparsification strategies for the equalization problem (filter length  $l = 5$ , time delay  $D = 2$ ).  
(b) Evolution of the expansion's size at each time instant, for each sparsification strategy. The user-defined parameters for the novelty detection approach were set to  $\delta_1 = 0.15$ ,  $\delta_2 = 0.2$ , for the coherence-based scenario were set to  $\epsilon_0 = 0.99$  and for the surprise-based sparsification were set to  $\lambda = 0.01$ ,  $\delta_1 = 2$ ,  $\delta_2 = -2$ .

more computationally demanding compared to the novelty criterion, as they involve several evaluations of the kernel function. Figure 17.18 compares the learning curves and the expansion' size evolution of the QKLMS and the novelty detection KLMS at the same experimental set up. There it is shown that QKLMS, while offering a significant sparser solution, at the same time accomplishes a lower steady state MSE. In fact, the convergence behavior of QKLMS is almost identical to the KLMS without sparsification! Moreover, in terms of computational resources QKLMS is comparable to the novelty detection sparsification scenario.

Finally, Figures 17.19 and 17.20 compare the performances of the aforementioned sparsification strategies in a set up where the channel undergoes a significant change. In this particular experiment, the input signal was fed to a channel consisting of the linear part  $t_n = -0.8y_n + 0.7y_{n-1} - 0.6y_{n-2} + 0.1y_{n-3}$  and the nonlinear part  $q_n = t_n + 0.08t_n^2$ . The signal was then corrupted by additive white Gaussian noise and then observed as  $x_n$ . After the 2000th time instant the channel changes so that  $t_n = 0.6y_n - 0.9y_{n-1} + 0.5y_{n-2} - 0.4y_{n-3}$  and  $q_n = t_n + 0.1t_n^2$ . Experiments were conducted on 50 sets of 4000 samples of the input signal (Gaussian random variable with zero mean and unit variance). The QKLMS in this test gives excellent results, as it achieves the same steady state MSE as the unsparsified KLMS using only the 1/8th of the training centers. The three sparsification strategies (novelty, coherence, surprise) carry the information learned while the channel was in its original state throughout the learning phase. However, the two first (novelty and coherence) seem to be able to cope with the change of the channel, while the latter fails. The code for the experiments presented in this section can be found in <http://bouboulis.mysch.gr/kernels.html>. More simulation results for the KLMS

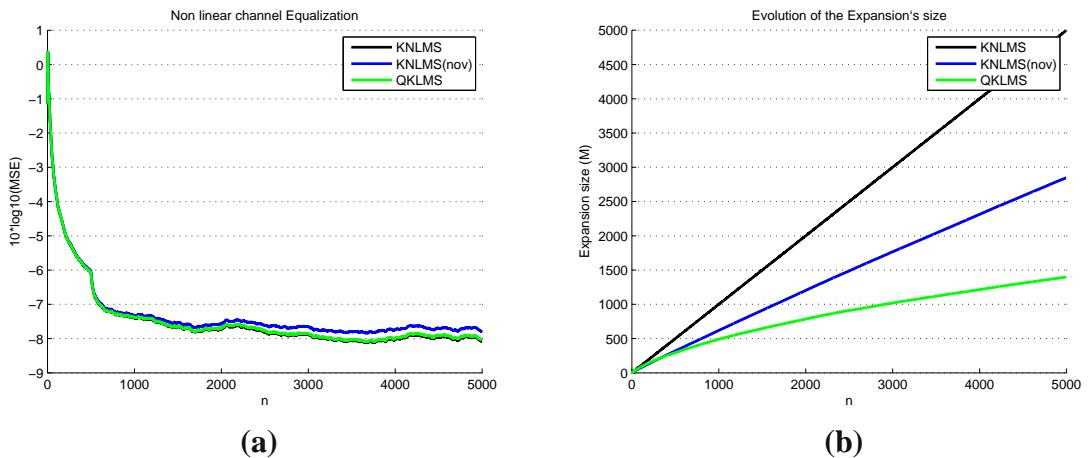

FIGURE 17.18

(a) Learning curves of the normalized Kernel LMS (KNLMS) with  $\mu = 1/2$ , using the Gaussian kernel ( $\sigma = 5$ ), the novelty-detection normalized KNLMS and the QKLMS for the equalization problem (filter length  $l = 5$ , time delay  $D = 2$ ). (b) Evolution of the expansion's size at each time instant, for the KNLMS, novelty KNLMS, QKNLMS. The user-defined parameters for the novelty detection approach were set to  $\delta_1 = 0.15$ ,  $\delta_2 = 0.2$ . The quantization size (for the QKNLMS) was set  $\delta = 1$ .

algorithm are given in Sections 1.17.6.6.1 and 1.17.7.6.2, where it is validated against other kernel-based online learning methodologies, such as the Kernel RLS, and the projection-based Adaptive Projected Subgradient Method (APSM).

### 1.17.6.3 The complex case

Complex-valued signals arise frequently in applications as diverse as communications, bioinformatics, radar, etc. In this section we present the LMS rationale suitably adjusted to treat data of this nature.

#### 1.17.6.3.1 Complex LMS

Let  $z_n \in \mathbb{C}^v$  and  $d_n \in \mathbb{C}$  be the input and the output of the original filter, respectively. In the typical Complex LMS (CLMS) rationale, we estimate the output of the filter using the so called C-linear function:  $\hat{d}_n = f_\theta(z_n) = \theta^H z_n$ . The CLMS aims to compute  $\theta \in \mathbb{C}^v$ , such that the error  $\mathcal{L}(\theta) = E[|d_n - \theta^H z_n|^2]$  is minimized. To compute the respective gradients, the notion of the Wirtinger's Calculus [46,47] is employed as it simplifies calculations. In a nutshell, Wirtinger's Calculus considers two types of derivatives, with respect to  $z$  and  $z^*$  respectively (following the standard differentiation rules). However, only the second one is important for optimization tasks. The alternative to using Wirtinger's calculus would be to consider the complex variables as pairs of two real ones and employ the common real partial derivatives. However, this approach, usually, is more time consuming and leads to more cumbersome expressions. Hence, applying the rules of Wirtinger's calculus to this case, we

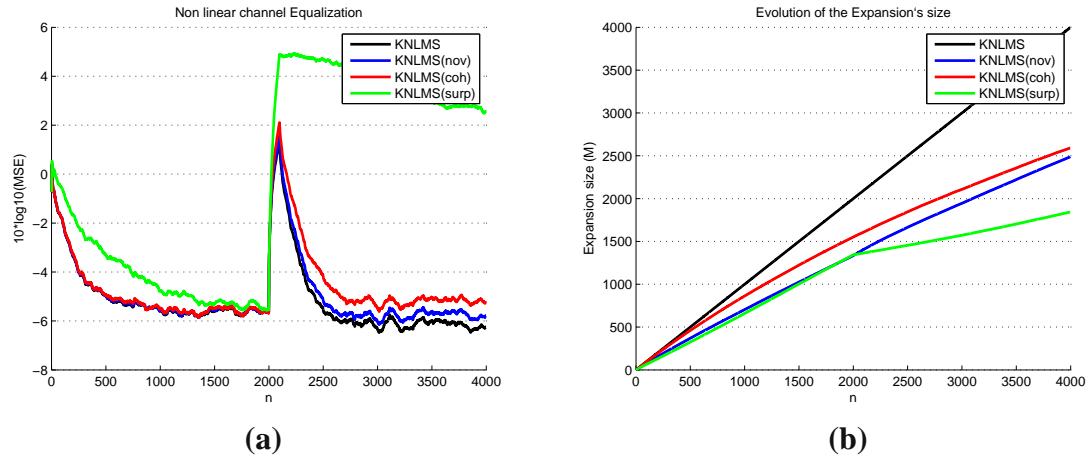

FIGURE 17.19

(a) Learning curves of the normalized Kernel LMS (KNLMS) with  $\mu = 1/2$ , using the Gaussian kernel ( $\sigma = 5$ ), under various sparsification strategies for the two states equalization problem (filter length  $l = 5$ , time delay  $D = 2$ ). (b) Evolution of the expansion's size at each time instant, for each sparsification strategy. The user-defined parameters for the novelty detection approach were set to  $\delta_1 = 0.15$ ,  $\delta_2 = 0.2$ , for the coherence-based scenario were set to  $\epsilon_0 = 0.99$  and for the surprise-based sparsification were set to  $\lambda = 0.01$ ,  $\delta_1 = 2$ ,  $\delta_2 = -2$ .

take that  $\frac{\partial \mathcal{L}(\theta)}{\partial \theta^*} = -e_n^* z_n$ , where  $e_n = d_n - \hat{d}_n$ . Thus, the step update for the CLMS is

$$\theta_n = \theta_{n-1} + \mu e_n^* z_n,$$

and the estimated output of the filter at iteration  $n$ , assuming that  $\theta_0 = \mathbf{0}$ , is

$$\hat{d}_n = \mu \sum_{i=1}^{n-1} e_i z_i^H z_n.$$

A different filtering structure has been brought to light more recently, mainly due to the works of Picinbono [48–50]. It is based on the notion of the *widely linear estimation functions*, where the output is estimated so that to be linear in terms of both  $z$  and  $z^*$ , i.e.,  $\tilde{d}_n = f_\theta, \eta(z_n) = \theta^H z_n + \eta^H z_n^*$ . It turns out that the traditional approach to linearity, as employed by the CLMS, is rather “unorthodox,” as it excludes a large class of linear functions from being considered in the estimation process. Moreover, it can be shown that the correct complex linear estimation is the widely linear one [51]. In the context of the widely linear, or Augmented, CLMS (ACLMS), the vectors  $\theta, \eta \in \mathbb{C}^v$  are computed, so that the error  $\mathcal{L}(\theta) = E[|d_n - f_{\theta,\eta}(z_n)|^2]$  is minimized. Applying Wirtinger’s Calculus we compute the respective gradients as  $\frac{\partial \mathcal{L}(\theta,\eta)}{\partial \theta^*} = -e_n^* z_n$  and  $\frac{\partial \mathcal{L}(\theta,\eta)}{\partial \eta^*} = -e_n^* z_n^*$ . Thus, the step updates of

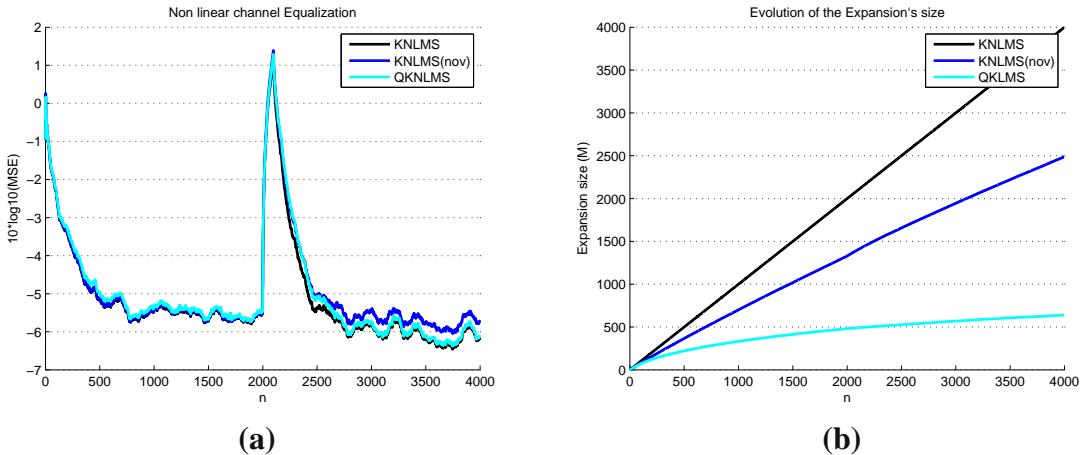

FIGURE 17.20

(a) Learning curves of the normalized Kernel LMS (KNLMS) with  $\mu = 1/2$ , using the Gaussian kernel ( $\sigma = 5$ ), the novelty-detection normalized KNLMS and the QKLMS for the two-states equalization problem (filter length  $l = 5$ , time delay  $D = 2$ ). (b) Evolution of the expansion's size at each time instant, for the KNLMS, novelty KNLMS, QKNLMS. The user-defined parameters for the novelty detection approach were set to  $\delta_1 = 0.15$ ,  $\delta_2 = 0.2$ . The quantization size (for the QKNLMS) was set  $\delta = 1$ .

the ACLMS become

$$\boldsymbol{\theta}_n = \boldsymbol{\theta}_{n-1} + \mu e_n^* \mathbf{z}_n, \quad (17.46a)$$

$$\boldsymbol{\eta}_n = \boldsymbol{\eta}_{n-1} + \mu e_n^* \mathbf{z}_n^*, \quad (17.46b)$$

and the estimated output at iteration  $n$ , assuming that  $\boldsymbol{\theta}_0 = \boldsymbol{\eta}_0 = \mathbf{0}$ , is

$$\tilde{d}_n = \mu \sum_{i=1}^{n-1} e_i (\mathbf{z}_i + \mathbf{z}_i^*)^H \mathbf{z}_n. \quad (17.47)$$

An important notion that has been associated with the case of complex data is the so called *circularity*. Circularity is intimately related to the rotation in the geometric sense. A complex random variable  $Z$  is called circular, if for any angle  $\phi$  both  $Z$  and  $Ze^{i\phi}$  (i.e., the rotation of  $Z$  by angle  $\phi$ ) follow the same probability distribution [52,53]. It has been shown that, in the case of circular inputs, ACLMS and CLMS have identical performances [48,49,52,53]. However, ACLMS may show some performance gains when non-circular input sources are considered, although its convergence rate is somewhat slower than the CLMS. This is due to the fact that widely linear estimation processes are able to capture the full second-order statistics of a given complex signal, especially in the case where the signal is non-circular, by considering both the covariance and the pseudo-covariance matrices [49,50].

### 1.17.6.3.2 Complex kernel LMS

Following a similar procedure, as the one adopted in the derivation of the KLMS from the standard LMS, kernel-based analogues of the CLMS can be produced. In general, to generate kernel adaptive

filtering algorithms on complex domains, according to [54], one can adopt two methodologies. A first straightforward approach is to use directly a complex RKHS, using one of the complex kernels given in Section 1.17.5, and map the original data to the complex RKHS through the associated feature map  $\Phi_{\mathbb{C}}(z) = \kappa_{\mathbb{C}}(\cdot, z)$ . This is equivalent to applying the kernel trick to the standard complex LMS rationale in the usual black-box approach. Another alternative technique is to use real kernels through a rationale that is called *complexification* of real RKHSs. This method has the advantage of allowing modeling in complex RKHSs, using popular well-established and well understood, from a performance point of view, real kernels (e.g., Gaussian, polynomial, etc). While in the first case, we map the data directly to the complex RKHS through the feature map, in the complexification scenario we employ the map  $\Phi(z) = \Phi_{\mathbb{R}}(x, y) + i\Phi_{\mathbb{R}}(x, y)$ , where  $z = x + iy$ , and  $\Phi_{\mathbb{R}}$  is the feature map of the chosen real kernel  $\kappa_{\mathbb{R}}$ , i.e.,  $\Phi_{\mathbb{R}}(x, y) = \kappa_{\mathbb{R}}(\cdot, (x, y))$ . In the following, we will deal with the first scenario only. The complexification case is treated in [54].

Consider the complex RKHS  $\mathbb{H}$ , with the respective complex reproducing kernel  $\kappa_{\mathbb{C}}(\cdot, \cdot)$  (meaning that it takes complex arguments and returns a complex number) defined on  $X \times X$ , where  $X \subseteq \mathbb{C}^v$ . We apply the feature map  $\Phi_{\mathbb{C}}$  of the RKHS,  $\mathbb{H}$ , to the points  $z_n$  and employ the LMS rationale to the transformed data  $\{(\Phi_{\mathbb{C}}(z_n), d_n) : n = 1, 2, \dots\}$ , modeling the desired output either as  $\hat{d}_n = \langle \Phi_{\mathbb{C}}(z_n), f \rangle_{\mathbb{H}}$ , for some  $f \in \mathbb{H}$ , or as  $\tilde{d}_n = \langle \Phi_{\mathbb{C}}(z_n), f \rangle_{\mathbb{H}} + \langle \Phi_{\mathbb{C}}^*(z_n), g \rangle_{\mathbb{H}}$ , for some  $f, g \in \mathbb{H}$ , if the more general widely linear approach is considered. In the first case, considering the corresponding loss as  $\mathcal{L}(f) = E[|d_n - \hat{d}_n|^2]$ , the Pure Complex KLMS (PCKLMS) is generated. To this end, the gradient descent rationale is adopted and the gradient of the loss function is estimated via its current measurement. To this end, Wirtinger's calculus had to be generalized in the framework of Freshet derivation, to cope with infinite dimensional complex Hilbert spaces, [55]. It turns out that,  $\nabla_{f^*}\mathcal{L}(f) = -E[e_n^*\Phi_{\mathbb{C}}(z_n)] \approx -e_n^*\Phi_{\mathbb{C}}(z_n)$ . This leads to the following step update equation:

$$f_n = f_{n-1} + \mu e_n^* \Phi_{\mathbb{C}}(z_n). \quad (17.48)$$

Assuming that  $f_0 = 0$ , and by applying a repetition of (17.48), we take formulas similar to the KLMS case. Algorithm 30 summarizes the procedure of PCKLMS.

To sparsify the solution one may employ any of the methods described in Section 1.17.6.2.1. Adopting the widely linear estimation process, i.e.,  $\tilde{d}_n = \langle \Phi_{\mathbb{C}}(z_n), f \rangle_{\mathbb{H}} + \langle \Phi_{\mathbb{C}}^*(z_n), g \rangle_{\mathbb{H}}$ , and following a similar procedure, the *Augmented Pure Complex KLMS (APCKLMS)* is produced. In this case, as the corresponding loss is  $\mathcal{L}(\theta, \eta) = E[|d_n - \tilde{d}_n|^2]$ , the respective estimation of gradients via their current measurements becomes  $\nabla_{f^*}\mathcal{L}(f, g) \approx -e_n^*\Phi_{\mathbb{C}}(z_n)$  and  $\nabla_{g^*}\mathcal{L}(f, g) \approx -e_n^*\Phi_{\mathbb{C}}^*(z_n)$ . It turns out that the step update equations become:

$$\begin{aligned} f_n &= f_{n-1} + \mu e_n^* \Phi_{\mathbb{C}}(z_n), \\ g_n &= g_{n-1} + \mu e_n^* \Phi_{\mathbb{C}}^*(z_n). \end{aligned}$$

The APCKLMS is treated in details in [51], where it is shown that it performs significantly better than the PCKLMS. The problem of complex estimation using kernels in the special case of finite dimensional Euclidean spaces has also been considered in [56].

**Algorithm 30.** Pure Complex Kernel LMS (PCKLMS)

---

**Require:**  $(z_1, d_1), \dots, (z_n, d_n), \dots$

- 1: Set  $\theta = 0$ ,  $\mathcal{D} = \emptyset$ ,  $M = 0$ . Select the step parameter  $\mu$  and the parameters of the kernel.
- 2: **for**  $n = 1, 2, \dots$ , **do**
- 3:   **if**  $n = 1$  **then**
- 4:      $\hat{d}_n = 0$ .
- 5:   **else**
- 6:     Compute the filter output:  $\hat{d}_n = \sum_{i=1}^M \theta_i \kappa_{\mathbb{C}}(\mathbf{u}_i, z_n)$ .
- 7:   **end if**
- 8:     Compute the error:  $e_n = d_n - \hat{d}_n$ .
- 9:      $\theta_n = \mu e_n$ .
- 10:   Check Sparsification Rules.
- 11:   **if** Sparsification Rules are satisfied,
- 12:      $M = M + 1$ .
- 13:     Add the new center  $\mathbf{u}_M = z_n$  to the list of centers, i.e.,  $\mathcal{D} = \mathcal{D} \cup \{z_n\}$ ,  $\theta = (\theta^T, \theta_n)^T$ .
- 14:   **end if**
- Output:** The  $M$ -dimensional vector  $\theta$  and the dictionary  $\mathcal{D} = \{\mathbf{u}_1, \dots, \mathbf{u}_M\}$ .

The solution is then given as  $f_n = \sum_{i=1}^M \theta_i \kappa(\mathbf{u}_i, \cdot)$ .

15: **end for**

---

**1.17.6.4 Recursive Least Squares (RLS)**

Recall that we assumed the sequence of examples  $\{(\mathbf{x}_1, y_1), (\mathbf{x}_2, y_2), \dots, (\mathbf{x}_n, y_n), \dots\}$ , where  $\mathbf{x}_n \in X \subset \mathcal{R}^l$ , and  $y_n \in \mathcal{R}$ . In the *Recursive Least Squares* (RLS) algorithm, we adopt the parametric class of linear functions, i.e.,  $\mathcal{F} = \{f_{\theta}(\mathbf{x}) = \theta^T \mathbf{x} : \theta \in \mathcal{R}^l\}$ , as the field in which we search for the optimal input-output relationship between  $\mathbf{x}_n$  and  $y_n$ , while the loss function at iteration  $n$  takes the form:

$$\mathcal{L}_n(\theta) = \sum_{i=1}^n |y_i - f_{\theta}(\mathbf{x}_i)|^2 + \lambda \|\theta\|^2, \quad n = 1, 2, \dots, \quad (17.49)$$

for some chosen  $\lambda > 0$ . Observe that the loss function consists of two parts. The first one measures the error between the estimated output,  $f_{\theta}(\mathbf{x}_i)$ , and the actual output,  $y_i$ , at each time instant,  $i$ , up to  $n$ , while the second is a regularization term. The existence of the second term is crucial to the algorithm, as it prevents it from being ill-posed and guards against overfitting. At each time instant,  $n$ , the RLS finds the solution to the minimization problem:

$$\min_{\theta} \mathcal{L}_n(\theta). \quad (17.50)$$

The RLS algorithm, usually, exhibits an order of magnitude faster convergence compared to the LMS, at the cost of higher computational complexity.

The rationale of the RLS algorithm can be described in a significant more compact form, if one adopts a matrix representation. To this end, we define the  $l \times n$  matrices  $X_n = (\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n)$  and

the vectors  $\mathbf{y}_n = (y_1, y_2, \dots, y_n)^T \in \mathcal{R}^n$ , for  $n = 1, 2, \dots$ . Then, the loss function (17.49) can be equivalently defined as:

$$\begin{aligned}\mathcal{L}_n(\boldsymbol{\theta}) &= \left\| \mathbf{y}_n - \mathbf{X}_n^T \boldsymbol{\theta} \right\|^2 + \lambda \|\boldsymbol{\theta}\|^2 = (\mathbf{y}_n - \mathbf{X}_n^T \boldsymbol{\theta})^T (\mathbf{y}_n - \mathbf{X}_n^T \boldsymbol{\theta}) + \lambda \|\boldsymbol{\theta}\|^2 \\ &= \|\mathbf{y}_n\|^2 - 2\boldsymbol{\theta}^T \mathbf{X}_n \mathbf{y}_n + \boldsymbol{\theta}^T \mathbf{X}_n \mathbf{X}_n^T \boldsymbol{\theta} + \lambda \boldsymbol{\theta}^T \boldsymbol{\theta}.\end{aligned}$$

As this is a strictly convex function, it has a unique minimum, which it is obtained at the point,  $\boldsymbol{\theta}_n := \operatorname{argmin}_{\boldsymbol{\theta}} \{\mathcal{L}_n(\boldsymbol{\theta})\}$ , where its gradient vanishes, i.e.,  $\nabla \mathcal{L}_n(\boldsymbol{\theta}_n) = 0$ . Note, that the gradient of the loss function can be derived using standard differentiation rules:

$$\nabla \mathcal{L}_n(\boldsymbol{\theta}) = -2\mathbf{X}_n \mathbf{y}_n + 2\mathbf{X}_n \mathbf{X}_n^T \boldsymbol{\theta} + 2\boldsymbol{\theta}. \quad (17.51)$$

Equating the gradient to zero, we obtain the solution to the minimization problem (17.50):

$$\boldsymbol{\theta}_n = (\lambda \mathbf{I}_l + \mathbf{X}_n \mathbf{X}_n^T)^{-1} \mathbf{X}_n \mathbf{y}_n, \quad (17.52)$$

where  $\mathbf{I}_l$  is the  $l \times l$  identity matrix. Observe, that this solution includes the inversion of a matrix at each time step, which is usually, a computationally demanding procedure. To overcome this obstacle, the RLS algorithm computes the solution recursively, exploiting the matrix inversion lemma:

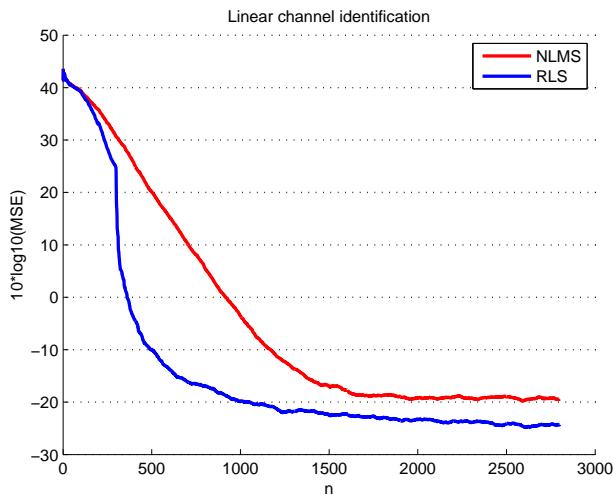

$$(\mathbf{A} + \mathbf{B} \mathbf{C} \mathbf{D})^{-1} = \mathbf{A}^{-1} - \mathbf{A}^{-1} \mathbf{B} (\mathbf{C}^{-1} + \mathbf{D} \mathbf{A}^{-1} \mathbf{B})^{-1} \mathbf{D} \mathbf{A}^{-1}. \quad (17.53)$$

Let  $\mathbf{P}_n = \lambda \mathbf{I}_l + \mathbf{x}_n \mathbf{x}_n^T$ . Then, we can easily deduce that  $\mathbf{P}_n = \mathbf{P}_{n-1} + \mathbf{x}_n \mathbf{x}_n^T$ . Thus, using the matrix inversion lemma (17.53) we take:

$$\mathbf{P}_n^{-1} = \left( \mathbf{P}_{n-1} + \mathbf{x}_n \mathbf{x}_n^T \right)^{-1} = \mathbf{P}_{n-1}^{-1} - \frac{\mathbf{P}_{n-1}^{-1} \mathbf{x}_n \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1}}{1 + \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{x}_n}.$$

Also, considering that  $\mathbf{X}_n \mathbf{y}_n = \mathbf{X}_{n-1} \mathbf{y}_{n-1} + \mathbf{x}_n y_n$ , the solution  $\boldsymbol{\theta}_n$  becomes

$$\begin{aligned}\boldsymbol{\theta}_n &= \mathbf{P}_n \mathbf{X}_n \mathbf{y}_n = \left( \mathbf{P}_{n-1}^{-1} - \frac{\mathbf{P}_{n-1}^{-1} \mathbf{x}_n \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1}}{1 + \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{x}_n} \right) (\mathbf{X}_{n-1} \mathbf{y}_{n-1} + \mathbf{x}_n y_n) \\ &= \mathbf{P}_{n-1}^{-1} \mathbf{X}_{n-1} \mathbf{y}_{n-1} + \mathbf{P}_{n-1}^{-1} \mathbf{x}_n y_n - \frac{\mathbf{P}_{n-1}^{-1} \mathbf{x}_n \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{P}_{n-1}^{-1} \mathbf{X}_{n-1} \mathbf{y}_{n-1}}{1 + \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{x}_n} - \frac{\mathbf{P}_{n-1}^{-1} \mathbf{x}_n \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{P}_{n-1}^{-1} \mathbf{x}_n y_n}{1 + \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{x}_n} \\ &= \boldsymbol{\theta}_{n-1} - \frac{\mathbf{P}_{n-1}^{-1} \mathbf{x}_n \mathbf{x}_n^T \boldsymbol{\theta}_{n-1}}{1 + \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{x}_n} + \left( \mathbf{P}_{n-1}^{-1} \mathbf{x}_n y_n - \frac{\mathbf{P}_{n-1}^{-1} \mathbf{x}_n \mathbf{x}_n^T \mathbf{P}_{n-1}^T \mathbf{x}_n y_n}{1 + \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{x}_n} \right) \\ &= \boldsymbol{\theta}_{n-1} - \frac{\mathbf{P}_{n-1}^{-1} \mathbf{x}_n \mathbf{x}_n^T \boldsymbol{\theta}_{n-1}}{1 + \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{x}_n} + \frac{\mathbf{P}_{n-1}^{-1} \mathbf{x}_n y_n}{1 + \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{x}_n} \\ &= \boldsymbol{\theta}_{n-1} + \frac{\mathbf{P}_{n-1}^{-1} \mathbf{x}_n}{1 + \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{x}_n} (y_n - \mathbf{x}_n^T \boldsymbol{\theta}_{n-1}).\end{aligned}$$

**FIGURE 17.21**

Learning curves of the normalized LMS ( $\mu = 1$ ) and the RLS ( $\lambda = 0.01$ ) for a filter identification problem (filter length  $l = 200$ ).

Thus, the solution  $\theta_n$  is computed recursively, as

$$\theta_n = \theta_{n-1} + \frac{\mathbf{P}_{n-1}^{-1} \mathbf{x}_n}{1 + \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{x}_n} e_n, \quad (17.54)$$

where  $e_n = y_n - \theta_{n-1}^T \mathbf{x}_n$  is the estimation error at iteration  $n$ .

As can be seen in Figure 17.21, which considers a 200-taps filter identification problem (where the input signal is a Gaussian random variable with zero mean and unit variance), the RLS learning procedure typically exhibits significantly faster convergence and achieves a lower steady state error compared to the NLMS (in this example the steady state MSE achieved by the RLS is 25% lower than the one achieved by the NLMS). Such a performance is expected for the stationary environment case. The RLS is a Newton-type algorithm and the LMS a gradient descent type. Moreover, concerning the excess error for the LMS, this is due to the non-diminishing value of  $\mu$ , which as we know increases the steady state error.

### 1.17.6.5 Exponentially weighted RLS

The RLS learning rationale utilizes information of all past data at each iteration step. Although this tactic enables RLS to achieve better convergence speed, it may become a burden in time-varying environments. In such cases, it would be preferable to simply “forget” some of the past data, which correspond to an earlier state of the learning task. We can incorporate such an approach to the RLS algorithm by

introducing some weighting factors to the cost function (17.49), i.e.,

$$\mathcal{L}_n(\boldsymbol{\theta}) = \sum_{i=1}^n w(n, i) |y_i - f_{\boldsymbol{\theta}}(\mathbf{x}_i)|^2 + \lambda w(n) \|\boldsymbol{\theta}\|^2, \quad n = 1, 2, \dots, \quad (17.55)$$

where  $w$  is an appropriately chosen weighting function. A typical weighting scenario that is commonly used is the *exponential weighting factor* (or the *forgetting factor*), where we choose  $w(n, i) = w^{n-i}$  and  $w(n) = w^n$ , for some  $0 < w \leq 1$ . Small values of  $w$  (close to 0) imply a strong forgetting mechanism, which makes the algorithm more sensitive to recent samples and might lead to poor performance. Hence, we usually select  $w$  such that it is close to 1. Obviously, for  $w = 1$  we take the ordinary RLS described in 1.17.6.4. In the method of *Exponentially Weighted RLS* (EWRLS) we minimize the cost function

$$\mathcal{L}_n(\boldsymbol{\theta}) = \sum_{i=1}^n w^{n-i} |y_i - \boldsymbol{\theta}^T \mathbf{x}_i|^2 + \lambda w^n \|\boldsymbol{\theta}\|^2, \quad n = 1, 2, \dots \quad (17.56)$$

Using the matrix notation the aforementioned cost function becomes  $\mathcal{L}(\boldsymbol{\theta}) = \left\| \mathbf{W}_n^{\frac{1}{2}} (\mathbf{y}_n - \mathbf{X}_n \boldsymbol{\theta}) \right\|^2 + w^n \lambda \boldsymbol{\theta}^T \boldsymbol{\theta}$ , where  $\mathbf{X}_n$  and  $\mathbf{y}_n$  are defined as in Section 1.17.6.4 and  $\mathbf{W}$  is the diagonal matrix with elements the powers of  $w$  up to  $n-1$ , i.e.,

$$\mathbf{W}_n = \begin{pmatrix} w^{n-1} & 0 & 0 & \dots & 0 \\ 0 & w^{n-2} & 0 & \dots & 0 \\ \vdots & \vdots & \vdots & & \vdots \\ 0 & 0 & 0 & & 1 \end{pmatrix}.$$

The solution to the respective minimization problem is

$$\boldsymbol{\theta}_n = (\mathbf{X}_n \mathbf{W}_n \mathbf{X}_n^T + w^n \lambda \mathbf{I}_l)^{-1} \mathbf{X}_n \mathbf{W}_n \mathbf{y}_n. \quad (17.57)$$

Following a similar rationale as in Section 1.17.6.4, it turns out that:

$$\mathbf{P}_n^{-1} = w^{-1} \mathbf{P}_{n-1}^{-1} - \frac{w^{-2} \mathbf{P}_{n-1}^{-1} \mathbf{x}_n \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1}}{1 + w^{-1} \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{x}_n},$$

and

$$\boldsymbol{\theta}_n = \boldsymbol{\theta}_{n-1} + \frac{w^{-1} \mathbf{P}_{n-1}^{-1} \mathbf{x}_n}{1 + w^{-1} \mathbf{x}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{x}_n} e_n.$$

Algorithm 31 describes the EWRLS machinery in details. We test the performance of the EWRLS in a time-varying channel identification problem. The signal (zero-mean unity-variance Gaussian random variable) is fed to a linear channel (length  $K = 200$ ) and then corrupted by white Gaussian noise. After 2000 samples of data, the coefficients of the linear channel undergo a significant change. Figure 17.22 shows the performance of the EWRLS algorithm compared to the standard RLS and the NLMS for

**Algorithm 31.** Exponential Weighted Recursive Least Squares (RLS)

**Require:** The data  $((\mathbf{x}_n, y_n))_{n \in \mathcal{N}_*}$ , the weighting factor  $w$  and the regularization parameter  $\lambda$ .

- 1: Set  $\mathbf{P} = \lambda \mathbf{I}_l$ ,  $\boldsymbol{\theta} = \mathbf{0}$ .
- 2: **for**  $n = 1, 2, \dots$ , **do**
- 3: Compute the learning system's output:  $\hat{y}_n = \boldsymbol{\theta}^T \mathbf{x}_n$ .
- 4: Compute the error:  $e_n = y_n - \hat{y}_n$ .
- 5:  $r = 1 + w^{-1} \mathbf{x}_n^T \mathbf{P}^{-1} \mathbf{x}_n$ .
- 6:  $\mathbf{k} = (rw)^{-1} \mathbf{P}^{-1} \mathbf{x}_n$ .
- 7: Update solution:  $\boldsymbol{\theta} = \boldsymbol{\theta} + e_n \mathbf{k}$ .
- 8: Update the inverse matrix:  $\mathbf{P}^{-1} = w^{-1} \mathbf{P}^{-1} - \mathbf{k} \mathbf{k}^T r$ .

**Output:** The vector  $\boldsymbol{\theta} \in \mathcal{R}^l$ .

- 9: **end for**

various values of the weighting coefficient  $w$ . While the standard RLS fails to adapt to the change of the environment, the EWRLS learns the new channel effectively, at a cost of a slightly larger steady state MSE due to the weighting of the error at each time step. Note that the tracking performance of both the LMS and the RLS algorithms depends on the input signal. For some signals the LMS can track better. This is in contrast to the initial convergence speed, where the RLS always converges faster. [5, 6].

### 1.17.6.6 The Kernel RLS

Similar to the case of the KLMS, in the *Kernel RLS* (KRLS) we estimate the learning system's output by a function  $f$  defined on the RKHS,  $\mathcal{H}$ , which is associated to a positive definite kernel  $\kappa$ . The sequence of examples are transformed via the feature map  $\Phi : X \rightarrow \mathcal{H}$ ,  $\Phi(\mathbf{x}) = \kappa(\cdot, \mathbf{x})$  to generate the input data

$$\{(\Phi(\mathbf{x}_1), y_1), (\Phi(\mathbf{x}_2), y_2), \dots, (\Phi(\mathbf{x}_n), y_n), \dots\}$$

and the employed loss function takes the form

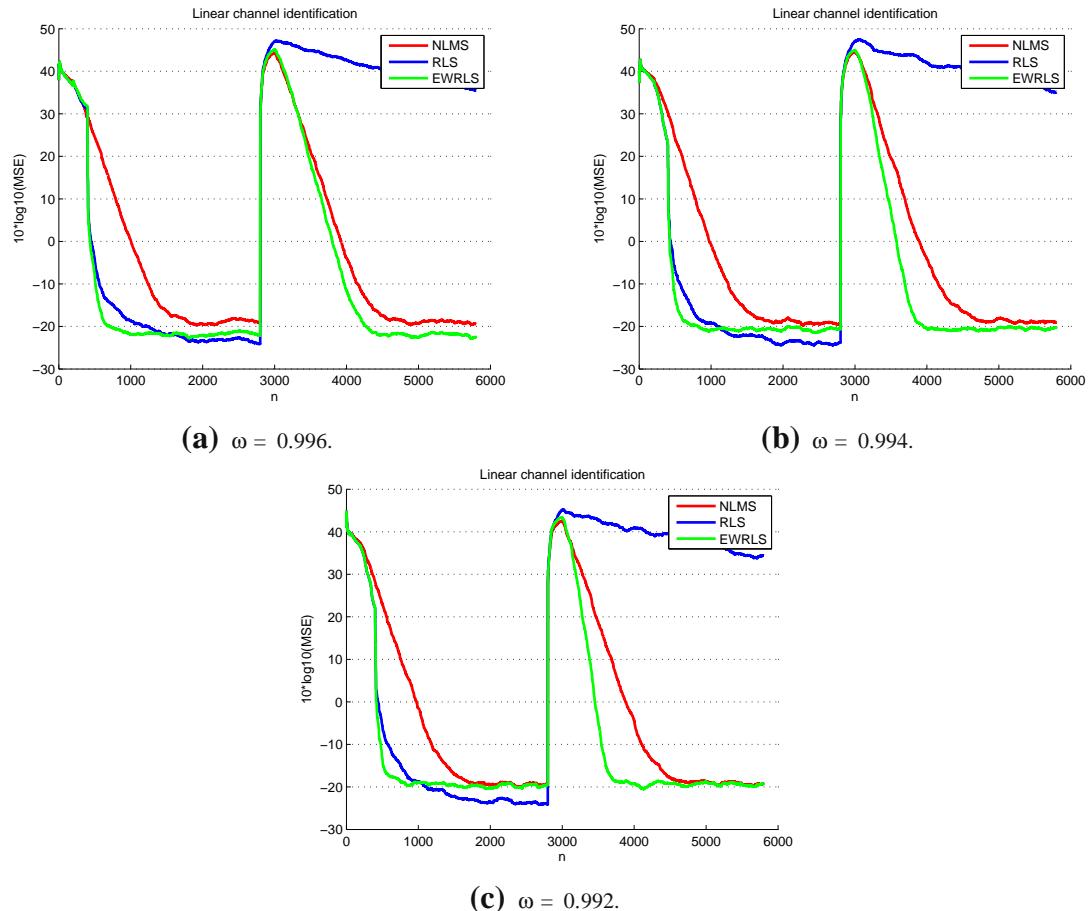

$$\mathcal{L}_n(f) = \sum_{i=1}^n |y_i - \langle \Phi(\mathbf{x}_i), f \rangle_{\mathcal{H}}|^2 + \lambda \|f\|_{\mathcal{H}}^2, \quad n = 1, 2, \dots \quad (17.58)$$

The Representer Theorem 16 ensures that the solution to the minimization task,  $f_n := \operatorname{argmin}_{f \in \mathcal{H}} \mathcal{L}_n(f)$ , lies in the finite dimensional subspace of the span of the  $n$  kernels that are centered on the training points  $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$ . In other words:

$$f_n = \sum_{i=1}^n \theta_{n,i} \kappa(\cdot, \mathbf{x}_i) \quad (17.59)$$

and thus, exploiting the kernel trick, the estimated output at iteration  $n$  will be given by

$$\hat{y}_n = \langle \Phi(\mathbf{x}_n), f_n \rangle_{\mathcal{H}} = \sum_{i=1}^n \theta_{n,i} \kappa(\mathbf{x}_i, \mathbf{x}_n). \quad (17.60)$$

**FIGURE 17.22**

Learning curves of the normalized LMS ( $\mu = 1$ ), the RLS and EWRLS ( $\lambda = 0.001$ ) for various values of the weighting factor  $w$ , for a time-varying filter identification problem (filter length  $l = 200$ ).

As this expansion grows unbounded while time evolves, analogous to the case of KLMS, a sparsification mechanism, which keeps the most informative training points and discards the rest, is also needed. KRLS's main task is to estimate the (growing) vector  $\theta_n = (\theta_{n,1}, \dots, \theta_{n,n})^T$  in a recursive manner.

The first approach to the KRLS task was presented in [44] by Engel, Mannor, and Meir as a part of Engel's Ph.D. thesis. Their method is built around a specific sparsification strategy, which is called *Approximate Linear Dependency* (ALD). To this end, consider a dictionary of centers  $\mathcal{D}_{n-1} = \{\mathbf{u}_1, \dots, \mathbf{u}_{M_{n-1}}\}$ , of size  $M_{n-1}$ , that keeps some of the past training points. In this setting, we test whether the newly arrived data  $\Phi(\mathbf{x}_n)$  is approximately linearly dependent on the dictionary elements  $\Phi(\mathbf{u}_1), \dots, \Phi(\mathbf{u}_{M_{n-1}})$ . If not,

we add it to the dictionary, otherwise  $\Phi(\mathbf{x}_n)$  is approximated by a linear combination of the dictionary's elements. The specific condition is whether

$$\delta_n = \min_{\mathbf{a}_n} \left\{ \left\| \sum_{m=1}^{M_{n-1}} a_{n,m} \Phi(\mathbf{u}_m) - \Phi(\mathbf{x}_n) \right\|^2 \right\} \leq \epsilon_0, \quad (17.61)$$

where  $\epsilon_0$  is a user-defined parameter. Using matrix-notation, this minimization problem can be equivalently recasted as:

$$\delta_n = \min_{\mathbf{a}_n} \left( \mathbf{a}_n^T \tilde{\mathbf{K}}_{n-1} \mathbf{a}_n - 2\mathbf{a}_n^T \boldsymbol{\beta}_n + \kappa(\mathbf{x}_n, \mathbf{x}_n) \right),$$

where  $(\tilde{\mathbf{K}}_{n-1})_{i,j} = \kappa(\mathbf{u}_i, \mathbf{u}_j)$ , for  $i, j = 1, 2, \dots, M_{n-1}$ , and  $\boldsymbol{\beta}_n = (\kappa(\mathbf{u}_1, \mathbf{x}_n), \kappa(\mathbf{u}_2, \mathbf{x}_n), \dots, \kappa(\mathbf{u}_{M_{n-1}}, \mathbf{x}_n))^T$ . Assuming that  $\tilde{\mathbf{K}}_{n-1}$  is invertible, the solution to this minimization problem is

$$\mathbf{a}_n = \tilde{\mathbf{K}}_{n-1}^{-1} \boldsymbol{\beta}_n, \quad (17.62)$$

while the attained minimum value is  $\delta_n = \kappa(\mathbf{x}_n, \mathbf{x}_n) - \boldsymbol{\beta}_n^T \mathbf{a}_n$ . In the case where  $\delta_n > \epsilon_0$ ,  $\mathbf{x}_n$  is added to the dictionary, which now contains  $M_n = M_{n-1} + 1$  centers. If  $\delta_n \leq \epsilon_0$ , then  $\mathbf{x}_n$  is not included to the dictionary, i.e.,  $\mathcal{D}_n = \mathcal{D}_{n-1}$ ,  $M_n = M_{n-1}$ , and we approximate  $\Phi(\mathbf{x}_n)$  as

$$\Phi(\mathbf{x}_n) \approx \sum_{m=1}^{M_n} a_{n,m} \Phi(\mathbf{u}_m). \quad (17.63)$$

Using (17.63), we can approximate the full kernel matrix  $\mathbf{K}_n$  (i.e.,  $(\mathbf{K}_n)_{i,j} = \kappa(\mathbf{x}_i, \mathbf{x}_j)$ , for  $i, j = 1, \dots, n$ ) as

$$\mathbf{K}_n \approx \mathbf{A}_n \cdot \tilde{\mathbf{K}}_n \cdot \mathbf{A}_n^T, \quad (17.64)$$

where  $\mathbf{A}_n = (\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_n)^T$  is the  $M_n \times M_n$  matrix that contains the coefficients of the linear combinations associated with each  $\mathbf{u}_m$ ,  $m = 1, \dots, M_n$ . This is due to the fact that at time index  $n$  each kernel evaluation is computed as

$$\begin{aligned} \kappa(\mathbf{x}_i, \mathbf{x}_j) &= \langle \Phi(\mathbf{x}_i), \Phi(\mathbf{x}_j) \rangle_{\mathcal{H}} = \left\langle \sum_{k=1}^{M_n} a_{i,k} \Phi(\mathbf{u}_k), \sum_{l=1}^{M_n} a_{j,l} \Phi(\mathbf{u}_l) \right\rangle_{\mathcal{H}} \\ &= \sum_{k=1}^{M_n} \sum_{l=1}^{M_n} a_{j,l} a_{i,k} \langle \Phi(\mathbf{u}_k), \Phi(\mathbf{u}_l) \rangle_{\mathcal{H}} = \sum_{k=1}^{M_n} \sum_{l=1}^{M_n} a_{j,l} a_{i,k} \kappa(\mathbf{u}_k, \mathbf{u}_l), \end{aligned}$$

for all  $k, l = 1, \dots, M_n$ . Note that  $a_{i,j} = 0$  for all  $j > i$ . This is the kick-off point of KRLS rationale.

In matrix notation, the respective loss of the KRLS minimization task at iteration  $n$  is given by

$$\mathcal{L}_n(\boldsymbol{\theta}) = \|\mathbf{y}_n - \mathbf{K}_n \boldsymbol{\theta}\|^2.$$

As  $\mathbf{K}_n \approx \mathbf{A}_n \cdot \tilde{\mathbf{K}}_n \cdot \mathbf{A}_n^T$ ,  $\mathcal{L}(\boldsymbol{\theta})$  can be recasted as

$$\mathcal{L}_n(\boldsymbol{\theta}) \approx \|\mathbf{y}_n - \mathbf{A}_n \tilde{\mathbf{K}}_n \mathbf{A}_n^T \boldsymbol{\theta}\|^2 = \|\mathbf{y}_n - \mathbf{A}_n \tilde{\mathbf{K}}_n \tilde{\boldsymbol{\theta}}\|^2 = \mathcal{L}_n(\tilde{\boldsymbol{\theta}}),$$

where  $\tilde{\theta} = A_n^T \theta$  is the new parameter to be optimized. Observe that while the original vector  $\theta_n \in \mathcal{R}^n$  is a  $n$ -dimensional vector, the new vector,  $\tilde{\theta}_n \in \mathcal{R}^{M_n}$ , is significantly smaller (depending on the sparsification strategy). The solution to the modified minimization task is

$$\begin{aligned}\tilde{\theta}_n &= (\tilde{K}_n^T A_n^T A_n \tilde{K}_n)^{-1} \tilde{K}_n^T A_n^T y_n \\ &= \tilde{K}_n^{-1} (A_n^T A_n)^{-1} \tilde{K}_n^{-T} \tilde{K}_n^T A_n^T y_n \\ &= K_n^{-1} P_n^{-1} A_n^T y_n,\end{aligned}\tag{17.65}$$

where  $P_n = A_n^T A_n$ , assuming that the inverse matrices exist. We distinguish the two different cases of the ALD sparsification and derive recursive relations for  $\tilde{\theta}_n$  accordingly.

**CASE I.** If  $\delta_n < \epsilon_0$ , then the data point arrived at iteration  $n$ , i.e.,  $(x_n, y_n)$ , is not added to the dictionary. Hence  $D_n = D_{n-1}$ ,  $M_n = M_{n-1}$ ,  $\tilde{K}_n = \tilde{K}_{n-1}$  and the expansion of  $\Phi(x_n)$  as a linear combination of the dictionary's elements is added to  $A_n$ , i.e.,

$$A_n = \begin{pmatrix} A_{n-1} \\ a_n^T \end{pmatrix},\tag{17.66}$$

where  $a_n$  is given by (17.62). Therefore,  $P_n = A_n^T A_n$  can be computed as

$$\begin{aligned}P_n &= A_n^T A_n = (A_{n-1}^T A_n) \begin{pmatrix} A_{n-1} \\ a_n^T \end{pmatrix} \\ &= A_{n-1}^T A_{n-1} + a_n a_n^T = P_{n-1} + a_n a_n^T.\end{aligned}$$

Applying the matrix inversion lemma, we take the recursive relation

$$P_n^{-1} = P_{n-1}^{-1} - \frac{P_{n-1}^{-1} a_n a_n^T P_{n-1}^{-1}}{1 + a_n^T P_{n-1}^{-1} a_n}.\tag{17.67}$$

Substituting in (17.65) and considering that  $A_n^T y_n = A_{n-1}^T y_{n-1} + a_n y_n$  we take

$$\begin{aligned}\tilde{\theta}_n &= \tilde{K}_n^{-1} P_n^{-1} A_n^T y_n \\ &= \tilde{K}_n^{-1} \left( P_{n-1}^{-1} - \frac{P_{n-1}^{-1} a_n a_n^T P_{n-1}^{-1}}{1 + a_n^T P_{n-1}^{-1} a_n} \right) (A_{n-1}^T y_{n-1} + a_n y_n) \\ &= \tilde{\theta}_{n-1} + \frac{\tilde{K}_n^{-1} P_{n-1}^{-1} a_n y_n - \tilde{K}_n^{-1} P_{n-1}^{-1} a_n a_n^T P_{n-1}^{-1} A_{n-1}^T y_{n-1}}{1 + a_n^T P_{n-1}^{-1} a_n} \\ &= \tilde{\theta}_{n-1} + \frac{K_n^{-1} P_{n-1}^{-1} a_n (y_n - a_n^T P_{n-1}^{-1} A_{n-1}^T y_{n-1})}{1 + a_n^T P_{n-1}^{-1} a_n}.\end{aligned}$$

However, relation (17.65) implies that  $\tilde{\mathbf{K}}_{n-1}\tilde{\boldsymbol{\theta}}_{n-1} = \mathbf{P}_{n-1}^{-1}\mathbf{A}_{n-1}^T\mathbf{y}_{n-1}$ . Hence,

$$\begin{aligned}\tilde{\boldsymbol{\theta}}_n &= \tilde{\boldsymbol{\theta}}_{n-1} + \frac{\mathbf{K}_n^{-1}\mathbf{P}_{n-1}^{-1}\mathbf{a}_n(y_n - \mathbf{a}_n^T\tilde{\mathbf{K}}_{n-1}\tilde{\boldsymbol{\theta}}_{n-1})}{1 + \mathbf{a}_n^T\mathbf{P}_{n-1}^{-1}\mathbf{a}_n} \\ &= \tilde{\boldsymbol{\theta}}_{n-1} + \frac{\mathbf{K}_n^{-1}\mathbf{P}_{n-1}^{-1}\mathbf{a}_n(y_n - \boldsymbol{\beta}_n^T\tilde{\boldsymbol{\theta}}_{n-1})}{1 + \mathbf{a}_n^T\mathbf{P}_{n-1}^{-1}\mathbf{a}_n} \\ &= \tilde{\boldsymbol{\theta}}_{n-1} + \frac{\mathbf{K}_n^{-1}\mathbf{P}_{n-1}^{-1}\mathbf{a}_ne_n}{1 + \mathbf{a}_n^T\mathbf{P}_{n-1}^{-1}\mathbf{a}_n},\end{aligned}$$

where the last relations are generated by substituting  $\boldsymbol{\beta}_n^T = \mathbf{a}_n^T\tilde{\mathbf{K}}_{n-1}$  (see relation (17.62)) and considering that the estimated output at time index  $n$  by the learning system is  $\hat{y}_n = \boldsymbol{\beta}_n^T\tilde{\boldsymbol{\theta}}_n = \mathbf{a}_n^T\tilde{\mathbf{K}}_n\tilde{\boldsymbol{\theta}}_n$ .

**CASE II.** If  $\delta_n > \epsilon_0$ , then the data point arrived at iteration  $n$ , i.e.,  $(\mathbf{x}_n, y_n)$ , is added to the dictionary, i.e.,  $\mathcal{D}_n = \mathcal{D}_{n-1} \cup \{\mathbf{x}_n\}$ ,  $M_n = M_{n-1} + 1$  and the matrices  $\mathbf{A}_n$  and  $\tilde{\mathbf{K}}_n$  are constructed as follows

$$\mathbf{A}_n = \begin{pmatrix} \mathbf{A}_{n-1} & \mathbf{0} \\ \mathbf{0}^T & 1 \end{pmatrix}, \quad \tilde{\mathbf{K}}_n = \begin{pmatrix} \tilde{\mathbf{K}}_{n-1} & \boldsymbol{\beta}_n \\ \boldsymbol{\beta}_n^T & \kappa(\mathbf{x}_n, \mathbf{x}_n) \end{pmatrix}.$$

Moreover,

$$\mathbf{P}_n = \mathbf{A}_n^T\mathbf{A}_n = \begin{pmatrix} \mathbf{A}_{n-1}^T & \mathbf{0}^T \\ \mathbf{0} & 1 \end{pmatrix} \begin{pmatrix} \mathbf{A}_{n-1} & \mathbf{0} \\ \mathbf{0}^T & 1 \end{pmatrix} = \begin{pmatrix} \mathbf{A}_{n-1}^T\mathbf{A}_{n-1} & \mathbf{0} \\ \mathbf{0}^T & 1 \end{pmatrix}.$$

Hence, applying the matrix inversion lemma to  $\tilde{\mathbf{K}}_n$  and substituting  $\mathbf{a}_n = \tilde{\mathbf{K}}_{n-1}^{-1}\boldsymbol{\beta}_n$ , we have

$$\tilde{\mathbf{K}}_n^{-1} = \begin{pmatrix} \tilde{\mathbf{K}}_{n-1}^{-1} + \frac{1}{\delta_n}\tilde{\mathbf{K}}_{n-1}^{-1}\boldsymbol{\beta}_n\boldsymbol{\beta}_n^T\tilde{\mathbf{K}}_{n-1}^{-1} & -\frac{1}{\delta_n}\tilde{\mathbf{K}}_{n-1}^{-1}\boldsymbol{\beta}_n \\ -\frac{1}{\delta_n}\boldsymbol{\beta}_n^T\tilde{\mathbf{K}}_n^{-1} & \frac{1}{\delta_n} \end{pmatrix} = \frac{1}{\delta_n} \begin{pmatrix} \delta_n\tilde{\mathbf{K}}_{n-1}^{-1} + \mathbf{a}_n\mathbf{a}_n^T & -\mathbf{a}_n \\ -\mathbf{a}_n^T & 1 \end{pmatrix}.$$

and

$$\mathbf{P}_n^{-1} = \begin{pmatrix} (\mathbf{A}_n^T\mathbf{A}_n)^{-1} & \mathbf{0} \\ \mathbf{0}^T & 1 \end{pmatrix} = \begin{pmatrix} \mathbf{P}_{n-1}^{-1} & \mathbf{0} \\ \mathbf{0}^T & 1 \end{pmatrix}.$$

Observe that while we replace  $\tilde{\mathbf{K}}_{n-1}^{-1}\boldsymbol{\beta}_n$  by  $\mathbf{a}_n$  using relation (17.62), the actual  $n$ th row of  $\mathbf{A}_n$  is  $(0, 0, \dots, 0, 1)$ . Substituting in (17.65) we take:

$$\begin{aligned}
\tilde{\theta}_n &= \frac{1}{\delta_n} \begin{pmatrix} \delta_n \tilde{K}_{n-1}^{-1} + \mathbf{a}_n \mathbf{a}_n^T & -\mathbf{a}_n \\ -\mathbf{a}_n^T & 1 \end{pmatrix} \begin{pmatrix} \mathbf{P}_{n-1}^{-1} & \mathbf{0} \\ \mathbf{0}^T & 1 \end{pmatrix} \begin{pmatrix} \mathbf{A}_{n-1}^T & \mathbf{0}^T \\ \mathbf{0} & 1 \end{pmatrix} \begin{pmatrix} \mathbf{y}_{n-1} \\ y_n \end{pmatrix} \\
&= \frac{1}{\delta_n} \begin{pmatrix} \delta_n \tilde{K}_{n-1}^{-1} \mathbf{P}_{n-1}^{-1} \mathbf{A}_{n-1}^T \mathbf{y}_{n-1} + \mathbf{a}_n \mathbf{a}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{A}_{n-1}^T \mathbf{y}_{n-1} - \mathbf{a}_n y_n \\ -\mathbf{a}_n^T \mathbf{P}_{n-1}^{-1} \mathbf{A}_{n-1}^T \mathbf{y}_{n-1} + y_n \end{pmatrix} \\
&= \frac{1}{\delta_n} \begin{pmatrix} \delta_n \tilde{\theta}_{n-1} + \mathbf{a}_n \mathbf{a}_n^T \tilde{K}_{n-1} \tilde{\theta}_{n-1} - \mathbf{a}_n y_n \\ -\mathbf{a}_n^T \tilde{K}_{n-1} \tilde{\theta}_{n-1} + y_n \end{pmatrix} \\
&= \frac{1}{\delta_n} \begin{pmatrix} \delta_n \tilde{\theta}_{n-1} + \mathbf{a}_n \beta_n^T \tilde{\theta}_{n-1} - \mathbf{a}_n y_n \\ -\beta_n^T \tilde{\theta}_{n-1} + y_n \end{pmatrix} \\
&= \begin{pmatrix} \tilde{\theta}_{n-1} - \frac{\mathbf{a}_n}{\delta_n} e_n \\ -\frac{e_n}{\delta_n} \end{pmatrix}.
\end{aligned}$$

The procedure is summarized in Algorithm 32. The KRLS algorithm has complexity  $O(M_n^2)$ , at time  $n$ , where  $M_n$  is the size of the dictionary. Note, that we developed the specific recursive strategy assuming the invertibility of  $\tilde{K}_n$  and  $\mathbf{A}_n^T \mathbf{A}_n$  for each  $n$ . For the case of the RKHS induced by the Gaussian kernel, which is the most popular kernel for practical applications, we can prove that  $\tilde{K}_n$  is indeed invertible. Furthermore, by construction, the matrix  $\mathbf{A}_n$  has full-rank. Hence,  $\mathbf{A}_n^T \mathbf{A}_n$  is strictly positive definite and thus invertible too.

A methodology of similar spirit to the KRLS, which also takes advantage of the loss function (17.58) in the Support Vector Machines (SVM) rationale, can be found in [57–60]. An alternative path to the KRLS was followed in [61], via a formulation based on Gaussian Processes. Such an approach allows for an explicit forgetting factor mechanism to be incorporated in the adaptation flow. An alternative philosophy for forgetting past data in kernel-based adaptive schemes, in the framework of regularization, which can efficiently be implemented via projections, will be discussed in Section 1.17.7.

#### 1.17.6.6.1 Simulation results

In order to study the behavior of the KRLS, we consider some nonlinear channel equalization set-ups similar to the ones used in Section 1.17.6.2.2. In the first experiment, the nonlinear channel consists of a linear filter:

$$t_n = -0.8 \cdot y_n + 0.7 \cdot y_{n-1} - 0.6 \cdot y_{n-2} + 0.4 \cdot y_{n-3}$$

and a memoryless nonlinearity

$$q_n = t_n + 0.08 \cdot t_n^2. \quad (17.68)$$

The input signal that was fed to the channel followed the Gaussian distribution with zero mean and unity variance. At the receiver end of the channels, the signal is corrupted by white Gaussian noise and then observed as  $x_n$ . The level of the noise was set to 15dB. To solve the equalization task, we apply the KRLS-based learning systems to the set of samples  $(\mathbf{x}_n, y_n) := ((x_n, x_{n-1}, \dots, x_{n-l+1}), y_{n-D})$ , where  $l > 0$  is the equalizer's length and  $D$  the equalization time delay. Figure 17.23 shows the performance of KRLS compared to KLMS over a set of 30 training sequences consisting of 5000 samples each. The Quantization sparsification strategy was adopted for the KLMS, as it demonstrates superior performance

**Algorithm 32.** Kernel Recursive Least Squares (KRLS)

---

**Require:** The data  $((\mathbf{x}_n, y_n))_{n \in \mathcal{N}_*}$ , and the ALD parameter  $\epsilon_0$ .

- 1: Set  $\tilde{\mathbf{K}}^{-1} = [1/\kappa(\mathbf{x}_1, \mathbf{x}_1)], \mathbf{P}^{-1} = [1], \tilde{\boldsymbol{\theta}} = [y_1/\kappa(\mathbf{x}_1, \mathbf{x}_1)], M = 1$ .
- 2: **for**  $n = 2, 3, \dots$  **do**
- 3:   Compute  $\boldsymbol{\beta} = (\kappa(\mathbf{u}_1, \mathbf{x}_n), \dots, \kappa(\mathbf{u}_M, \mathbf{x}_n))^T$ .
- 4:   Compute the learning system's output:  $\hat{y}_n = \boldsymbol{\theta}^T \boldsymbol{\beta}$ .
- 5:   Compute the error:  $e_n = y_n - \hat{y}_n$ .
- 6:   FOR ALD TEST:
- 7:     Compute  $\mathbf{a} = \tilde{\mathbf{K}}^{-1} \boldsymbol{\beta}$ .
- 8:     Compute  $\delta = \kappa(\mathbf{x}_n, \mathbf{x}_n) - \boldsymbol{\beta}^T \mathbf{a}$ .
- 9:     **if**  $\delta > \epsilon_0$  **then**
- 10:       Include the new sample to the dictionary:  $\mathcal{D} = \mathcal{D} \cup \{\mathbf{x}_n\}, M = M + 1$ .
- 11:       Update  $\tilde{\mathbf{K}}^{-1} = \frac{1}{\delta} \begin{pmatrix} \delta \tilde{\mathbf{K}}^{-1} + \mathbf{a} \mathbf{a}^T & -\mathbf{a} \\ -\mathbf{a} & 1 \end{pmatrix}$ .
- 12:       Update  $\mathbf{P}^{-1} = \begin{pmatrix} \mathbf{P}^{-1} & \mathbf{0} \\ \mathbf{0}^T & 1 \end{pmatrix}$ .
- 13:       Update solution:  $\tilde{\boldsymbol{\theta}} = \begin{pmatrix} \tilde{\boldsymbol{\theta}} - \frac{\mathbf{a}}{\delta} e_n \\ -\frac{e_n}{\delta} \end{pmatrix}$ .
- 14:     **else**
- 15:        $\mathbf{q} = \frac{\mathbf{P}^{-1} \mathbf{a}}{1 + \mathbf{a}^T \mathbf{P}^{-1} \mathbf{a}}$ .
- 16:       Update  $\mathbf{P}^{-1} = \mathbf{P}^{-1} - \mathbf{q} \mathbf{a}^T \mathbf{P}^{-1}$ .
- 17:       Update solution:  $\tilde{\boldsymbol{\theta}} = \tilde{\boldsymbol{\theta}} + \mathbf{K}^{-1} \mathbf{q} e_n$ .
- 18:     **end if**
- Output:** The vector  $\tilde{\boldsymbol{\theta}} \in \mathbb{R}^M$  and the dictionary  $\mathcal{D} = \{\mathbf{u}_1, \dots, \mathbf{u}_M\}$ .
- 19: **end for**

---

(see Section 1.17.6.2.2). The sparsification parameters were set to  $\epsilon_0 = 0.1$  for the KRLS, and  $\delta = 4$  for the quantization of KLMS. It is clear that KRLS significantly outperforms KLMS both in terms of convergence and sparsity.

In the second experiment, the linear part of the channel is reduced, i.e.,

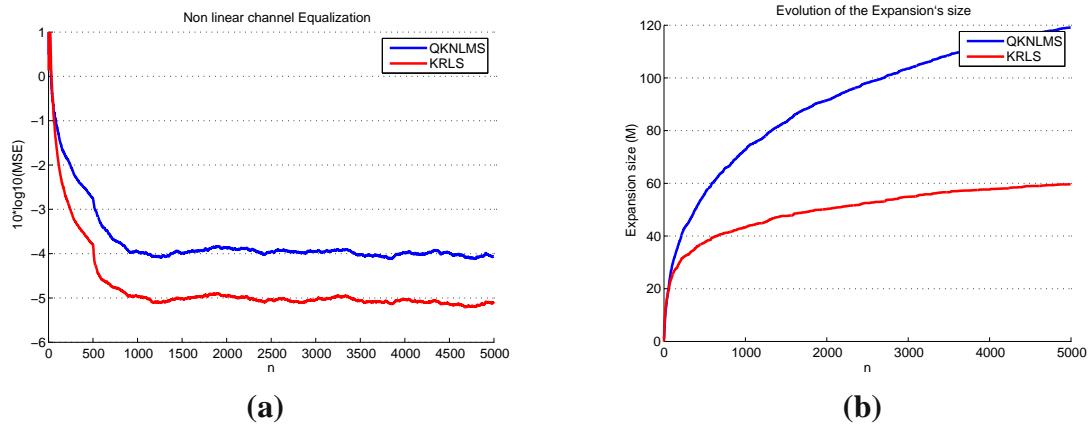

$$t_n = -0.8 \cdot y_n + 0.7 \cdot y_{n-1} \quad (17.69)$$

and the memoryless nonlinearity remains the same. Figure 17.24 shows the performance of the two algorithms over a set of 30 training sequences consisting of 5000 samples each. The parameters used for sparsification were set to  $\epsilon_0 = 0.1$  for the KRLS, and  $\delta = 6$  for the quantization of KLMS.

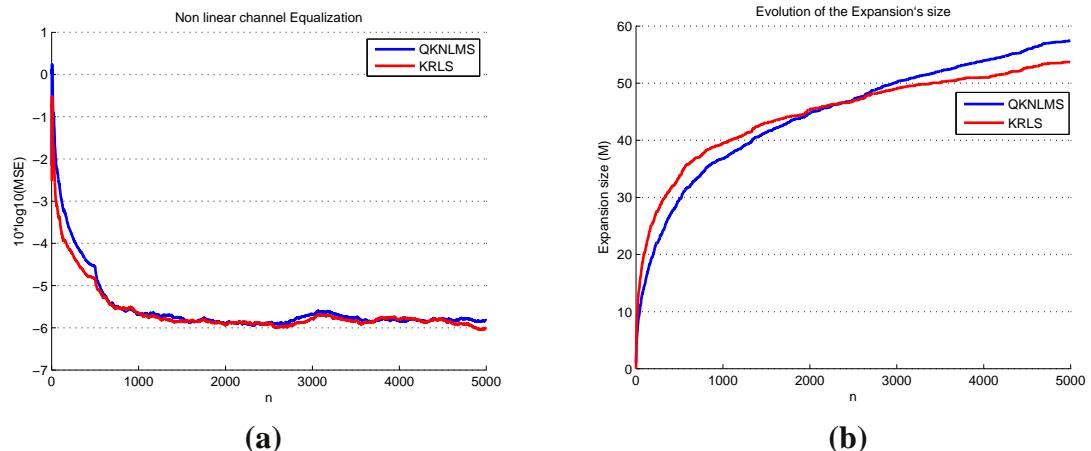

Finally, in the third experiment, the linear part is identical to (17.69), while the non linear part is

$$q_n = t_n + 0.25 \cdot t_n^2 + 0.11 \cdot t_n^3 \quad (17.70)$$

and the memoryless nonlinearity remains the same. Figure 17.25 shows the performance of the two algorithms over a set of 30 training sequences consisting of 5000 samples each, using the same parameters for the sparsification as in the second experiment. In general, KRLS shows the best performance, as

**FIGURE 17.23**

(a) Learning curves of the quantized KNLMS ( $\mu = 1/2$ ), and KRLS based on the ALD sparsification scenario ( $\epsilon_0 = 0.1$ ) using the Gaussian kernel ( $\sigma = 5$ ), for the equalization problem (17.68) (filter length  $l = 5$ , time delay  $D = 2$ ). The quantization size was set to  $\delta = 4$ . (b) Evolution of the expansion's size at each time instant, for each algorithm.

**FIGURE 17.24**

(a) Learning curves of the quantized KNLMS ( $\mu = 1/2$ ), and KRLS based on the ALD sparsification scenario ( $\epsilon_0 = 0.1$ ) using the Gaussian kernel ( $\sigma = 5$ ), for the equalization problem (17.69) (filter length  $l = 5$ , time delay  $D = 2$ ). The quantization size was set to  $\delta = 6$ . (b) Evolution of the expansion's size at each time instant, for each algorithm.

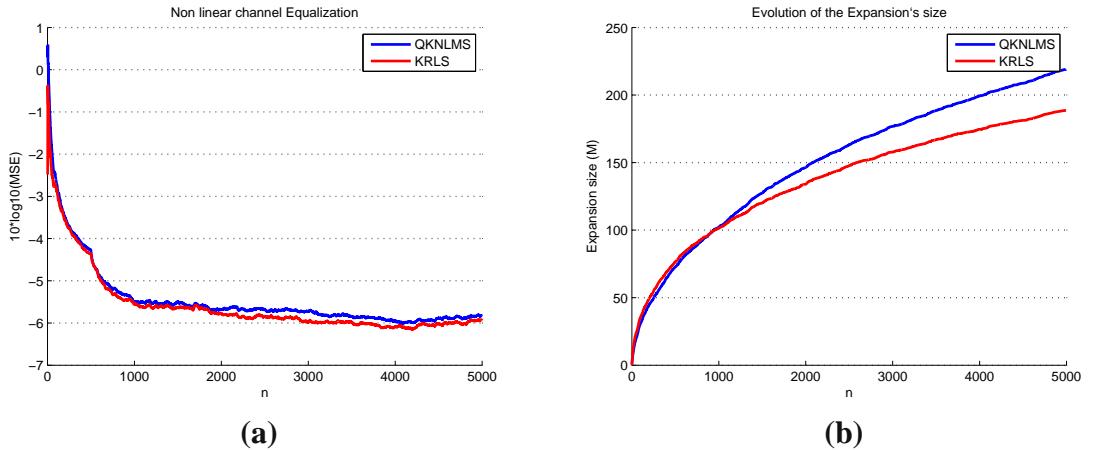

FIGURE 17.25

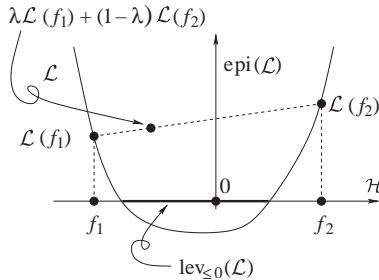

(a) Learning curves of the quantized KNLMS ( $\mu = 1/2$ ), and KRLS based on the ALD sparsification scenario ( $\epsilon_0 = 0.1$ ) using the Gaussian kernel ( $\sigma = 5$ ), for the equalization problem (17.70) (filter length  $l = 5$ , time delay  $D = 2$ ). The quantization size was set to  $\delta = 4$ . (b) Evolution of the expansion's size at each time instant, for each algorithm.

it appears to achieve lower or the same steady state MSE as the QKLMS using somewhat sparser representations. However, there are cases where its performance is quite similar to the QKNLMS. The code for the experiments presented in this section can be found in [<http://bouboulis.mysch.gr/kernels.html>](http://bouboulis.mysch.gr/kernels.html).

## 1.17.7 A convex analytic toolbox for online learning

During the last ten years or so, convex analysis [34, 62] has emerged as the main stage where mathematically sound optimization tools for signal processing and machine learning tasks are developed. This section attempts to give a short introduction on several convex analytic arguments which are central to modern optimization techniques. We do not follow the mainstream of the literature which develops around the classical Lagrange multipliers' methodology [63] or the powerful interior point algorithms [64], but instead, we abide by the less popular, to the engineering community, *operator/mapping* and *fixed point theoretic* framework [65–67], established in general Hilbert spaces. The reason to adopt such a framework is its geometrical nature, generality, and ability to engulf numerous modern tools of convex and variational analysis [62, 65]. Our objective here is to highlight a few fragments of this powerful framework. For more details, and for a deeper view of the subject, the interested reader is referred to [62, 65–67].

In the sequel, the stage of our discussion is a real Hilbert space  $\mathcal{H}$ , equipped with an inner product  $\langle \cdot, \cdot \rangle$ , and with an induced norm  $\|\cdot\| := \sqrt{\langle \cdot, \cdot \rangle}$ . A sequence  $(f_n)_{n \in \mathcal{N}}$  of elements of  $\mathcal{H}$  is said to converge *strongly* to an  $f_* \in \mathcal{H}$ , and it will be denoted as  $f_n \rightarrow f_*$ , if  $\lim_{n \rightarrow \infty} \|f_n - f_*\| = 0$ . The sequence  $(f_n)_{n \in \mathcal{N}}$  is said to converge *weakly* to an  $f_* \in \mathcal{H}$ , and it will be denoted as  $f_n \rightharpoonup f_*$ ,

**FIGURE 17.26**

A convex function  $\mathcal{L}$ , its epigraph, and the lower level set of  $\mathcal{L}$  at height 0.

if  $\forall g \in \mathcal{H}, \lim_{n \rightarrow \infty} \langle f_n - f_*, g \rangle = 0$ . Strong convergence implies the weak one, but, in general, the converse does not hold true in Hilbert spaces. However, it does hold true in the case of Euclidean spaces.

We start, now, with few notions of fundamental importance to convex analysis.

### 1.17.7.1 Closed convex sets and metric projection mappings

**Definition 33 (Convex set, convex function).** A non-empty subset  $C$  of  $\mathcal{H}$  is called *convex* if  $\forall f_1, f_2 \in C$ , and  $\forall \lambda \in [0, 1]$ , the following holds true:  $\lambda f_1 + (1 - \lambda) f_2 \in C$ .

Moreover, a function  $\mathcal{L} : \mathcal{H} \rightarrow \mathbb{R}$  is called *convex* if  $\forall f_1, f_2 \in \mathcal{H}$ , and  $\forall \lambda \in [0, 1]$ ,  $\mathcal{L}(\lambda f_1 + (1 - \lambda) f_2) \leq \lambda \mathcal{L}(f_1) + (1 - \lambda) \mathcal{L}(f_2)$ . The function  $f$  is called *strictly convex* if  $\forall \lambda \in (0, 1)$  and  $\forall f_1, f_2 \in \mathcal{H}$ , such that  $f_1 \neq f_2$ , we have  $\mathcal{L}(\lambda f_1 + (1 - \lambda) f_2) < \lambda \mathcal{L}(f_1) + (1 - \lambda) \mathcal{L}(f_2)$ . Finally, if there exists a  $\beta > 0$  such that  $\forall \lambda \in (0, 1)$  and  $\forall f_1, f_2 \in \mathcal{H}$ , the following holds true:

$$\mathcal{L}(\lambda f_1 + (1 - \lambda) f_2) + \lambda(1 - \lambda) \frac{\beta}{2} \|f_1 - f_2\|^2 \leq \lambda \mathcal{L}(f_1) + (1 - \lambda) \mathcal{L}(f_2),$$

then  $\mathcal{L}$  is called *strongly convex with constant  $\beta$* . ◇

The *epigraph* of a convex function  $\mathcal{L}$  is defined as the set

$$\text{epi}(\mathcal{L}) := \{(h, r) \in \mathcal{H} \times \mathbb{R} : \mathcal{L}(h) \leq r\}.$$

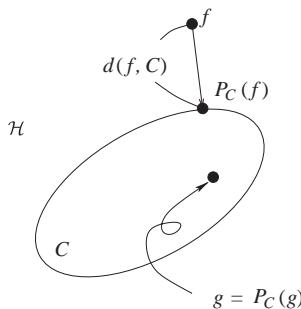

In other words, the epigraph of  $\mathcal{L}$  is the set of all points of  $\mathcal{H} \times \mathbb{R}$  which belong to and lie above the graph of  $\mathcal{L}$ . Moreover, given a real number  $\xi$ , the *lower level set of  $\mathcal{L}$  at height  $\xi$*  is defined as the set

$$\text{lev}_{\leq \xi}(\mathcal{L}) := \{h \in \mathcal{H} : \mathcal{L}(h) \leq \xi\}.$$

For the geometry behind the previous definitions, see Figure 17.26. A simple inspection of Figure 17.26 suggests that  $\mathcal{L}$  is convex if and only if  $\text{epi}(\mathcal{L})$  is convex.

**Definition 34 (The metric distance function).** Given a closed convex set  $C \subset \mathcal{H}$ , the *metric distance function to  $C$*  is defined as follows:

$$\forall f \in \mathcal{H}, \quad d(f, C) := \inf \{\|f - g\| : g \in C\}.$$

**FIGURE 17.27**

A closed convex subset of  $\mathcal{H}$ , and the associated metric projection mapping.

In the case where the set  $C$  is a singleton, i.e., it contains a single element  $C = \{g\}$ , then, clearly, the metric distance  $d(f, C)$  becomes our familiar distance of  $f$  from  $g$ :  $d(f, g)$ .

It can be easily verified by the triangle inequality of  $\|\cdot\|$ , that  $d(\cdot, C)$  is a convex function. Moreover, notice that  $\text{lev}_{\leq 0}(d(\cdot, C)) = C$ .  $\diamond$

**Definition 35 (The metric projection mapping).** Given a non-empty *closed* convex set  $C \subset \mathcal{H}$ , the *metric projection mapping onto*  $C$  is defined as the operator that maps to each  $f \in \mathcal{H}$  the *unique*  $P_C(f) \in C$  such that

$$\|f - P_C(f)\| = d(f, C).$$

In other words, the point  $P_C(f)$  is the unique minimizer of the function  $\|f - g\|$ ,  $g \in C$ . Obviously, in the case where  $g \in C$ , then  $P_C(g) = g$ . For the geometry behind the mapping  $P_C$ , see Figure 17.27.  $\diamond$

Let us give now a couple of examples of closed convex sets in order to illustrate the previous concepts.

**Example 36 (Closed ball).** Given a radius  $\Delta > 0$  and a center  $g_0 \in \mathcal{H}$ , the *closed ball*  $B[g_0, \Delta]$  is defined as the following closed convex set

$$B[g_0, \Delta] := \{g \in \mathcal{H} : \|g - g_0\| \leq \Delta\}.$$

The associated metric projection mapping  $P_{B[g_0, \Delta]}$  can be easily verified to be

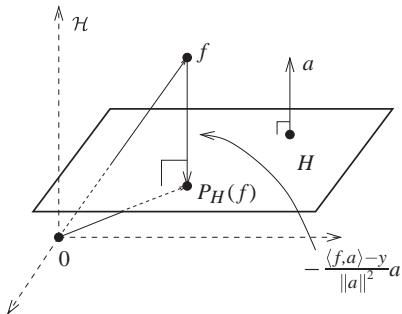

$$P_{B[g_0, \Delta]}(f) = g_0 + \frac{\Delta}{\max\{\Delta, \|f - g_0\|\}}(f - g_0), \quad \forall f \in \mathcal{H}.$$

**Example 37 (Hyperplane).** A *hyperplane*  $H$  is the closed convex subset of  $\mathcal{H}$  which is defined as

$$H := \{g \in \mathcal{H} : \langle a, g \rangle = y\},$$

for some nonzero  $a \in \mathcal{H}$  and some  $y \in \mathcal{R}$ . The (metric) projection mapping  $P_H$  onto  $H$  is given as follows:

$$P_H(f) = f - \frac{\langle f, a \rangle - y}{\|a\|^2}a, \quad \forall f \in \mathcal{H}. \tag{17.71}$$

**FIGURE 17.28**

A hyperplane and its associated projection mapping.

For the geometry behind the previous concepts, see Figure 17.28. Notice that  $a$  stands as the *normal vector* of the hyperplane.

In the special case of an RKHS  $\mathcal{H}$ , which is associated to a kernel function  $\kappa$ , let  $a := \kappa(\mathbf{x}, \cdot)$ , for some  $\mathbf{x} \in \mathcal{R}^l$ . Then, due to the kernel trick, the hyperplane  $H$  obtains a simple form:  $H = \{g \in \mathcal{H} : g(\mathbf{x}) = y\}$ . Moreover, the (metric) projection mapping becomes as follows:

$$P_H(f) = f - \frac{f(\mathbf{x}) - y}{\kappa(\mathbf{x}, \mathbf{x})} \kappa(\mathbf{x}, \cdot), \quad \forall f \in \mathcal{H}. \quad (17.72)$$

The previous example helps us calculate the metric projection mapping onto the following renowned closed convex set.

**Example 38 ((Closed) hyperslab).** A *(closed) hyperslab*  $S[\epsilon]$ , where  $\epsilon > 0$  is a user-defined parameter, is defined as the following closed convex set:

$$S[\epsilon] := \{g \in \mathcal{H} : |\langle g, a \rangle - y| \leq \epsilon\},$$

where  $a$  is a non-zero element of  $\mathcal{H}$ , and  $y \in \mathcal{R}$ . Geometrically, a hyperslab can be visualized as the set of all those points which belong onto and between the following two “parallel” hyperplanes;  $H_{+\epsilon} := \{g \in \mathcal{H} : \langle g, a \rangle = y + \epsilon\}$  and  $H_{-\epsilon} := \{g \in \mathcal{H} : \langle g, a \rangle = y - \epsilon\}$ . Based on this fundamental observation, the metric projection mapping  $P_{S[\epsilon]}$  can be directly calculated by employing the results of Example 37;  $\forall f \in \mathcal{H}$ ,

$$P_{S[\epsilon]}(f) = \begin{cases} P_{H_{+\epsilon}}(f), & \text{if } \langle f, a \rangle > y + \epsilon, \\ f, & \text{if } |\langle f, a \rangle - y| \leq \epsilon, \\ P_{H_{-\epsilon}}(f), & \text{if } \langle f, a \rangle < y - \epsilon. \end{cases} = \begin{cases} f - \frac{\langle f, a \rangle - y - \epsilon}{\|a\|^2} a, & \text{if } \langle f, a \rangle > y + \epsilon, \\ f, & \text{if } |\langle f, a \rangle - y| \leq \epsilon, \\ f - \frac{\langle f, a \rangle - y + \epsilon}{\|a\|^2} a, & \text{if } \langle f, a \rangle < y - \epsilon. \end{cases} \quad (17.73)$$

As in Example 37, in the special case of an RKHS  $\mathcal{H}$ , which is associated to a kernel function  $\kappa$ , let  $a := \kappa(\mathbf{x}, \cdot)$ , for some  $\mathbf{x} \in \mathcal{R}^l$ . Then, under such a scenario, (17.73) takes the following special form:  $\forall f \in \mathcal{H}$ ,

$$P_{S[\epsilon]}(f) = \begin{cases} f - \frac{f(\mathbf{x}) - y - \epsilon}{\kappa(\mathbf{x}, \mathbf{x})} \kappa(\mathbf{x}, \cdot), & \text{if } f(\mathbf{x}) > y + \epsilon, \\ f, & \text{if } |f(\mathbf{x}) - y| \leq \epsilon, \\ f - \frac{f(\mathbf{x}) - y + \epsilon}{\kappa(\mathbf{x}, \mathbf{x})} \kappa(\mathbf{x}, \cdot), & \text{if } f(\mathbf{x}) < y - \epsilon. \end{cases} \quad (17.74)$$

**Example 39 (Affine set).** Assume a positive integer  $m$ , a number of nonzero elements  $\{a_1, a_2, \dots, a_m\}$  of  $\mathcal{H}$ , and a set of real numbers  $\{y_1, y_2, \dots, y_m\}$ . Upon defining the hyperplanes  $H_i := \{g \in \mathcal{H} : \langle a_i, g \rangle = y_i\}$ ,  $\forall i = 1, \dots, m$ , let the set of all common points of the previous hyperplanes:

$$V := \bigcap_{i=1}^m H_i. \quad (17.75)$$

Since the previous  $V$  might be empty, let us generalize it as follows in order to cover also such an unpleasant situation. Define the linear mapping  $A : \mathcal{H} \rightarrow \mathcal{R}^m$  as follows:

$$A(f) := \begin{bmatrix} \langle a_1, f \rangle \\ \vdots \\ \langle a_m, f \rangle \end{bmatrix}, \quad \forall f \in \mathcal{H}.$$

Notice here that in the case where our Hilbert space  $\mathcal{H}$  becomes a Euclidean one, e.g.,  $\mathcal{R}^l$ , and the elements  $\{a_1, a_2, \dots, a_m\}$  become the  $l$ -dimensional vectors  $\{\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_m\}$ , then the mapping  $A$  is nothing but the following matrix  $\mathbf{A} := [\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_m]^T$ , where the superscript  $T$  stands for transposition.

If we let  $\mathbf{y} := [y_1, y_2, \dots, y_m]^T$ , then define

$$V := \operatorname{argmin}_{g \in \mathcal{H}} \|\mathbf{y} - A(g)\|^2. \quad (17.76)$$

Notice that if the previous minimum attains the value 0, then the intersection in (17.75) is nonempty. Hence, the Definition (17.76) generalizes the special (17.75) one. It can be shown that  $V$  is a nonempty *affine* set. Notice also here that in the case where our Hilbert space  $\mathcal{H}$  becomes a Euclidean one  $\mathcal{R}^l$ , then the affine set of (17.76) becomes the classical  $V = \operatorname{argmin}_{\theta \in \mathcal{R}^l} \|\mathbf{y} - \mathbf{A}\theta\|^2$ , which is often met in least-squares penalized learning tasks.

Under the previous setting, it can be verified [68] that the metric projection mapping  $P_V$  onto the affine set  $V$  of (17.76) is given as:

$$P_V(f) = f + A^\dagger (\mathbf{y} - A(f)), \quad \forall f \in \mathcal{H}, \quad (17.77)$$

where  $A^\dagger : \mathcal{R}^m \rightarrow \mathcal{H}$  stands for the (Moore-Penrose) pseudoinverse mapping of  $A$ .

Upon defining the adjoint mapping  $A^*$  of  $A$  as the mapping  $A^* : \mathcal{R}^m \rightarrow \mathcal{H}$  which satisfies  $\xi^T A(f) = \langle f, A^*(\xi) \rangle$ ,  $\forall f \in \mathcal{H}, \forall \xi \in \mathcal{R}^m$ , then it can be verified that

$$A^*(\xi) = \sum_{i=1}^m \xi_i a_i, \quad \forall \xi \in \mathcal{R}^m.$$

Notice that in the case where our Hilbert space  $\mathcal{H}$  becomes a Euclidean  $\mathcal{R}^l$  one, then the adjoint mapping is nothing but the transpose of  $A$ , i.e.,  $A^* = A^T$ . A classical result states that  $A^\dagger = A^* (AA^*)^{-1}$  [69]. Notice that the mapping  $AA^* : \mathcal{R}^m \rightarrow \mathcal{R}^m$  is nothing but the Gram matrix

$$AA^* = \begin{bmatrix} \langle a_1, a_1 \rangle & \langle a_1, a_2 \rangle & \cdots & \langle a_1, a_m \rangle \\ \langle a_2, a_1 \rangle & \langle a_2, a_2 \rangle & \cdots & \langle a_2, a_m \rangle \\ \vdots & \vdots & \ddots & \vdots \\ \langle a_m, a_1 \rangle & \langle a_m, a_2 \rangle & \cdots & \langle a_m, a_m \rangle \end{bmatrix}.$$

In the case where the Hilbert space  $\mathcal{H}$  becomes an RKHS associated to a kernel function  $\kappa$ , and  $a_i := \kappa(\mathbf{x}_i, \cdot)$ , for some  $\mathbf{x}_i \in \mathcal{R}^l$ ,  $\forall i = 1, 2, \dots, m$ , then the previous Gram matrix  $AA^*$  is usually called the *kernel matrix* associated to the set  $\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_m\}$ ; the  $(i, j)$ th element of  $AA^*$  becomes  $\kappa(\mathbf{x}_i, \mathbf{x}_j)$ .

### 1.17.7.2 The subgradient

**Definition 40 (Subdifferential, subgradient).** Given a convex function  $\mathcal{L}$ , defined on  $\mathcal{H}$ , and a point  $f \in \mathcal{H}$ , the *subdifferential of  $\mathcal{L}$  at  $f$*  is defined as the set-valued operator  $\partial\mathcal{L}$  that maps to  $f$  the set of all the *subgradients of  $\mathcal{L}$  at  $f$* , i.e.,

$$\partial\mathcal{L}(f) := \{g \in \mathcal{H} : \langle g, h - f \rangle + \mathcal{L}(f) \leq \mathcal{L}(h), \forall h \in \mathcal{H}\}. \quad \diamond$$

Let us give now a geometrical point of view to the notion of the subgradient. Fix an  $f \in \mathcal{H}$ , and choose any subgradient  $g \in \partial\mathcal{L}(f)$ . This subgradient defines the following hyperplane in the space  $\mathcal{H} \times \mathcal{R}$ :

$$\mathcal{X}_g := \{(h, r) \in \mathcal{H} \times \mathcal{R} : 0 = \langle g, h - f \rangle + \mathcal{L}(f) - r\}. \quad (17.78)$$

Moreover, the following interesting result can be easily obtained.

**Proposition 41 (Geometric interpretation of the subgradient).** Given a convex function  $\mathcal{L}$ , assume without any loss of generality that  $\text{lev}_{\leq 0}(\mathcal{L}) \neq \emptyset$  (if not, a vertical shift of the  $\mathcal{L}$  downwards by some constant suffices to guarantee the non-emptiness of  $\text{lev}_{\leq 0}(\mathcal{L})$ ). Assume, also, an  $f \in \mathcal{H} \setminus \text{lev}_{\leq 0}(\mathcal{L})$  (see Figure 17.29). Then, for any subgradient  $g$  of  $\mathcal{L}$  at  $f$ , i.e.,  $g \in \partial\mathcal{L}(f)$ , the  $\mathcal{X}_g$ , defined in (17.78), acts as a separating hyperplane between the point  $(f, 0)$  and  $\text{epi}(\mathcal{L})$ .  $\diamond$

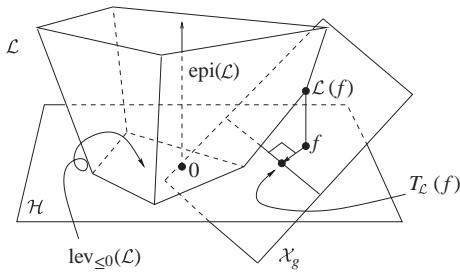

**Proof.** Since  $f \notin \text{lev}_{\leq 0}(\mathcal{L})$ , it is easy to see that  $\mathcal{L}(f) > 0$ . Hence, for the point  $(f, 0)$ ,

$$\langle g, f - f \rangle + \mathcal{L}(f) - 0 = \mathcal{L}(f) > 0. \quad (17.79)$$

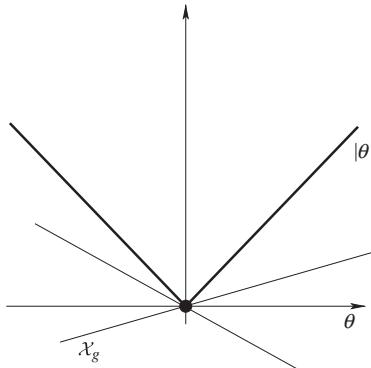

On the other hand, for every  $(h, r) \in \text{epi}(\mathcal{L})$ , the definition of the subgradient suggests that

$$\langle g, h - f \rangle + \mathcal{L}(f) - r \leq \langle g, h - f \rangle + \mathcal{L}(f) - \mathcal{L}(h) \leq 0. \quad (17.80)$$

A simple inspection of (17.79) and (17.80) implies that  $\mathcal{X}_g$  stands as a separating hyperplane between  $(f, 0)$  and  $\text{epi}(\mathcal{L})$ .  $\square$

**FIGURE 17.29**

The hyperplane  $\mathcal{X}_g$  (17.78), generated by a subgradient  $g$  of  $\mathcal{L}$  at  $f$ , stands as a separating hyperplane between the point  $(f, 0)$  and  $\text{epi}(\mathcal{L})$  in the augmented space  $\mathcal{H} \times \mathcal{R}$ .

**FIGURE 17.30**

The graph of the function  $|\cdot|$ , and the supporting hyperplanes generated by the subgradients of  $|\cdot|$  at 0.

Since  $\text{lev}_{\leq 0}(\mathcal{L})$  belongs to  $\text{epi}(\mathcal{L})$ , then  $\mathcal{X}_g$  separates  $f$  and  $\text{lev}_{\leq 0}(\mathcal{L})$  (see Figure 17.29). It can be readily verified that the point  $(f, \mathcal{L}(f))$  belongs to  $\mathcal{X}_g$ . Hence, as it can be also verified by Figure 17.29,  $\mathcal{X}_g$  supports the  $\text{epi}(\mathcal{L})$  at the point  $(f, \mathcal{L}(f))$ .

Let us give now the subdifferentials of some celebrated convex functions.

**Example 42 ( $\ell_1$  norm).** The stage of discussion is the Euclidean  $\mathcal{R}^l$ . Assume, first, the classical case of  $\mathcal{L}(\theta) := |\theta|$ ,  $\theta \in \mathcal{R}$ . Then, the subdifferential of  $\mathcal{L}$  is given as follows:

$$\partial \mathcal{L}(\theta) = \begin{cases} [-1, 1], & \text{if } \theta = 0, \\ \text{sign}(\theta), & \text{if } \theta \neq 0, \end{cases}$$

where  $\text{sign}(\cdot)$  stands for the sign of a real number. For the geometry associated to this cost function see Figure 17.30.

Assume, now, that the function  $\mathcal{L}$  becomes the more involved  $\ell_1$  norm, i.e.,

$$\mathcal{L}(\boldsymbol{\theta}) := \|\boldsymbol{\theta}\|_1 := \sum_{i=1}^l |\theta_i|, \quad \forall \boldsymbol{\theta} \in \mathcal{R}^l.$$

Then, the subdifferential of  $\mathcal{L}$  becomes as follows; given any  $\boldsymbol{\theta} \in \mathcal{R}^l$  define first the index set  $\mathcal{J}_{\boldsymbol{\theta}} := \{j \in \{1, 2, \dots, l\} : \theta_j = 0\}$ . Then, based on  $\mathcal{J}_{\boldsymbol{\theta}}$ , let a set of vectors  $\boldsymbol{\tau}_1, \boldsymbol{\tau}_2, \dots, \boldsymbol{\tau}_{2^v}$ , where  $v := \text{card}(\mathcal{J}_{\boldsymbol{\theta}})$ , and where the  $j$ th component of the  $i$ th  $\boldsymbol{\tau}_i$  is given by

$$\tau_{ij} := \begin{cases} \text{sign}(\theta_j), & \text{if } j \notin \mathcal{J}_{\boldsymbol{\theta}}, \\ +1 \text{ or } -1, & \text{if } j \in \mathcal{J}_{\boldsymbol{\theta}}. \end{cases}$$

Then,

$$\partial \mathcal{L}(\boldsymbol{\theta}) = \begin{cases} \left\{ (\text{sign}(\theta_1), \dots, \text{sign}(\theta_l))^T \right\}, & \text{if } \boldsymbol{\theta} \neq \mathbf{0} \text{ and } \mathcal{J}_{\boldsymbol{\theta}} = \emptyset, \\ \text{conv}(\boldsymbol{\tau}_1, \boldsymbol{\tau}_2, \dots, \boldsymbol{\tau}_{2^v}), & \text{if } \boldsymbol{\theta} \neq \mathbf{0} \text{ and } \mathcal{J}_{\boldsymbol{\theta}} \neq \emptyset, \\ \text{conv}(\boldsymbol{\tau}_1, \boldsymbol{\tau}_2, \dots, \boldsymbol{\tau}_{2^l}), & \text{if } \boldsymbol{\theta} = \mathbf{0}, \end{cases}$$

where  $\text{conv}(\cdot)$  stands for the convex hull of a set [34, 62].  $\diamond$

**Example 43 (Distance function).** The subdifferential of the metric distance function to a closed convex set  $C \subset \mathcal{H}$  is given as follows:

$$\partial d(f, C) = \begin{cases} N_C(f) \cap B[0, 1], & \text{if } f \in C, \\ \left\{ \frac{f - P_C(f)}{d(f, C)} \right\}, & \text{if } f \in \mathcal{H} \setminus C, \end{cases}$$

where  $N_C(f) := \{v \in \mathcal{H} : \langle v, g - f \rangle \leq 0, \forall g \in C\}$ , and  $B[0, 1] := \{f \in \mathcal{H} : \|f\| \leq 1\}$ . Moreover, the function  $d^2(\cdot, C)$  is (Fréchet) differentiable:

$$\partial d^2(f, C) = \nabla d^2(f, C) = \{2(f - P_C(f))\}, \quad \forall f \in \mathcal{H}.$$

### 1.17.7.3 Nonexpansive and quasi-nonexpansive mappings

Let us start with a few fundamental concepts regarding a mapping  $T : \mathcal{H} \rightarrow \mathcal{H}$  which is defined in the Hilbert space  $\mathcal{H}$ .

**Definition 44 (A toolbox of mappings).**

1. The fixed point set of  $T$  is the set of all those points of  $\mathcal{H}$  which are unaffected by  $T$ , i.e.,  $\text{Fix}(T) := \{f \in \mathcal{H} : T(f) = f\}$ .
2. The mapping  $T$  is called  $\gamma$ -Lipschitzian, or  $\gamma$ -Lipschitz continuous, if there exists a  $\gamma > 0$  such that  $\|T(f_1) - T(f_2)\| \leq \gamma \|f_1 - f_2\|, \forall f_1, f_2 \in \mathcal{H}$ .
3. The mapping  $T$  is called nonexpansive if it is 1-Lipschitzian. It is well-known that whenever  $\text{Fix}(T)$  is nonempty, then it is a closed convex subset of  $\mathcal{H}$  [65]. A subclass of nonexpansive mappings are the averaged ones. More specifically, the mapping  $T$  is called  $\alpha$ -averaged nonexpansive, with  $\alpha \in (0, 1)$ , if there exists a nonexpansive mapping  $R : \mathcal{H} \rightarrow \mathcal{H}$  such that  $T = (1 - \alpha)I + \alpha R$ . A celebrated example of an  $\frac{1}{2}$ -averaged nonexpansive mapping is the metric projection mapping  $P_C$  onto a nonempty, closed convex subset  $C$  of  $\mathcal{H}$ . In this case, it can be easily verified that  $\text{Fix}(P_C) = C$ . For an illustration of a nonexpansive mapping, see Figure 17.31.

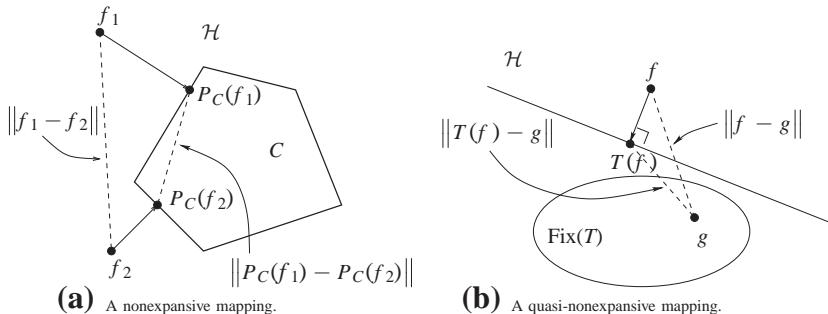

FIGURE 17.31

Illustration of a nonexpansive and a quasi-nonexpansive mapping.

4. The mapping  $T$  is called *strictly contractive* if it is  $\gamma$ -Lipschitzian, with  $\gamma \in (0, 1)$ . Such a mapping is the engine behind the celebrated *Banach-Picard fixed point theorem* [65], which states that the sequence generated by the repetition of  $T$  converges strongly to the *unique* fixed point of  $T$ , i.e., for an arbitrary  $f_0 \in \mathcal{H}$ , the sequence  $f_{n+1} := T(f_n)$ ,  $\forall n$ , converges strongly to  $f_*$ , where  $\text{Fix}(T) = \{f_*\}$ .
5. The mapping  $T$ , with  $\text{Fix}(T) \neq \emptyset$ , is called *quasi-nonexpansive* if

$$\|T(f) - g\| \leq \|f - g\|, \quad \forall f \in \mathcal{H}, \forall g \in \text{Fix}(T).$$

The fixed point set of a quasi-nonexpansive mapping is closed and convex. Every nonexpansive mapping is a quasi-nonexpansive one, but, in general, not vice-versa. The illustration of a quasi-nonexpansive mapping can be found in Figure 17.31b.

◇

The following is a celebrated example of a  $\gamma$ -Lipschitzian mapping.

**Example 45.** Consider a Euclidean space  $\mathcal{R}^l$ , and the following quadratic function:

$$\mathcal{L}(\boldsymbol{\theta}) := \frac{1}{2} \boldsymbol{\theta}^T \mathbf{R} \boldsymbol{\theta} - \mathbf{r}^T \boldsymbol{\theta} + \xi, \quad \forall \boldsymbol{\theta} \in \mathcal{R}^l,$$

where  $\mathbf{R}$  is a positive semidefinite matrix, of dimensions  $l \times l$ , with maximum eigenvalue  $\sigma_{\max} > 0$ , and  $\xi \in \mathcal{R}$ ,  $\mathbf{r} \in \mathcal{R}^l$ .

It can be easily verified that  $\mathcal{L}'(\boldsymbol{\theta}) = \mathbf{R}\boldsymbol{\theta} - \mathbf{r}$ ,  $\forall \boldsymbol{\theta} \in \mathcal{R}^l$ . Then,  $\forall \boldsymbol{\theta}_1, \boldsymbol{\theta}_2 \in \mathcal{R}^l$ ,

$$\|\mathcal{L}'(\boldsymbol{\theta}_1) - \mathcal{L}'(\boldsymbol{\theta}_2)\| = \|\mathbf{R}(\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2)\| \leq \|\mathbf{R}\| \|\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2\| = \sigma_{\max} \|\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2\|,$$

where  $\|\mathbf{R}\| = \sigma_{\max}$  is the spectral norm of  $\mathbf{R}$ . Hence,  $\mathcal{L}'$  is  $\sigma_{\max}$ -Lipschitzian.

As the following theorem suggests, there is a strong link between  $\gamma$ -Lipschitz continuity and nonexpansiveness.

**Fact 46 (The Baillon-Haddad theorem [70,71]).** Assume a differentiable convex function  $\mathcal{L} : \mathcal{H} \rightarrow \mathcal{R}$ , with its gradient denoted by  $\mathcal{L}' : \mathcal{H} \rightarrow \mathcal{H}$ . Then the following two statements are equivalent.

1.  $\mathcal{L}'$  is  $\gamma$ -Lipschitzian.
2. The mapping  $T := I - \frac{2}{\gamma} \mathcal{L}' : \mathcal{H} \rightarrow \mathcal{H}$  is nonexpansive, where  $I$  stands for the identity mapping in  $\mathcal{H}$ .

The following is an example of an averaged nonexpansive mapping.

**Example 47 (Proximal mapping).** Given a convex continuous<sup>2</sup> function  $\mathcal{L} : \mathcal{H} \rightarrow \mathcal{R}$ , the *Moreau envelope of index  $\gamma > 0$*  of  $\mathcal{L}$  is the function

$$\gamma \mathcal{L} : \mathcal{H} \rightarrow \mathcal{R} : f \mapsto \inf_{g \in \mathcal{H}} \left( \mathcal{L}(g) + \frac{1}{2\gamma} \|f - g\|^2 \right). \quad (17.81)$$

Then, the *proximal mapping*  $\text{prox}_{\gamma \mathcal{L}}$  is defined as the mapping which maps to an  $f \in \mathcal{H}$  the *unique* minimizer of (17.81) [72–74]. It can be verified that the proximal mapping  $\text{prox}_{\gamma \mathcal{L}}$  is  $\frac{1}{2}$ -averaged nonexpansive with fixed point set  $\text{Fix}(\text{prox}_{\gamma \mathcal{L}}) = \text{argmin}_{f \in \mathcal{H}} \mathcal{L}(f)$  [72, 73].

A well-known example of the proximal mapping is the classical projection operator onto closed convex sets. Indeed, if  $C$  is a non-empty closed convex subset of  $\mathcal{H}$ , then  $\text{prox}_{\gamma \mathcal{L}} = P_C$ ,  $\forall \gamma > 0$ , if the function  $\mathcal{L}$  takes the special form of the *indicator function of  $C$* ,  $\iota_C : \mathcal{H} \rightarrow \mathcal{R} \cup \{+\infty\}$ , which is defined as follows;  $\iota_C(f) = 0$ , if  $f \in C$ , and  $\iota_C(f) = +\infty$ , if  $f \notin C$ .<sup>3</sup> Another celebrated example of a proximal mapping is the well-known soft-thresholding operator (Example 2.16) [72].

Let us give now an example of a quasi-nonexpansive mapping.

**Example 48 (Subgradient projection mapping).** Assume a convex function  $\mathcal{L} : \mathcal{H} \times \mathcal{R}$ , such that its level set of height 0 is nonempty, i.e.,  $\text{lev}_{\leq 0}(\mathcal{L}) \neq \emptyset$ . Then, the subgradient projection mapping  $T_{\mathcal{L}} : \mathcal{H} \rightarrow \mathcal{H}$  with respect to  $\mathcal{L}$  is defined as follows:

$$T_{\mathcal{L}}(f) := \begin{cases} f - \frac{\mathcal{L}(f)}{\|\mathcal{L}'(f)\|^2} \mathcal{L}'(f), & \text{if } f \notin \text{lev}_{\leq 0}(\mathcal{L}), \\ f, & \text{otherwise,} \end{cases}$$

where  $\mathcal{L}'(f)$  is any subgradient taken from the subdifferential  $\partial \mathcal{L}(f)$  at the point  $f$ . For the geometry behind the concept of  $T_{\mathcal{L}}$  see Figure 17.29. It can be verified that  $T_{\mathcal{L}}(f)$  is a quasi-nonexpansive mapping, with  $\text{Fix}(T) = \text{lev}_{\leq 0}(\mathcal{L})$  [65].

**Remark 49.** If we rely again on geometry, it can be seen that in the case where  $f \notin \text{lev}_{\leq 0}(\mathcal{L})$ , then the image of  $f$  under  $T_{\mathcal{L}}$  is nothing but the (metric) projection of  $f$  onto the hyperplane which is defined by the intersection of  $\mathcal{X}_{\mathcal{L}'(f)}$  with  $\mathcal{H}$ ; see Figure 17.29.

**Proof.** In Figure 17.29, the intersection of  $\mathcal{X}_g$ , or better  $\mathcal{X}_{\mathcal{L}'(f)}$ , with  $\mathcal{H}$  is given if we set  $r = 0$  in (17.78). In other words,

$$\begin{aligned} \mathcal{X}_{\mathcal{L}'(f)} \cap \mathcal{H} &= \{h \in \mathcal{H} : 0 = \langle \mathcal{L}'(f), h - f \rangle + \mathcal{L}(f)\} \\ &= \{h \in \mathcal{H} : \langle \mathcal{L}'(f), h \rangle = \langle \mathcal{L}'(f), f \rangle - \mathcal{L}(f)\}. \end{aligned}$$

This is clearly a hyperplane, and by using Example 37 the previous claim is established.  $\square$

<sup>2</sup>In general,  $\mathcal{L}$  is assumed to be lower semicontinuous [65].

<sup>3</sup>Notice that the function  $\iota_C$  is convex and lower semicontinuous.

For the sake of illustration, let us calculate the subgradient projection mappings of several loss functions.

**Example 50.** Assume the loss function

$$\mathcal{L}(f) := d(f, C), \quad \forall f \in \mathcal{H},$$

where  $C$  is a nonempty subset of  $\mathcal{H}$ .

It is easy to see that  $\text{lev}_{\leq 0}(\mathcal{L}) = \text{lev}_{\leq 0}(d(\cdot, C)) = C$ . Hence, in the case where  $f \notin C$ , we have by Example 48 and Example 43 that

$$\begin{aligned} T_{d(\cdot, C)}(f) &= f - \frac{\mathcal{L}(f)}{\|\mathcal{L}'(f)\|^2} \mathcal{L}'(f) \\ &= f - \frac{d(f, C)}{\left\| \frac{f - P_C(f)}{d(f, C)} \right\|^2} \frac{f - P_C(f)}{d(f, C)} \\ &= f - (f - P_C(f)) = P_C(f). \end{aligned} \quad (17.82)$$

In other words, the subgradient projection mapping with respect to the metric distance function is nothing but the classical metric projection mapping  $P_C$ .

◊

**Example 51.** It is interesting to calculate the subgradient projection mapping  $T_{\mathcal{L}}$  with respect to the loss function  $\mathcal{L}(\cdot) = d^2(\cdot, C)$ . By following a procedure similar to the previous one, and by using Example 43, one can verify that

$$T_{d^2(\cdot, C)} = \frac{I + P_C}{2},$$

where  $I$  stands for the identity mapping in  $\mathcal{H}$ .

We stress here the difference between the subgradient projection mappings  $T_{d(\cdot, C)}$  and  $T_{d^2(\cdot, C)}$ . Although both of the loss functions  $d(\cdot, C)$  and  $d^2(\cdot, C)$  have the same level set  $\text{lev}_{\leq 0}(d(\cdot, C)) = \text{lev}_{\leq 0}(d^2(\cdot, C)) = C$ , it seems better to use the *non-differentiable* function  $d(\cdot, C)$  in order to approach  $C$ ; a *single* application of  $T_{d(\cdot, C)}$  takes us directly onto  $C$ , while the application of  $T_{d^2(\cdot, C)}$  covers only half of the distance.

Finally, let us give an example which will be useful in Section 1.17.7.5. The following example introduces the *concurrent* or *parallel* processing of multiple closed convex sets by the single application of a properly defined mapping.

**Example 52.** Assume a number of  $q$  closed convex sets  $\{C_1, C_2, \dots, C_q\}$  such that  $\bigcap_{i=1}^q C_i \neq \emptyset$ . Assume, also, a point  $f \in \mathcal{H}$ , which, for the sake of illustration, is assumed to satisfy  $f \notin \bigcap_{i=1}^q C_i$ . How could we use the concept of the subgradient projection mapping in order to employ concurrently all of  $\{C_1, C_2, \dots, C_q\}$  and to push the point  $f$  closer to  $\bigcap_{i=1}^q C_i$ ?

Since  $f \notin \bigcap_{i=1}^q C_i$ , then there exists an index set  $\mathcal{I}_f$  which indicates those closed convex sets that  $f$  does not belong to, i.e.,

$$\mathcal{I}_f := \{i \in \{1, 2, \dots, q\} : f \notin C_i\}.$$

Given  $\mathcal{I}_f$ , assign to each  $C_i, i \in \mathcal{I}_f$ , a convex weight  $\omega_i$ , i.e.,  $\omega_i \in (0, 1]$  such that  $\sum_{i \in \mathcal{I}_f} \omega_i = 1$ .

Define the function:

$$\mathcal{L}(h) := \sum_{i \in \mathcal{I}_f} \frac{\omega_i d(f, C_i)}{\sum_{j \in \mathcal{I}_f} \omega_j d(f, C_j)} d(h, C_i), \quad \forall h \in \mathcal{H}.$$

Notice here that if we define

$$\beta_i := \frac{\omega_i d(f, C_i)}{\sum_{j \in \mathcal{I}_f} \omega_j d(f, C_j)}, \quad \forall i \in \mathcal{I}_f,$$

then it is easy to verify that  $\mathcal{L}(\cdot) = \sum_{i \in \mathcal{I}_f} \beta_i d(\cdot, C_i)$  with  $\sum_{i \in \mathcal{I}_f} \beta_i = 1$ . In other words,  $\mathcal{L}$  is a convex combination of the convex functions  $d(\cdot, C_i)$ ,  $i \in \mathcal{I}_f$ ; hence, it is convex. Notice, also, that  $\text{lev}_{\leq 0}(\mathcal{L}) = \bigcap_{i \in \mathcal{I}_f} C_i$ .

One can verify by Example 43 that

$$\begin{aligned} \mathcal{L}'(f) &= \sum_{i \in \mathcal{I}_f} \frac{\omega_i d(f, C_i)}{\sum_{j \in \mathcal{I}_f} \omega_j d(f, C_j)} \frac{f - P_{C_i}(f)}{d(f, C_i)} \\ &= \frac{1}{L} \sum_{i \in \mathcal{I}_f} \omega_i (f - P_{C_i}(f)), \end{aligned}$$

where  $L := \sum_{j \in \mathcal{I}_f} \omega_j d(f, C_j)$ . Then, the subgradient projection mapping, applied to  $f$ , becomes as follows:

$$\begin{aligned} T_{\mathcal{L}}(f) &= f - \frac{\frac{1}{L} \sum_{i \in \mathcal{I}_f} \omega_i d^2(f, C_i)}{\frac{1}{L^2} \left\| \sum_{i \in \mathcal{I}_f} \omega_i (f - P_{C_i}(f)) \right\|^2} \frac{1}{L} \sum_{i \in \mathcal{I}_f} \omega_i (f - P_{C_i}(f)) \\ &= f + \mathcal{M} \left( \sum_{i \in \mathcal{I}_f} \omega_i P_{C_i}(f) - f \right), \end{aligned}$$

where

$$\mathcal{M} := \frac{\sum_{i \in \mathcal{I}_f} \omega_i d^2(f, C_i)}{\left\| \sum_{i \in \mathcal{I}_f} \omega_i (f - P_{C_i}(f)) \right\|^2}. \quad (17.83)$$

It becomes clear by the convexity of the function  $\|\cdot\|^2$  that  $\mathcal{M} \geq 1$ .

The *relaxed* version of  $T_{\mathcal{L}}$  is defined as the mapping  $(1 - \mu')I + \mu' T_{\mathcal{L}}$ , where  $\mu' \in (0, 2)$ , and  $I$  is the identity mapping in  $\mathcal{H}$ . Hence, the relaxation of  $T_{\mathcal{L}}$ , applied to the previous  $f$ , becomes as follows:

$$\begin{aligned} (1 - \mu')f + \mu' T_{\mathcal{L}}(f) &= f + \mu' \mathcal{M} \left( \sum_{i \in \mathcal{I}_f} \omega_i P_{C_i}(f) - f \right) \\ &= f + \mu \left( \sum_{i \in \mathcal{I}_f} \omega_i P_{C_i}(f) - f \right), \end{aligned}$$

where  $\mu := \mu' \mathcal{M} \in (0, 2\mathcal{M})$ . Notice that since  $\mathcal{M} \geq 1$ , the parameter  $\mu$  can attain values larger than or equal to 2.

In the case where  $f \in \bigcap_{i=1}^q C_i$ , it is natural to leave  $f$  as it is. To summarize, the previous discussion introduced the following mapping:

$$f \mapsto \begin{cases} f + \mu \left( \sum_{i \in \mathcal{I}_f} \omega_i P_{C_i}(f) - f \right), & \text{if } f \notin \bigcap_{i=1}^q C_i, \\ f, & \text{if } f \in \bigcap_{i=1}^q C_i, \end{cases}$$

where  $\mu \in (0, 2\mathcal{M})$ , with  $\mathcal{M}$  given by (17.83). We will again meet these concepts later on, in Example 67.  $\diamond$

#### 1.17.7.4 The basic algorithmic ingredients for nonsmooth convex batch learning

In this section, we lay the foundations on which the subsequent section of online learning (Section 1.17.7.5) will be based. The objective of this section is to study several basic algorithmic components related to *batch learning*, i.e., the task of solving an estimation problem *after all* the training data have been gathered and made available. Such training data are utilized in order to generate a *fixed* convex loss function  $\mathcal{L} : \mathcal{H} \rightarrow \mathcal{R}$ , which quantifies the designer's perception of penalty or deviation from the underlying model. If a nonempty closed convex set  $C \subset \mathcal{H}$  is also used as the available *a priori constraint* to the problem at hand, then batch learning breaks down to the following fundamental optimization task:

$$\text{minimize } \mathcal{L}(f) \text{ such that } f \in C \subset \mathcal{H}. \quad (17.84)$$

The only assumption we make on the convex function  $\mathcal{L}$  is to be a continuous one. Neither smoothness, i.e., any form of differentiability, nor strict convexity is assumed for  $\mathcal{L}$ . Such a generality is crucial if one wishes to build algorithmic tools for modern learning tasks; indeed, the  $\ell_1 : \mathcal{R}^l \rightarrow \mathcal{R}$  loss function is a celebrated example of a nonsmooth, nonstrict, convex penalty function which infuses sparsity attributes in a learning task.

The backbone of this section will be the following fundamental recursion; fix arbitrarily an initial point  $f_0 \in \mathcal{H}$  and execute  $\forall n \in \mathcal{N}_*$ ,

$$f_n := P_C(f_{n-1} - \mu_n \mathcal{L}'(f_{n-1})), \quad (17.85)$$

where  $P_C$  stands for the metric projection mapping onto  $C$ ,  $\mathcal{L}'(f_{n-1})$  is the subgradient of  $\mathcal{L}$  at  $f_{n-1}$ , and  $(\mu_n)_{n \in \mathcal{N}_*}$  is a sequence of user-defined, non-negative real numbers, which are usually fixed judiciously in order for the sequence  $(f_n)_{n \in \mathcal{N}}$  to converge in some sense.

Recently, the fundamental recursion (17.85) lent itself to generalizations, and more specifically, to the replacement of the metric projection mapping  $P_C$  of (17.85) with the more general *proximal* mappings (see Example 47), in order to derive the proximal-gradient, aka forward-backward algorithm, and the Douglas-Rachford method [65, 72, 73, 75, 76]. Such a generalization corresponds to the minimization of a sum of convex functions  $\mathcal{L} := \Theta + \psi$ , where  $\Theta$  is a convex function, which accommodates the misfit of the observed data to the model, and  $\psi$  is the proximal function, introduced in order to serve a variety of objectives, depending on the problem at hand. For example,  $\psi$  takes up the role of a regularizer in order to control the “size” of an estimate in classification or regression tasks, or that of a penalty term

which enforces a-priori knowledge, like sparsity, into the design. Such a path, is followed also by the machine learning community in the very recent studies of [77, 78].

**Algorithm 53 (Projected Gradient Method (PGM))** [79, 80]. Assume a nonempty closed convex set  $C \subset \mathcal{H}$ , and a differentiable convex function  $\mathcal{L} : \mathcal{H} \rightarrow \mathcal{R}$ , such that its derivative  $\mathcal{L}' : \mathcal{H} \rightarrow \mathcal{H}$  is  $\gamma$ -Lipschitzian, and  $\operatorname{argmin}_{f \in C} \mathcal{L}(f) \neq \emptyset$ . Then, for any starting point  $f_0 \in \mathcal{H}$ , and any  $\mu \in (0, \frac{2}{\gamma})$ , the sequence  $(f_n)_{n \in \mathcal{N}}$  generated by the *Projected Gradient Method (PGM)*:

$$f_n := P_C(f_{n-1} - \mu \mathcal{L}'(f_{n-1})), \quad \forall n \in \mathcal{N}_*, \quad (17.86)$$

converges weakly to a point in  $\operatorname{argmin}_{f \in C} \mathcal{L}(f)$ .

**Remark 54 (Alternative view of the PGM).** According to the Baillon-Haddad theorem, i.e., Theorem 46, the mapping  $T := I - \frac{2}{\gamma} \mathcal{L}'$  is nonexpansive. Hence, PGM is nothing but the composition of the projection mapping  $P_C$  and the  $\alpha$ -averaged nonexpansive mapping  $\alpha T + (1 - \alpha)I$  (see Definition 44), for  $\alpha \in (0, 1)$ , i.e.,

$$f_n := P_C \left( \alpha \left( I - \frac{2}{\gamma} \mathcal{L}' \right) + (1 - \alpha)I \right) (f_{n-1}), \quad \forall n \in \mathcal{N}_*.$$

Given several scenarios, with respect to  $\mathcal{H}$ ,  $\mathcal{L}$ , and  $C$ , the PGM is hidden behind celebrated algorithmic tools, as the following examples suggest.

**Example 55 (Projected Landweber Method [65]).** Assume a matrix  $A \in \mathcal{R}^{m \times l}$ , a vector  $y \in \mathcal{R}^m$ , and a nonempty closed convex set  $C \subset \mathcal{R}^l$ . For an arbitrarily fixed initial point  $\theta_0 \in \mathcal{R}^l$ , and an  $\mu \in (0, 2/\|A\|^2)$ , where  $\|A\|$  stands for the spectral norm of  $A$ , the *Projected Landweber Method*:

$$\theta_n := P_C \left( \theta_{n-1} - \mu A^T (A\theta_{n-1} - y) \right), \quad \forall n \in \mathcal{N}_*,$$

converges to a point in  $\operatorname{argmin}_{\theta \in C} \frac{1}{2} \|A\theta - y\|^2 \neq \emptyset$ .  $\diamond$

**Proof.** If we define  $\mathcal{L}(\theta) := \frac{1}{2} \|A\theta - y\|^2$ ,  $\forall \theta \in \mathcal{R}^l$ , then it can be easily verified that

$$\mathcal{L}(\theta) = \frac{1}{2} \theta^T A^T A \theta - y^T A \theta + \frac{1}{2} \|y\|^2, \quad \theta \in \mathcal{R}^l.$$

According to Example 45, the derivative  $\mathcal{L}'(\theta) = A^T A \theta - A^T y$ ,  $\forall \theta \in \mathcal{R}^l$ , is  $\sigma_{\max}$ -Lipschitzian, where  $\sigma_{\max}$  is the maximum eigenvalue of  $A^T A$ . Since by definition  $\sigma_{\max} = \|A\|^2$  [81], if we also set  $C := \mathcal{H}$ , then the Projected Landweber Method is a direct application of the PGM to the specific  $\mathcal{L}$ .  $\square$

**Example 56 (Minimum Mean-Squared Error (MMSE) estimation [5, 6]).** Assume the linear model:

$$y = \mathbf{x}^T \boldsymbol{\theta} + \eta, \quad (17.87)$$

where  $\boldsymbol{\theta} \in \mathcal{R}^l$  is a parameter vector,  $y \in \mathcal{R}$  is the observed signal, and  $\mathbf{x} \in \mathcal{R}^l$ ,  $\eta \in \mathcal{R}$  are the vector-valued input signal and the noise random variables, respectively. The correlation matrix of the

input signal  $\mathbf{R} := \mathbb{E}[\mathbf{x}\mathbf{x}^T]$ , where  $\mathbb{E}[\cdot]$  stands for the expectation operator, is obviously a positive semidefinite matrix. In practice, available to us are only realizations of (17.87) via the sequences  $(\mathbf{x}_n, y_n)_{n \in \mathcal{N}_*}$  and  $(\eta_n)_{n \in \mathcal{N}_*}$  which are related to each other via  $y_n = \mathbf{x}_n^T \boldsymbol{\theta} + \eta_n, \forall n \in \mathcal{N}_*$ .

Define the mean square error as follows:

$$\mathcal{L}(\boldsymbol{\theta}) := \frac{1}{2} \mathbb{E}[(y - \mathbf{x}^T \boldsymbol{\theta})^2], \quad \forall \boldsymbol{\theta} \in \mathcal{R}^l.$$

Our objective is to compute an *estimate* of  $\boldsymbol{\theta}$ , by the *least mean squares* rationale:

$$\text{find } \boldsymbol{\theta}_* \in \underset{\boldsymbol{\theta} \in \mathcal{R}^l}{\operatorname{argmin}} \mathcal{L}(\boldsymbol{\theta}). \quad (17.88)$$

It is easy to verify that

$$\mathcal{L}(\boldsymbol{\theta}) = \frac{1}{2} \boldsymbol{\theta}^T \mathbf{R} \boldsymbol{\theta} - \mathbb{E}[y \mathbf{x}^T] \boldsymbol{\theta} + \frac{1}{2} \mathbb{E}[y^2] = \frac{1}{2} \boldsymbol{\theta}^T \mathbf{R} \boldsymbol{\theta} - \mathbf{r}^T \boldsymbol{\theta} + \xi,$$

where  $\mathbf{R} := \mathbb{E}[y \mathbf{x}]$  and  $\xi := \frac{1}{2} \mathbb{E}[y^2]$ .

According to Example 45, the function  $\mathcal{L}$  is  $\sigma_{\max}$ -Lipschitzian, where  $\sigma_{\max}$  is the maximum eigenvalue of  $\mathbf{R}$ . Hence, the sequence  $(\boldsymbol{\theta}_n)_{n \in \mathcal{N}}$  generated by the PGM of Algorithm 53:

$$\boldsymbol{\theta}_n := \boldsymbol{\theta}_{n-1} - \mu (\mathbf{R} \boldsymbol{\theta}_{n-1} - \mathbf{r}), \quad \forall n \in \mathcal{N}_*, \quad (17.89)$$

converges to a point  $\boldsymbol{\theta}_* \in \operatorname{argmin}_{\boldsymbol{\theta} \in C} \mathcal{L}(\boldsymbol{\theta})$ , provided that  $\mu \in (0, \frac{2}{\sigma_{\max}})$ . Indeed, this iterative procedure is of paramount importance to the celebrated MMSE and Wiener estimation theory [5, 6]. Moreover, this iteration is the motivation for the classical LMS algorithm (17.34). To see this, notice that (17.89) can be equivalently written  $\forall n \in \mathcal{N}_*$  as:

$$\begin{aligned} \boldsymbol{\theta}_n &= \boldsymbol{\theta}_{n-1} - \mu (\mathbf{R} \boldsymbol{\theta}_{n-1} - \mathbf{r}) \\ &= \boldsymbol{\theta}_{n-1} - \mu \left( \mathbb{E}[\mathbf{x}_n \mathbf{x}_n^T] \boldsymbol{\theta}_{n-1} - \mathbb{E}[y_n \mathbf{x}_n] \right) \\ &= \boldsymbol{\theta}_{n-1} - \mu \mathbb{E}[(\mathbf{x}_n^T \boldsymbol{\theta}_{n-1} - y_n) \mathbf{x}_n]. \end{aligned}$$

It can be readily verified that (17.34) is an approximation of the previous iteration. Notice also that the Lipschitz constant  $\frac{2}{\sigma_{\max}}$  of the  $\mathcal{L}'$  mapping is of central importance for the proof of convergence in the mean of the LMS algorithm (see Section 1.17.6.1).

Let us now go back to (17.85) for the case where  $\mathcal{L}$  is not differentiable. Although there are several strategies to control the step-sizes  $(\mu_n)_{n \in \mathcal{N}}$  in (17.85), in this note we focus on the following method.

**Algorithm 57 (Projected Subgradient Method (PSMa))** [82, 83]. For any  $f_0 \in \mathcal{H}$ , let the following recursion

$$f_n := P_C \left( f_{n-1} - \frac{\mu_n}{\max\{1, \|\mathcal{L}'(f_{n-1})\|\}} \mathcal{L}'(f_{n-1}) \right), \quad n = 1, 2, \dots,$$

(17.90)

where  $\mathcal{L}'(f_{n-1})$  stands for the subgradient of  $\mathcal{L}$  at  $f_{n-1}$ , and the non-negative numbers  $(\mu_n)_{n \in \mathcal{N}_*}$  satisfy the following conditions:

$$\sum_{n=1}^{\infty} \mu_n = \infty, \quad (17.91a)$$

$$\sum_{n=1}^{\infty} \mu_n^2 < \infty. \quad (17.91b)$$

Regarding the previous algorithm, the following hold true.

1. If the previous algorithm generates an infinite sequence  $(f_n)_{n \in \mathcal{N}}$ , then  $\liminf_{n \rightarrow \infty} \mathcal{L}(f_n) = \inf_{f \in C} \mathcal{L}(f)$ .
2. If the set of solutions  $C_{\mathcal{L}_*}$  of (17.84) is nonempty, then either (17.90) stops at some iteration  $n_*$ , in which case  $f_{n_*} \in C_{\mathcal{L}_*}$ , or it generates an infinite sequence which converges *weakly* to some  $f_* \in C_{\mathcal{L}_*}$ .
3. If  $C_{\mathcal{L}_*}$  is empty, then  $(f_n)_{n \in \mathcal{N}}$  is unbounded.

**Remark 58.** The previous convergence results hold also true in the case where the  $\mathcal{L}'(f_n)$  is taken from the  $\epsilon$ -subdifferential ( $\epsilon \geq 0$ ) of  $\mathcal{L}$  at  $f_n$ , which stands as a generalization of the classical subdifferential [62]. It has been observed in [83] that a slight variation of (17.90) is sufficient to guarantee convergence of the sequence of estimates  $(f_n)_{n \in \mathcal{N}}$  in the strong sense.

The unrestricted case of (17.84), i.e., the case where  $C := \mathcal{H}$ , was studied in [84]. In [84], the condition (17.91b) is relaxed to the  $\lim_{n \rightarrow \infty} \mu_n = 0$ , and the recursion is formed as [84]

$$f_n := \begin{cases} f_{n-1} - \frac{\mu_n}{\|\mathcal{L}'(f_{n-1})\|} \mathcal{L}'(f_{n-1}), & \text{if } \mathcal{L}'(f_{n-1}) \neq 0, \\ f_{n-1}, & \text{otherwise.} \end{cases} \quad (17.92)$$

It is proved in [84] that the generating sequence  $(f_n)_{n \in \mathcal{N}}$  is a minimizing one, i.e.,  $\liminf_{n \rightarrow \infty} \mathcal{L}(f_n) = \inf_{f \in C} \mathcal{L}(f)$ , but no results on the convergence of the  $(f_n)_{n \in \mathcal{N}}$  are given. The finite dimensional unconstrained case of (17.85), i.e.,  $\mathcal{H}$  is a Euclidean space and  $C := \mathcal{H}$ , but with different strategies on designing the quantities  $(\mu_n)_{n \in \mathcal{N}_*}$ , was studied in [85, 86].

For the sake of illustration, let us apply the PSMa to a classical learning task, and show that this classical rule falls under the previously generic recursion.

**Example 59 (The Perceptron).** Let two patterns  $\Pi_1, \Pi_2$ , from which a number of finite dimensional observations emanate:  $\mathbf{x}_i \in \mathcal{R}^l$ ,  $i = 1, 2, \dots, N_1$ , from  $\Pi_1$ , and  $\boldsymbol{\xi}_j \in \mathcal{R}^l$ ,  $j = 1, 2, \dots, N_2$ , from  $\Pi_2$ . Assume also a *reproducing kernel* function  $\kappa$  which generates an RKHS  $\mathcal{H}$  of very high, possibly infinite, dimension. The observed data are mapped into  $\mathcal{H}$  by means of the following mapping:  $\mathbf{x}_i \mapsto \kappa(\mathbf{x}_i, \cdot)$ , and  $\boldsymbol{\xi}_j \mapsto \kappa(\boldsymbol{\xi}_j, \cdot)$ .

We assume that the patterns  $\Pi_1, \Pi_2$  are *linearly*, or better, *affinely separable* in the feature space  $\mathcal{H}$ , i.e., there exist  $f \in \mathcal{H}$  and  $\beta \in \mathcal{R}$ , such that

$$\begin{aligned} \langle f, \kappa(\mathbf{x}_i, \cdot) \rangle + \beta &= f(\mathbf{x}_i) + \beta \geq 0, \quad \forall i \in \{1, 2, \dots, N_1\}, \\ \langle f, \kappa(\boldsymbol{\xi}_j, \cdot) \rangle + \beta &= f(\boldsymbol{\xi}_j) + \beta \leq 0, \quad \forall j \in \{1, 2, \dots, N_2\}. \end{aligned} \quad (17.93)$$

Our task becomes that of employing an iterative algorithm in order to find an  $f \in \mathcal{H}$  and a  $\beta \in \mathcal{R}$  which achieve the previous goal. An example of such an iterative procedure is the *perceptron*, which was introduced in [87, 88], in order to solve the task (17.93).

**Proposition 60.** *Assume that there exist  $f \in \mathcal{H}$  and  $\beta \in \mathcal{R}$  such that*

$$\begin{aligned} f(\mathbf{x}_i) + \beta &> 0, \quad \forall i \in \{1, 2, \dots, N_1\}, \\ f(\xi_j) + \beta &< 0, \quad \forall j \in \{1, 2, \dots, N_2\}. \end{aligned}$$

*Then, Algorithm 57 (PSMa) solves the task (17.93) in a finite number of steps.* ◇

**Proof.** See Appendix B. □

According to the studies of [84, 85], the PSMa of Algorithm 57 and its variants exhibit in general a rather slow convergence performance, due to the selection policies of the step-sizes  $(\mu_n)_{n \in \mathcal{N}}$ . To remedy such a situation, Polyak [89] introduced the following algorithm.

**Algorithm 61 (Projected Subgradient Method (PSMb) [89]).** Define, first,  $\mathcal{L}_* := \inf_{f \in C} \mathcal{L}(f)$ . For an arbitrarily fixed  $f_0 \in \mathcal{H}$ , assume the recursion  $\forall n \in \mathcal{N}_*$ :

$$f_n := \begin{cases} P_C \left( f_{n-1} - \mu_n \frac{\mathcal{L}(f_{n-1}) - \mathcal{L}_*}{\|\mathcal{L}'(f_{n-1})\|^2} \mathcal{L}'(f_{n-1}) \right), & \text{if } \mathcal{L}'(f_{n-1}) \neq 0, \\ P_C(f_{n-1}), & \text{otherwise,} \end{cases} \quad (17.94)$$

where  $\mu_n \in (0, 2)$ .

Assume that the set of solutions  $C_{\mathcal{L}_*}$  of (17.84) is nonempty, and let a point  $f_* \in C_{\mathcal{L}_*}$ . If, in addition, there exists an  $\epsilon > 0$  such that  $\mu_n \in [\epsilon, 2 - \epsilon]$ ,  $\forall n$ , and there exists a  $c > 0$  such that  $\|\mathcal{L}'(f)\| \leq c$ ,  $\forall f \in B[f_*, \|f_0 - f_*\|] \cap C$ , where  $B[f_*, \|f_0 - f_*\|]$  stands for the closed ball centered at  $f_*$  with radius  $\|f_0 - f_*\|$ , then

1.  $\lim_{n \rightarrow \infty} \mathcal{L}(f_n) = \mathcal{L}_*$ .
2. The sequence  $(f_n)_{n \in \mathcal{N}}$  converges weakly to a point in  $C_{\mathcal{L}_*}$ . ◇

**Proof.** See Appendix C. □

The following proposition shows that the PSMB, i.e., Algorithm 61, has a clear geometric description as the composition of two projections, a relaxed version of a subgradient one, and a metric one.

**Proposition 62.** *If we assume that the set of all minimizers of the function  $\mathcal{L}$  on  $C$  is nonempty, i.e.,  $C_{\mathcal{L}_*} \neq \emptyset$ , then the PSM Algorithm 61 can be cast in the following equivalent form:*

$$f_n = P_C \left( (1 - \mu_n)I + \mu_n T_{\tilde{\mathcal{L}}} \right) (f_{n-1}), \quad \forall n \in \mathcal{N}_*,$$

where  $I$  stands for the identity mapping in  $\mathcal{H}$ , and the mapping  $T_{\tilde{\mathcal{L}}} : \mathcal{H} \rightarrow \mathcal{H}$  stands for the subgradient projection mapping (see Example 48) with respect to the function  $\tilde{\mathcal{L}}(\cdot) := \mathcal{L}(\cdot) - \mathcal{L}_*$ . ◇

**Proof.** First, notice that the mapping

$$(1 - \mu)I + \mu T_{\tilde{\mathcal{L}}}, \quad \mu \in (0, 2),$$

is called the *relaxed*  $T_{\tilde{\mathcal{L}}}$  [65].

It is also easy to verify that  $\text{lev} \leq 0(\tilde{\mathcal{L}}) = \{f \in \mathcal{H} : \mathcal{L}(f) \leq \mathcal{L}_*\}$ . Since  $C_{\mathcal{L}_*} \neq \emptyset$ , it can be clearly seen that  $\emptyset \neq C_{\mathcal{L}_*} \subset \text{lev} \leq 0(\tilde{\mathcal{L}})$ . Moreover, since  $\tilde{\mathcal{L}}$  is nothing but a vertical shift of  $\mathcal{L}$ , it can be also readily seen that  $\partial \tilde{\mathcal{L}} = \partial \mathcal{L}$ . Under this setting, the claim of the proposition can be easily established by a simple inspection of Example 48.  $\square$

### 1.17.7.5 Algorithmic tools for nonsmooth convex online learning

Based on Section 1.17.7.4, we will present here a variety of algorithmic tools designed for *online learning*, i.e., learning tasks where the training data *keep on flowing sequentially* into the processing unit. As it has already been stated in the introduction of the chapter, such a *continuous* flow is dictated by the need to monitor possible fluctuations or abrupt changes of the surrounding environment, as well as any time-varying a-priori knowledge about the model under study. The *sequential* flow of the training data is dictated by real-time units where the need for processing those data one by one, and not in batches as in Section 1.17.7.4, is the key ingredient for simpler computational operations, and thus, for less consumed power, as well as for easier handling of massive volumes of incoming data.

In order to cast the previous considerations into a mathematical formulation, we let the non-negative integer index  $n$  to account not only for the recursion index, as this was the case in Section 1.17.7.4, but also to denote *time instants*. In other words, the set of all non-negative integers  $\mathcal{N}$  stands also for the entire *time horizon*. Hence, instead of the fixed loss function  $\mathcal{L}$  and the constraint set  $C$  of (17.84), we will deal here with a sequence of loss functions  $(\mathcal{L}_n)_{n \in \mathcal{N}_*}$  and constraint sets  $(C_n)_{n \in \mathcal{N}_*}$ , and the task of (17.84) becomes now that of an *asymptotic* minimization one.

As in Section 1.17.7.4, the loss functions  $(\mathcal{L}_n)_{n \in \mathcal{N}_*}$  are not confined to be either differentiable or strictly convex. In such a way, design freedom is favored against easiness; although the differentiability or strict convexity of  $(\mathcal{L}_n)_{n \in \mathcal{N}_*}$  might result into elegant and easy-to-implement algorithmic tools, as well as stronger convergence results, our priority is not the mathematical tractability, but the selection of those convex loss functions that are *in agreement* with the available model and the a-priori knowledge.

Our data generation model, in its most general form, is given as follows:

$$y_n = f_*(\mathbf{x}_n) + \eta_n, \quad \forall n \in \mathcal{N}_*, \quad (17.95a)$$

where  $f_*$  is an element of an RKHS  $\mathcal{H}$ , and thus, it is in general a *nonlinear* function  $f_* : \mathcal{R}^l \rightarrow \mathcal{R}$ , and  $(\eta_n)_{n \in \mathcal{N}_*}$  is the noise stochastic process. Notice that due to the reproducing property of the RKHS, the quantity  $f_*(\mathbf{x}_n) = \langle f_*, \kappa(\mathbf{x}_n, \cdot) \rangle$ ; in other words, the  $l$ -dimensional input data  $(\mathbf{x}_n)_{n \in \mathcal{N}_*}$  are mapped into the highly dimensional feature space  $\mathcal{H}$  as  $\mathbf{x}_n \mapsto \kappa(\mathbf{x}_n, \cdot)$ . The real-valued sequence  $(y_n)_{n \in \mathcal{N}_*}$  contains the observed data. For short, the sequence  $(y_n, \mathbf{x}_n)_{n \in \mathcal{N}_*}$  will be called the sequence of *training data* in the sequel. Given these training data, our task is to estimate the *unknown* nonlinear function  $f_*$ .

The nonlinear model of (17.95a) takes a simpler form whenever the kernel behind the feature RKHS  $\mathcal{H}$  is chosen to be the linear one. In such a case,  $\mathcal{H}$  becomes an  $l$ -dimensional Euclidean space, and (17.95a) reduces to the classical *linear* model

$$y_n = \mathbf{x}_n^T \boldsymbol{\theta}_* + \eta_n, \quad \forall n \in \mathcal{N}_*, \quad (17.95b)$$

where  $\boldsymbol{\theta}_* \in \mathcal{R}^l$  is now the unknown vector to be estimated.

The previous training data  $(y_n, \mathbf{x}_n)_{n \in \mathcal{N}_*}$  as well as the underlying model (17.95a) are used to construct the sequence of loss functions  $(\mathcal{L}_n)_{n \in \mathcal{N}_*}$ . Given also the sequence of closed convex sets  $(C_n)_{n \in \mathcal{N}_*}$ , which depicts the time-varying a-priori information, the recursion which runs beneath almost all of the algorithmic tools developed for convex online learning tasks is a generalization of (17.85) to the current time-adaptive setting; given any initial point  $f_0 \in \mathcal{H}$ , execute

$$f_n := P_{C_n} (f_{n-1} - \mu_n \mathcal{L}'_n(f_{n-1})), \quad \forall n \in \mathcal{N}_*. \quad (17.96)$$

In what follows, and as a special case of (17.96), we provide with a classical time-adaptive algorithm.

**Algorithm 63 (Least Mean Squares (LMS) algorithm [5,6,36,38]).** Regarding (17.95a), assume the loss function

$$\mathcal{L}_n(f) := \frac{1}{2} (y_n - f(\mathbf{x}_n))^2 = \frac{1}{2} (y_n - \langle f, \kappa(\mathbf{x}_n, \cdot) \rangle)^2, \quad \forall f \in \mathcal{H}.$$

Clearly, this loss function is everywhere differentiable, and

$$\mathcal{L}'_n(f) = (f(\mathbf{x}_n) - y_n) \kappa(\mathbf{x}_n, \cdot), \quad \forall f \in \mathcal{H}.$$

Adopting the rationale of the PGM, i.e., Algorithm 53, leads to the *Kernel Least Mean Squares (KLMS)* recursion:

$$\begin{aligned} f_n &:= f_{n-1} - \mu \mathcal{L}'_n(f_{n-1}) \\ &= f_{n-1} - \mu (f_{n-1}(\mathbf{x}_n) - y_n) \kappa(\mathbf{x}_n, \cdot), \quad \forall n \in \mathcal{N}, \end{aligned} \quad (17.97)$$

where  $\mu$  takes values in order to guarantee the convergence of the sequence  $(f_n)_{n \in \mathcal{N}}$  in some sense.

In the case where the RKHS  $\mathcal{H}$  becomes the Euclidean  $\mathcal{R}^l$ , via a linear kernel, the nonlinear model (17.95a) reduces to (17.95a), and the KLMS (17.97) becomes the classical LMS algorithm:

$$\boldsymbol{\theta}_n = \boldsymbol{\theta}_{n-1} - \mu (\mathbf{x}_n^T \boldsymbol{\theta}_{n-1} - y_n) \mathbf{x}_n, \quad \forall n \in \mathcal{N}_*. \quad \diamond$$

Motivated by the geometry behind the batch Algorithm 61, the following online counterpart was introduced in [90,91].

**Algorithm 64 (Adaptive Projected Subgradient Method (APSM) [90,91]).** Assume a sequence of non-negative, continuous, convex loss functions  $(\mathcal{L}_n : \mathcal{H} \rightarrow \mathcal{R})_{n \in \mathcal{N}_*}$ , not necessarily differentiable. Let, also, a nonempty closed convex set  $C \subset \mathcal{H}$ . Then, for an arbitrarily fixed initial point  $f_0$ , the *Adaptive Projected Subgradient Method (APSM)* is formulated as follows;  $\forall n \in \mathcal{N}_*$ ,

$$f_n := \begin{cases} P_C \left( (1 - \mu_n) f_{n-1} + \mu_n \left( f_{n-1} - \frac{\mathcal{L}_n(f_{n-1})}{\|\mathcal{L}'_n(f_{n-1})\|^2} \mathcal{L}'_n(f_{n-1}) \right) \right), & \text{if } \mathcal{L}'_n(f_{n-1}) \neq 0, \\ P_C(f_{n-1}), & \text{if } \mathcal{L}'_n(f_{n-1}) = 0, \end{cases} \quad (17.98)$$

where  $\mu_n \in (0, 2)$ , and  $\mathcal{L}'_n(f_{n-1})$  stands for any subgradient of the function  $\mathcal{L}_n$  at  $f_{n-1}$ ,  $\forall n \in \mathcal{N}_*$ .  $\diamond$

**Algorithm 65.** Adaptive Projected Subgradient Method (APSM)

**Require:** The training data  $((x_n, y_n))_{n \in \mathcal{N}_*}$ , the sequence of non-negative convex loss functions  $(\mathcal{L}_n)_{n \in \mathcal{N}_*}$ , an RKHS  $\mathcal{H}$ , and a closed convex set  $C$ .

```

1: Choose any  $f_0 \in \mathcal{H}$ .
2: for  $n = 1, 2, \dots$  do
3: Available is the current estimate  $f_{n-1}$ .
4: Choose any  $\mu_n \in (0, 2)$ .
5: if  $\mathcal{L}'_n(f_{n-1}) \neq 0$  then
6:    $f_n := P_C \left( (1 - \mu_n) f_{n-1} + \mu_n \left( f_{n-1} - \frac{\mathcal{L}_n(f_{n-1})}{\|\mathcal{L}'_n(f_{n-1})\|^2} \mathcal{L}'_n(f_{n-1}) \right) \right)$ .
7: else
8:    $f_n := P_C(f_{n-1})$ .
9: end if
10: end for
```

**Output:** The sequence of estimates  $(f_n)_{n \in \mathcal{N}}$ .

**Remark 66.** In order to spread the applicability range of the APSM to scenarios with more involved a-priori information usage than the single projection mapping  $P_C$  in (17.98), the study in [92] extended the APSM to the case where certain nonexpansive mappings take the place of  $P_C$  in (17.98). Moreover, very recently, further generalization has been achieved for the case where the more flexible and general *quasi-nonexpansive* mappings, which include, for example, the proximal ones (see Example 47) as a special case, take up the role of handling the time-varying a-priori information [92–94]. Indeed, such generalizations span the applicability of the APSM [95] from classification [96] and regression tasks [42] in RKHSs, to sparsity-aware signal recovery [97], and sensor network [98] applications. ◇

The following section provides several important versions of the generic scheme of Algorithm 65.

### 1.17.7.6 The kernel adaptive projected subgradient method (KAPSM)

We are now ready to state the kernel APSM algorithm, which together with the KLMS and KRLS, comprise three major online/time adaptive schemes in Signal Processing. Moreover, as we will see, the KAPSM, as it is the case with its linear counterpart, enjoys a number of advantages, including its agility to cope efficiently both with regression as well as with classification problems, and also to allow for straightforward modifications to cope with robustness, when the environment dictates so. The reason behind this agility lies on the freedom of choice for the sequence of convex loss functions  $(\mathcal{L}_n)_{n \in \mathcal{N}_*}$  in Algorithm 65; the nature of the problem, e.g., a classification or a regression task, and the objectives of the designer dictate the choice of  $(\mathcal{L}_n)_{n \in \mathcal{N}_*}$ . In order to be more concrete, we start our discussion with Example 67, which incorporates a sequence of specialized loss functions  $(\mathcal{L}_n)_{n \in \mathcal{N}_*}$  in the APSM, but with a wide applicability range. For example, the KNLMS (see (17.41)), as well as the Kernel Affine Projection Algorithm (KAPA) [37, 68], which is a kernelized version of the classical APA [6, 99, 100], become its special cases.

**Example 67 ([101]).** Assume a sequence of closed convex sets  $(C_n)_{n \in \mathcal{N}_*}$ , where each  $C_n$  is associated to a pair of training data  $(y_n, \mathbf{x}_n)$ . Given a positive integer  $q$ , the following discussion will evolve along the lines of the rationale given in Example 52, and it will introduce the *concurrent* or *parallel* processing of multiple closed convex sets or data per time instant  $n$ . Hence, given a point  $f_{n-1} \in \mathcal{H}$ , define, first, the index set

$$\mathcal{I}_{f_{n-1}} := \{i \in \{n-q+1, \dots, n\} : f_{n-1} \notin C_i\}.$$

To each  $i \in \mathcal{I}_{f_{n-1}}$ , we assign a convex weight  $\omega_i^{(n)}$ , i.e.,  $\omega_i^{(n)} \in (0, 1]$  such that  $\sum_{i \in \mathcal{I}_{f_{n-1}}} \omega_i^{(n)} = 1$ .

Define the function:

$$\mathcal{L}_n(f) := \sum_{i \in \mathcal{I}_{f_{n-1}}} \frac{\omega_i^{(n)} d(f_{n-1}, C_i)}{\sum_{j \in \mathcal{I}_{f_{n-1}}} \omega_j^{(n)} d(f_{n-1}, C_j)} d(f, C_i), \quad \forall f \in \mathcal{H}. \quad (17.99)$$

By mimicking the subgradient projection mapping, the procedure of Example 52, and for some  $\mu'_n \in (0, 2)$ , we obtain

$$\begin{aligned} & (1 - \mu'_n) f_{n-1} + \mu'_n \left( f_{n-1} - \frac{\mathcal{L}_n(f_{n-1})}{\|\mathcal{L}'_n(f_{n-1})\|^2} \mathcal{L}'_n(f_{n-1}) \right) \\ &= f_{n-1} - \mu'_n \frac{\mathcal{L}_n(f_{n-1})}{\|\mathcal{L}'_n(f_{n-1})\|^2} \mathcal{L}'_n(f_{n-1}) \\ &= f_{n-1} + \mu'_n \mathcal{M}'_n \left( \sum_{i \in \mathcal{I}_{f_{n-1}}} \omega_i^{(n)} P_{C_i}(f_{n-1}) - f_{n-1} \right), \end{aligned}$$

where

$$\mathcal{M}'_n := \frac{\sum_{i \in \mathcal{I}_{f_{n-1}}} \omega_i^{(n)} d^2(f_{n-1}, C_i)}{\left\| \sum_{i \in \mathcal{I}_{f_{n-1}}} \omega_i^{(n)} (f_{n-1} - P_{C_i}(f_{n-1})) \right\|^2}.$$

Hence, the APSM for this special case of  $(\mathcal{L}_n)_{n \in \mathcal{N}_*}$  becomes as follows:

$$f_n = f_{n-1} + \mu_n \left( \sum_{i \in \mathcal{I}_{f_{n-1}}} \omega_i^{(n)} P_{C_i}(f_{n-1}) - f_{n-1} \right), \quad (17.100a)$$

where the *extrapolation parameter*  $\mu_n \in (0, 2\mathcal{M}_n)$ , with

$$\mathcal{M}_n := \begin{cases} \mathcal{M}'_n, & \text{if } \sum_{i \in \mathcal{I}_{f_{n-1}}} \omega_i^{(n)} (f_{n-1} - P_{C_i}(f_{n-1})) \neq 0, \\ 1, & \text{otherwise.} \end{cases} \quad (17.100b)$$

As the following example demonstrates, a couple of celebrated Signal Processing and Machine Learning tools stem from (17.100a).

**Example 68 (Kernel Affine Projection Algorithm (KAPA) [6,37,68,99,100] and Kernel Normalized Least Mean Squares (KNLMS) algorithm [5,6,37,102–104]).** Given the sequence of training data  $(y_n, \mathbf{x}_n)_{n \in \mathcal{N}_*}$ , and a user-defined positive integer parameter  $m$ , define the following linear mapping according to Example 39:

$$A_n(f) := \begin{bmatrix} \langle f, \kappa(\mathbf{x}_n, \cdot) \rangle \\ \vdots \\ \langle f, \kappa(\mathbf{x}_{n-m+1}, \cdot) \rangle \end{bmatrix} = \begin{bmatrix} f(\mathbf{x}_n) \\ \vdots \\ f(\mathbf{x}_{n-m+1}) \end{bmatrix}, \quad \forall f \in \mathcal{H}, \forall n \in \mathcal{N}_*.$$

Let also  $\mathbf{y}_n := [y_n, \dots, y_{n-m+1}]^T \in \mathcal{R}^m$ , and define the sequence of affine sets:

$$V_n := \operatorname{argmin}_{f \in \mathcal{H}} \| \mathbf{y}_n - A_n(f) \|^2, \quad n \in \mathcal{N}_*,$$

and the sequence of loss functions:

$$\mathcal{L}_n(f) := d(f, V_n), \quad \forall f \in \mathcal{H}, \forall n \in \mathcal{N}_*.$$

Note that this scenario is a special case of the APSM of Example 67, where  $q := 1$ , and  $C_n := V_n, \forall n \in \mathcal{N}_*$ .

Now, motivated by (17.77) and (17.82), and for a sequence of user-defined parameters  $\mu_n \in (0, 2)$ ,  $n \in \mathcal{N}_*$ , we form the following recursive process by means of a relaxed version of the subgradient projection mapping  $T_{\mathcal{L}_n}$  with respect to  $\mathcal{L}_n$ ; for an arbitrary initial point  $f_0 \in \mathcal{H}$ , and  $\forall n \in \mathcal{N}_*$ ,

$$\begin{aligned} f_n &:= (1 - \lambda_n) f_{n-1} + \mu_n T_{\mathcal{L}_n}(f_{n-1}) = (1 - \mu_n) f_{n-1} + \mu_n P_{V_n}(f_{n-1}) \\ &= f_{n-1} + \mu_n (P_{V_n}(f_{n-1}) - f_{n-1}) = f_{n-1} - \mu_n A_n^\dagger(A_n(f_{n-1}) - \mathbf{y}_n), \end{aligned} \quad (17.101)$$

where  $A_n^\dagger$  stands for the pseudoinverse mapping of  $A_n$ . Equation (17.101) is nothing but the Kernel APA [37,68].

In the case where the linear kernel is chosen for  $\mathcal{H}$ , then  $\mathcal{H}$  reduces to a Euclidean  $\mathcal{R}^l$ , and the linear mapping  $A_n$  becomes:

$$A_n(\boldsymbol{\theta}) := \begin{bmatrix} \mathbf{x}_n^T \boldsymbol{\theta} \\ \vdots \\ \mathbf{x}_{n-m+1}^T \boldsymbol{\theta} \end{bmatrix} = \begin{bmatrix} \mathbf{x}_n^T \\ \vdots \\ \mathbf{x}_{n-m+1}^T \end{bmatrix} \boldsymbol{\theta} = \mathbf{A}_n \boldsymbol{\theta}, \quad \forall \boldsymbol{\theta} \in \mathcal{R}^l, \forall n \in \mathcal{N}_*,$$

where  $\mathbf{A}_n := [\mathbf{x}_n, \dots, \mathbf{x}_{n-m+1}]^T$ . Hence, (17.101) reduces to the classical APA [99,100]; for an arbitrarily fixed initial point  $\boldsymbol{\theta}_0$ , for  $\mu_n \in (0, 2)$ , and  $\forall n \in \mathcal{N}_*$ ,

$$\boldsymbol{\theta}_n = \boldsymbol{\theta}_{n-1} - \mu_n \mathbf{A}_n^\dagger(\mathbf{A}_n \boldsymbol{\theta}_{n-1} - \mathbf{y}_n),$$

where  $\mathbf{A}_n^\dagger$  is the Moore-Penrose pseudoinverse of  $\mathbf{A}_n$ .

It is straightforward to verify also that in the case where  $m := 1$  in the KAPA, then the KNLMS algorithm (17.41) is obtained. Thus, KNLMS and its Euclidean version, i.e., the classical NLMS [5, 6, 102, 104], become also special cases of the APSM of Example 67.

It is worthy to notice here that the APA appears to be sensitive when operating in substantially noisy environments [101]. Moreover, it is prone to numerical instability issues due to the need for computation of the Moore-Penrose pseudoinverse in (17.101). However, this is not the case for the APSM. The study [101] showed that the APSM version of Example 67 is resilient to noise, and that no computation of a Moore-Penrose pseudoinverse is needed in order to achieve the same goal as the APA; indeed, given the sequence of training data  $((\mathbf{x}_n, y_n))_{n \in \mathcal{N}_*}$ , define  $C_n := H_n, \forall n \in \mathcal{N}_*$ , where

$$H_n := \{f \in \mathcal{H} : \langle f, \kappa(\mathbf{x}_n, \cdot) \rangle = y_n\}, \quad \forall n \in \mathcal{N}_*,$$

and set  $q := m$  in Example 67 in order to obtain an algorithmic procedure with the same objective as the APA, but free from the computationally thirsty task of calculating the Moore-Penrose pseudoinverse of a matrix.

Let us tailor now the APSM of Example 67 to suit regression tasks. To this end, we will use a special class of closed convex sets, namely the (closed) hyperslabs of Example 38. Given the sequence of training data  $((\mathbf{x}_n, y_n))_{n \in \mathcal{N}_*}$ , and a user-defined parameter  $\epsilon > 0$ , let the (closed) hyperslab ( $\forall n \in \mathcal{N}_*$ ):

$$\begin{aligned} S_n[\epsilon] &:= \{f \in \mathcal{H} : |f(\mathbf{x}_n) - y_n| \leq \epsilon\} \\ &= \{f \in \mathcal{H} : |\langle f, \kappa(\mathbf{x}_n, \cdot) \rangle - y_n| \leq \epsilon\}, \end{aligned}$$

be the set that gathers all those points of the RKHS  $\mathcal{H}$  which achieve a fitness to the observed value  $y_n$  of tolerance up to  $\epsilon$ , when evaluated onto  $\mathbf{x}_n$ . To illustrate the way that the APSM operates, let us apply the sequence of the previous hyperslabs  $(S_n[\epsilon])_{n \in \mathcal{N}_*}$  to Example 67, i.e., use the specific  $(S_n[\epsilon])_{n \in \mathcal{N}_*}$  in the place of the closed convex sets  $(C_n)_{n \in \mathcal{N}_*}$  in Example 67. The objective of the APSM, as well as of any other online learning algorithm, is the following; given the training data  $((\mathbf{x}_i, y_i))_{i=1}^n$ , compute an  $n$ -dimensional real-valued vector  $\boldsymbol{\theta} = (\theta_1, \dots, \theta_n)^T$  in order to produce the estimate  $f_n \in \mathcal{H}$  as a linear combination of the elements of the dictionary  $\{\kappa(\mathbf{x}_i, \cdot)\}_{i=1}^n$ , i.e.,

$$f_n = \sum_{i=1}^n \theta_i \kappa(\mathbf{x}_i, \cdot). \tag{17.102}$$

In general, the vector  $\boldsymbol{\theta}$  depends on the time index  $n$ . However, we have suppressed here this dependency for notational convenience. Each learning algorithm has its own way to calculate  $\boldsymbol{\theta}$ ; for example, the APSM of Example 67 follows the way illustrated in Algorithm 1.17.7.6.

The Algorithm 69 is nothing but a realization of Algorithm 65, where  $(S_n[\epsilon])_{n \in \mathcal{N}_*}$  take the place of  $(C_n)_{n \in \mathcal{N}_*}$ , and where calculations take place in the domain of coefficients  $\boldsymbol{\theta}$ , instead of the functional space  $\mathcal{H}$ . To be more rigorous, such a transfer of operations from  $\mathcal{H}$  to the domain of coefficients is due to the linear mapping:

$$\begin{aligned} \text{span}(\{\kappa(\mathbf{x}_i, \cdot)\}_{i=1}^n) &\rightarrow \mathbb{R}^n \\ f_n = \sum_{i=1}^n \theta_i \kappa(\mathbf{x}_i, \cdot) &\mapsto (\theta_1, \dots, \theta_n)^T = \boldsymbol{\theta}. \end{aligned}$$

---

**Algorithm 69.** The APSM of Example 67 with hyperslabs

---

**Require:** The training data  $((\mathbf{x}_n, y_n))_{n \in \mathcal{N}_*}$ , an RKHS  $\mathcal{H}$ , and an integer  $q > 1$ .

- 1: Set  $\mathcal{D} := \emptyset$ .
  - 2: **for**  $n = 1, 2, \dots$  **do**
  - 3: Insert  $\mathbf{x}_n$  into  $\mathcal{D}$ , i.e., set  $\mathbf{u}_n := \mathbf{x}_n$ , and  $\mathcal{D} := \{\mathbf{u}_1, \dots, \mathbf{u}_{n-1}, \mathbf{u}_n\}$ .
  - 4: Increase the length of  $\boldsymbol{\theta}$  by one, i.e., let  $\boldsymbol{\theta} := (\theta_1, \dots, \theta_{n-1}, \theta_n)^T$ , where  $\theta_n := 0$ .
  - 5: Define  $\mathcal{J} := \{\max\{1, n - q + 1\}, \dots, n\}$ , of length  $q$ , at most.
  - 6: For every  $i \in \mathcal{J}$ , define
$$\beta_i := \begin{cases} \frac{\sum_{j=1}^{n-1} \theta_j \kappa(\mathbf{u}_j, \mathbf{u}_i) - y_i - \epsilon}{\kappa(\mathbf{u}_j, \mathbf{u}_i)} & \text{if } \sum_{j=1}^{n-1} \theta_j \kappa(\mathbf{u}_j, \mathbf{u}_i) > y_i + \epsilon, \\ 0, & \text{if } -\epsilon \leq \sum_{j=1}^{n-1} \theta_j \kappa(\mathbf{u}_j, \mathbf{u}_i) < y_i - \epsilon, \\ \frac{\sum_{j=1}^{n-1} \theta_j \kappa(\mathbf{u}_j, \mathbf{u}_i) - y_i - \epsilon}{\kappa(\mathbf{u}_j, \mathbf{u}_i)} & \text{if } \sum_{j=1}^{n-1} \theta_j \kappa(\mathbf{u}_j, \mathbf{u}_i) < y_i - \epsilon. \end{cases}$$
  - 7: Define the index set  $\mathcal{I}_{f_{n-1}} := \{i \in \mathcal{J} : \beta_i \neq 0\}$ .
  - 8: Choose the convex weights  $\omega_i^{(n)} \in (0, 1]$ ,  $\forall i \in \mathcal{I}_{f_{n-1}}$ , such that  $\sum_{i \in \mathcal{I}_{f_{n-1}}} \omega_i^{(n)} = 1$ .
  - 9: **if**  $\sum_{i,j \in \mathcal{I}_{f_{n-1}}} \omega_i^{(n)} \omega_j^{(n)} \beta_i \beta_j \kappa(\mathbf{u}_i, \mathbf{u}_j) \neq 0$ , **then**
  - 10: Define  $\mathcal{M}_n := \frac{\sum_{i \in \mathcal{I}_{f_{n-1}}} \omega_i^{(n)} \beta_i^2 \kappa(\mathbf{u}_i, \mathbf{u}_i)}{\sum_{i,j \in \mathcal{I}_{f_{n-1}}} \omega_i^{(n)} \omega_j^{(n)} \beta_i \beta_j \kappa(\mathbf{u}_i, \mathbf{u}_j)}$ .
  - 11: **else**
  - 12: Let  $\mathcal{M}_n := 1$ .
  - 13: **end if**
  - 14: Choose any  $\mu_n \in (0, 2\mathcal{M}_n)$ .
  - 15: For every  $i \in \mathcal{I}_{f_{n-1}}$ , define  $\theta_i := \theta_i - \mu_n \omega_i^{(n)} \beta_i$ .
  - 16: **end for**
- 

Let us give here a few more comments in order for the reader to grasp the connection between the Algorithms 12 and 13. Given the estimate  $f_{n-1} = \sum_{i=1}^{n-1} \theta_i \kappa(\mathbf{x}_i, \cdot)$ , Step 6 of Algorithm 69 is based on (17.74), and it contains the decisive term in order to calculate  $P_{S_i[\epsilon]}(f_{n-1})$  in Example 67. If the quantity  $\beta_i$  is non-zero, then it follows from (17.74) that  $f_{n-1} \notin S_i[\epsilon]$ ; this is hidden behind the Step 7 of Algorithm 69. Finally, notice that Step 15 refers to (17.100a).

The way to incorporate the hyperslab  $S_n[\epsilon]$  in Example 67 was via the non-negative distance function  $d(\cdot, S_n[\epsilon])$ , as (17.99) clearly suggests. The connection between  $S_n[\epsilon]$  and  $d(\cdot, S_n[\epsilon])$  has been already made clear by Def. 34; indeed,  $\text{lev}_{\leq 0}(d(\cdot, S_n[\epsilon])) = S_n[\epsilon]$ . However, by the freedom that the general form of the APSM in (17.98) infuses into the design, as well as by the way that the loss function is defined in Example 67, one would expect also other candidates of convex loss functions, which take the place of  $d(\cdot, S_n[\epsilon])$  in (17.99), but still maintain  $S_n[\epsilon]$  as their 0th level set, i.e.,  $\text{lev}_{\leq 0}(\cdot)$ . For example, the  $\epsilon$ -insensitive loss:

$$\ell : \mathcal{H} \rightarrow \mathcal{R} : f \mapsto \ell(f) := (|f(\mathbf{x}_n) - y_n| - \epsilon)_+,$$

where  $(\cdot)_+$  stands for the positive part of a real number (see Figure 17.33), is a non-negative convex function that achieves the previous objective. The previous loss function candidate was not a random choice; it has been used extensively in *Support Vector Regression (SVR)* [2, 7, 13], due to its remarkable robustness attributes. The previous discussion illustrates the flexibility of the APSM with respect to the choice of the loss function in (17.98) or in (17.99). Such a choice is often dictated by the nature of the learning task at hand; a sequence of halfspaces were utilized in [96], as a special case of the  $(C_n)_{n \in \mathcal{N}_*}$  in Example 67, in order to attack a classification problem. Moreover, another choice for the sequence of loss functions  $(\mathcal{L}_n)_{n \in \mathcal{N}_*}$  in (17.98) led to a convex analytic alternative for the celebrated RLS in [105], where the need for inverting an autocorrelation matrix is bypassed.

### 1.17.7.6.1 Sparsification

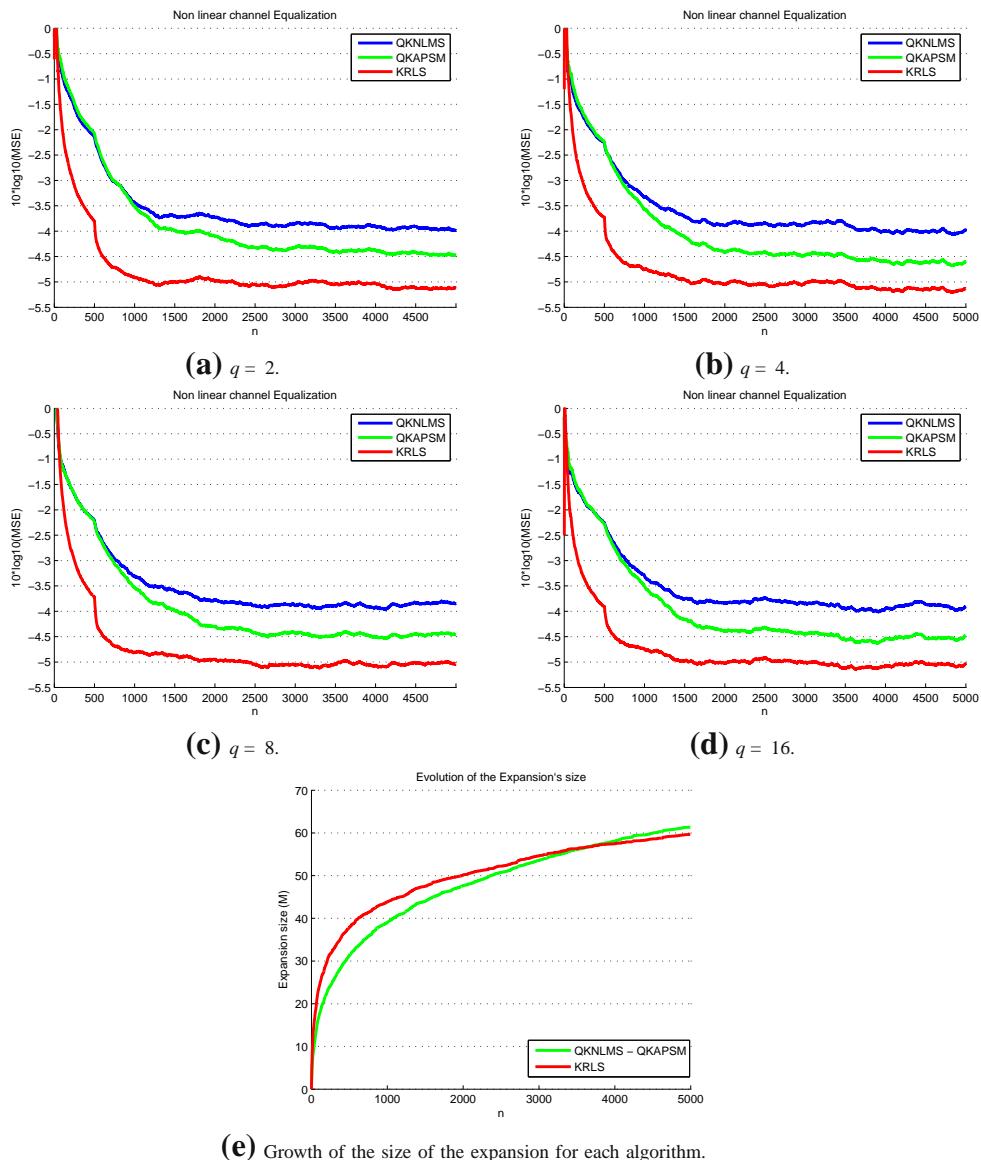

As we have seen in Section 1.17.6.2.1, any online learning algorithm, which operates in a potentially infinite dimensional RKHS, suffers from the large number of incoming training data  $(\mathbf{x}_n, y_n)_{n \in \mathcal{N}_*}$ , since such an abundance of data causes an explosion of the system's computational complexity and memory requirements, via kernel series expansions, like (17.39) and (17.102). This can be also observed in Algorithm 69. Hence, sparsification of the expansions in (17.39) or (17.102) is needed. To make these concepts as concrete as possible, let us elaborate more on the realization of the APSM given in Algorithm 69. In order to enforce sparsification into the algorithm, and motivated by the discussion related to (17.11), the study in [96] imposed an additional constraint to the sequence of estimates  $(f_n)_{n \in \mathcal{N}}$ ; the following closed ball, with center 0 and radius  $\Delta > 0$  (see also Example 36):

$$B[0, \Delta] := \{f \in \mathcal{H} : \|f\| \leq \Delta\},$$

was used in the place of the closed convex set  $C$  in (17.98). It turns out that such a sparsification scheme is equivalent to a forgetting factor mechanism that forgets data in the remote past; see [96] for a more detailed presentation. Since such a forgetting mechanism renders the contribution of “old” training data weak in kernel series expansions like (17.102), it is natural to adopt a buffer of length  $M$  where only the  $M$  more recent training data are kept. For the sake of illustration, this sparsification strategy is summarized by the pseudocode formulation of Algorithm 70. For more advances on the capability of the APSM to incorporate constraints in its formulation, the interested reader is referred to [42, 92, 93].

The main difference between the Algorithms 13 and 14 lies on the previous closed-ball sparsification strategy, which is realized in the latter algorithm. More specifically, this strategy can be seen from Step 15 to Step 29 of Algorithm 70. In Step 15,  $v$  stands for the square of the norm of the term  $f_{n-1} + \mu_n \left( \sum_{i \in \mathcal{I}_{f_{n-1}}} \omega_i^{(n)} P_{C_i}(f_{n-1}) - f_{n-1} \right)$ , met in (17.100a). The lines from Step 17 to Step 22 refer to the application of the metric projection mapping  $P_{B[0, \Delta]}$ , i.e., Example 36, onto the closed ball constraint  $B[0, \Delta]$ , according to the scheme of the general APSM, depicted in (17.98). Finally, the lines starting from Step 23 to Step 29, ensure that the size of the dictionary stays at most  $M$ , by “throwing away” the “oldest” contribution in  $\mathcal{D}$ . As it was explained in [96], such a brute-force method is justified by the effect that the mapping  $P_{B[0, \Delta]}$  has on the coefficients of  $\theta$ ; it has the tendency to trim down the “oldest” ones.

In principle, any other sparsification scheme, as the ones discussed in Section 1.17.6.2.1, can be used instead of the closed-ball one, seen in Algorithm 70. For example, instead of “throwing away” the “oldest” coefficient of  $\theta$  in Algorithm 70, a more “gentle” approach would be to discard that coefficient

**FIGURE 17.32**

Learning curves for the QKAPSM of Example 67 employing the Quantization sparsification procedure (section 1.17.6.2.1), QKNLMS, and KRLS, and for the same nonlinear equalization task as in Sections 1.17.6.2.2 and 1.17.6.6.1, for various values of the parameter  $q$ . Note that the expansions of QKNLMS and QKAPSM are identical in terms of the training point, as shown in (d). The parameters of each expansion, though, are different.

of  $\theta$  with the least contribution in the kernel series expansion of (17.102). All of these sparsification strategies which rely on the closed ball constraint exhibit a linear computational complexity with respect to the number of elements of  $\mathcal{D}$  [96]. The APSM, combined with a more involved sparsification strategy along the lines of the ALD strategy of the KRLS, can be found in [68]. Finally, inspired by the sparsification scheme of the QKLMS (see Algorithm 27.6.3), a quantized alternative to Algorithm 70 is given by the QKAPSM in Algorithm 71. Here, the size of the dictionary  $\mathcal{D}$  is determined by the quantization parameter  $\delta$ . Although this sparsification strategy shows a computational complexity lower than the one of Algorithm 70, it demonstrates a remarkable performance, as this can be seen by the numerical results of Section 1.17.7.6.2.

**1.17.7.6.2 Simulation results**

In order to validate the APSM of Example 67, we consider the same nonlinear channel equalization scenario to the one used in Sections 1.17.6.2.2 and 1.17.6.6.1. More specifically, the nonlinear channel consists of a linear filter  $t_n = -0.8 \cdot y_n + 0.7 \cdot y_{n-1} - 0.6 \cdot y_{n-2} + 0.4 \cdot y_{n-3}$ , and a memoryless nonlinearity  $q_n = t_n + 0.08 \cdot t_n^2$ ,  $\forall n \in \mathcal{N}_*$ . The parameters for the QKNLMS and the KRLS are identical to the ones used in Sections 1.17.6.2.2 and 1.17.6.6.1. As for the APSM, its QKAPSM version, i.e., Algorithm 71, was employed. For the present scenario, the following parameters were used for the APSM;  $q := 2, 4, 8, 16$ ,  $\mu_n = 0.5$ ,  $\epsilon := 10^{-10}$ ,  $\forall n \in \mathcal{N}_*$ , while the parameter for the sparsification procedure was set to  $\delta = 6$ , for both APSM and QKNLMS (See fig. 17.32).

Notice that the APSM achieves superior performance, when compared to the QKNLMS, while both achieve the same expansion size. This is a natural consequence of the ability of the APSM to activate data reuse or concurrent processing, by letting the parameter  $q$  to take values larger than 1. Recall, by Example 68, that the KNLMS is a byproduct of the APSM for  $q = 1$ . In general, the more the  $q$  is increased, the faster the convergence of the KAPSM becomes. The flexibility offered to the APSM by the theory of convex analysis pays off, also, in the case where the APSM is compared to the classical APA, or KAPA (see Example 68). Even if both APSM and APA employ data reuse, the way the APSM is derived (Example 67) precludes the system from the calculation of a matrix inversion, as is the case for the APA where the computation of a pseudoinverse is necessary. This becomes beneficial in cases where algorithmic stability is the issue. Notice also that the misadjustment level of the APSM is inferior

to the KRLS. Recall, here, that the computational complexity of the KRLS is  $O(M_n^2)$ , as opposed to the  $O(qM_n)$ , where  $M_n$  is the size of the dictionary at the time instant  $n$ . Recall, also, that the computational complexity of the QKNLMS is  $O(M_n)$ .

More on the validation of the APSM, for several learning tasks, can be found in [41–43, 95, 97, 98, 106, 107, 112]. The code for the experiments presented in this section can be found in <<http://bouboulis.mysch.gr/kernels.html>>.

---

**Algorithm 71.** Quantized Kernel APSM (QKAPSM) for Example 67 with hyperslabs

---

**Require:** The training data  $((\mathbf{x}_n, y_n))_{n \in \mathcal{N}_*}$ , an RKHS  $\mathcal{H}$ , an integer  $q > 1$ , and the quantization parameter  $\delta > 0$ .

- 1: Set  $\mathcal{D} := \emptyset$ , and  $M := 0$ .
- 2: **for**  $n = 1, 2, \dots$ , **do**
- 3:   Compute the distance of  $\mathbf{x}_n$  from  $\mathcal{D}$ :  

$$d(\mathbf{x}_n, \mathcal{D}) = \inf_{\mathbf{u}_i \in \mathcal{D}} \|\mathbf{x}_n - \mathbf{u}_i\| = \|\mathbf{x}_n - \mathbf{u}_{l_0}\|, \text{ for some } l_0 \in \{1, \dots, M\}.$$

In the case where there are multiple such  $l_0$ s, then choose the largest one.  
To leave no place for ambiguities, let also  $d(\mathbf{x}_n, \emptyset) := +\infty$ .
- 4:   **if**  $d(\mathbf{x}_n, \mathcal{D}) > \delta$ , **then**
- 5:     Insert  $\mathbf{x}_n$  into  $\mathcal{D}$ , i.e., set  $\mathbf{u}_{M+1} = \mathbf{x}_n$ , and  $\mathcal{D} = \{\mathbf{u}_1, \dots, \mathbf{u}_M, \mathbf{u}_{M+1}\}$ .
- 6:     Increase the length of  $\boldsymbol{\theta}$  by one, i.e., let  $\boldsymbol{\theta} := (\theta_1, \dots, \theta_M, \theta_{M+1})^T$ , where  $\theta_{M+1} := 0$ .
- 7:     Define  $\mathcal{J} := \{\max\{1, M - q + 2\}, \dots, M + 1\}$ .
- 8:   **else**
- 9:     **if**  $l_0 \geq \max\{1, M - q + 1\}$ , **then**
- 10:        $\mathcal{J} := \{\max\{1, M - q + 1\}, \dots, M\}$ .
- 11:     **else**
- 12:        $\mathcal{J} := \{l_0, M - q + 2, \dots, M\}$ .
- 13:     **end if**
- 14:   **end if**
- 15:   For every  $i \in \mathcal{J}$ , define  

$$\beta_i := \begin{cases} \frac{\sum_{j=1}^M \theta_j \kappa(\mathbf{u}_j, \mathbf{u}_i) - y_i - \epsilon}{\kappa(\mathbf{u}_i, \mathbf{u}_i)}, & \text{if } \sum_{j=1}^M \theta_j \kappa(\mathbf{u}_j, \mathbf{u}_i) > y_i + \epsilon, \\ 0, & \text{if } -\epsilon \leq \sum_{j=1}^M \theta_j \kappa(\mathbf{u}_j, \mathbf{u}_i) - y_i \leq \epsilon, \\ \frac{\sum_{j=1}^M \theta_j \kappa(\mathbf{u}_j, \mathbf{u}_i) - y_i + \epsilon}{\kappa(\mathbf{u}_i, \mathbf{u}_i)}, & \text{if } \sum_{j=1}^M \theta_j \kappa(\mathbf{u}_j, \mathbf{u}_i) < y_i - \epsilon. \end{cases}$$
- 16:   Define the index set  $\mathcal{I}_{f_{n-1}} := \{i \in \mathcal{J} : \beta_i \neq 0\}$ .
- 17:   Choose the convex weights  $\omega_i^{(n)} \in (0, 1], \forall i \in \mathcal{I}_{f_{n-1}}$ , such that  $\sum_{i \in \mathcal{I}_{f_{n-1}}} \omega_i^{(n)} = 1$ .
- 18:   **if**  $\sum_{i, j \in \mathcal{I}_{f_{n-1}}} \omega_i^{(n)} \omega_j^{(n)} \beta_i \beta_j \kappa(\mathbf{u}_i, \mathbf{u}_j) \neq 0$ , **then**
- 19:     Define  $\mathcal{M}_n := \frac{\sum_{i \in \mathcal{I}_{f_{n-1}}} \omega_i^{(n)} \beta_i^2 \kappa(\mathbf{u}_i, \mathbf{u}_i)}{\sum_{i, j \in \mathcal{I}_{f_{n-1}}} \omega_i^{(n)} \omega_j^{(n)} \beta_i \beta_j \kappa(\mathbf{u}_i, \mathbf{u}_j)}$ .
- 20:   **else**

---

**Algorithm 71.** (Continued)

---

```

21: Let  $\mathcal{M}_n := 1$ .
22: end if
23: Choose any  $\mu_n \in (0, 2\mathcal{M}_n)$ .
24: For every  $i \in \mathcal{I}_{f_{n-1}}$ , define  $\theta_i := \theta_i - \mu_n \omega_i^{(n)} \beta_i$ .
25: if  $d(\mathbf{x}_n, \mathcal{D}) > \delta$ , then
26:    $M := M + 1$ .
27: end if
```

**Output:** The dictionary  $\mathcal{D} = \{\mathbf{u}_1, \dots, \mathbf{u}_M\}$ , and the real-valued vector  $\boldsymbol{\theta} = (\theta_1, \dots, \theta_M)^T$ , which produce the estimate  $f_n = \sum_{i=1}^M \theta_i \kappa(\mathbf{u}_i, \cdot)$ .

```
28: end for
```

## 1.17.8 Related work and applications

The recursions (17.86), (17.90), (17.94), and (17.96), met in the previous section, are the basis of a plethora of algorithmic solutions for signal processing [5, 6, 27, 41–43, 45, 68, 94, 95, 97, 98, 106–113] and machine learning [57–61, 77, 78, 114–128], and, thus, they are the engine behind numerous applications which span from echo cancellation, equalization of linear/nonlinear channels, image processing, and wireless sensor networks, to pattern recognition and classification, social network analysis, bioinformatics, and sparsity-aware learning. This section aims to shedding light on the connection of the convex analytic framework of Section 1.17.7 with several recent works on online learning. We focus mainly on machine learning techniques, since their connection with the framework of Section 1.17.7 is not as much illuminated as is the signal processing side of learning [95, 129, 130].

The recursion (17.96) is the basic ingredient hidden behind the NORMA method of [122]. In [122], the sequence of closed convex sets  $(C_n)_{n \in \mathcal{N}_*}$  is not imposed into the design, i.e., the unconstrained case, and the loss function  $\mathcal{L}_n := \Theta_n + \lambda \|\cdot\|^2$ ,  $\forall n \in \mathcal{N}_*$ , where  $\lambda > 0$  is a regularization parameter. This form of loss functions originates from the very successful Support Vector Machines (SVM) rationale. By assuming Lipschitz continuity for all the loss functions  $(\Theta_n)_{n \in \mathcal{N}_*}$ , a convergence analysis is conducted in [122] in order to derive error bounds whenever the learning step sizes  $(\mu_n)_{n \in \mathcal{N}_*}$  follow the diminishing rule of  $\mu_n \propto \frac{1}{\sqrt{n}}$ ,  $\forall n \in \mathcal{N}_*$ . The SVM rationale and the recursion (17.96) is also hidden behind [126]. The Lipschitz continuity assumption of [122] on  $(\Theta_n)_{n \in \mathcal{N}_*}$  is bypassed, the sequence  $(C_n)_{n \in \mathcal{N}_*}$  is fixed to a single closed convex set, e.g., a closed ball, and the convergence analysis for the error bounds is conducted on the assumption of  $(\mathcal{L}_n)_{n \in \mathcal{N}_*}$  being a sequence of strongly convex functions (see Definition 33), with  $\mu_n \propto \frac{1}{n}$ ,  $\forall n \in \mathcal{N}_*$ . Notice, here, that the rules for the learning step parameters  $(\mu_n)_{n \in \mathcal{N}_*}$ , adopted in both [122, 126], are very closely related to the discussion on (17.92), and the classical method of [84]. A study on the stability of the basic recursion (17.96), under a stochastic framework, in the case where the loss functions  $(\mathcal{L}_n)_{n \in \mathcal{N}_*}$  are differentiable, is given in the very recent work of [125]. Moreover, by

following the rationale of proximal mappings (see Example 47), as well as the strategies of the forward-backward and the Douglas-Rachford algorithms [65, 72, 73, 75, 76] (see the discussion below (17.85)), generalizations of (17.96) in the online learning context can be found in [77, 78, 110, 113, 124].

The classical LMS recursion (17.34) is studied through the machine learning magnifying glass in [118]. Inner products, in properly defined inner product spaces, are used in order to model estimates. The gradient descent algorithm of [118] is utilized to derive several worst-case bounds of the total sum of the squared prediction errors. A normalized version of the gradient descent algorithm, which is nothing but the direct analogue of the NLMS method (17.37) to general inner product spaces, appears and is analyzed also in [118]. The interaction of the gradient descent rationale with noisy environments was very recently studied in [117], where, in particular, several theoretical results were stated regarding the question of to what extent independently perturbed copies of each training datum assist the gradient descent algorithm in its online learning task.

An algorithm of the same spirit to the KNLMS (see Section 1.17.6.2) is studied in [119]. The kernel series expansion estimate is updated every time instant by projecting the current estimate onto a single halfspace, whenever a classification problem is considered, or a hyperslab (see Example 38), whenever a regression task is studied. These solution sets are defined by the newly arrived training data as the set of all minimizers of properly defined *hinge* loss functions. Variants of this scheme are also studied in [119] by means of a parameter which controls how much aggressive the projection onto the halfspace should be. A generalization of [119], towards using multiple halfspaces at each time instant, similarly to the strategy of Examples 52, 67, and 68, is given in [114]. However, the study of [114] follows a different approach than the one in Examples 52, 67, and 68, by transferring the original problem to the dual domain, by approximating it via a multiple number of simpler problems, and by elaborating inner iterations, at each step of the algorithm, in order to calculate various optimal step parameters.

---

## 1.17.9 Conclusions

This manuscript presented an overview of online learning techniques; both classical and modern. To serve the needs of both the signal processing and machine learning communities, this work has focused on bringing forth the basic principles of a fundamental machine learning tool, the Reproducing Kernel Hilbert Spaces, and on highlighting a theoretical device, mostly known to the signal processing community, i.e., the elegant and geometrically rich convex analytic side of operators/mappings in general Hilbert spaces. Despite its tutorial nature, the manuscript does not spare mathematical rigor; proofs are given in detail in places where we feel that the way to use the previous mathematical tools should be demonstrated. We have also tried to provide with a framework that unites classical and modern stuff; numerous classical online learning techniques stem as special cases of the introduced mathematical framework. Numerical examples have been also given in order to exemplify the common attributes which run along the spine of online learning tasks in both signal processing and machine learning principles, i.e., the nonlinear estimation theory and the classification/regression framework.

## Appendices

### A Key properties of the gaussian kernel

As the Gaussian kernel is the most widely used in applications, we dedicate this section to present some of its most important properties. We begin our study showing that the Gaussian radial basis function is indeed a reproducing kernel. To this end, we introduce some new notions.

**Definition A.1 (Negative Definite Kernel).** Let  $X$  be a set. A function  $\kappa : X \times X \rightarrow \mathcal{R}$  is called a negative definite kernel if it is symmetric, i.e.,  $\kappa(\mathbf{y}, \mathbf{x}) = \kappa(\mathbf{x}, \mathbf{y})$ , and

$$\sum_{n,m=1}^N c_n c_m \kappa(\mathbf{x}_n, \mathbf{x}_m) \leq 0,$$

for any  $\mathbf{x}_1, \dots, \mathbf{x}_N \in X$ ,  $c_1, \dots, c_N \in \mathcal{R}$ , with  $\sum_{n=1}^N c_n = 0$ , and for all  $N \in \mathcal{N}_*$ .  $\diamond$

Examples of negative kernels are the constant functions and all functions of the form  $-\kappa$ , where  $\kappa$  is a positive definite kernel. Furthermore, the following proposition holds:

**Proposition A.2.** Let  $X$  be a non empty set, the functions  $\psi_k : X \times X \rightarrow \mathcal{R}$  be negative kernels and  $\alpha_k > 0$ , for  $k \in \mathcal{N}_*$ . Then

- Any positive combination of a finite number of negative kernels is also a negative kernel, i.e.,  $\psi = \sum_k \alpha_k \psi_k$ , with  $\alpha_1, \dots, \alpha_n > 0$  is a negative kernel.
- The limit of any converging sequence of negative kernels is also a negative kernel, i.e. if  $\psi(\mathbf{x}, \mathbf{y}) = \lim_k \psi_k(\mathbf{x}, \mathbf{y})$ , for all  $\mathbf{x}, \mathbf{y} \in X$ , then  $\psi$  is a negative kernel.

$\diamond$

**Proof.** For the first part, consider the numbers  $c_1, \dots, c_N$  such that  $\sum_{n=1}^N c_n = 0$ ,  $\mathbf{x}_1, \dots, \mathbf{x}_N \in X$  and  $M \in \mathcal{N}_*$ . Then

$$\sum_{n,m=1}^N c_n c_m \sum_{k=1}^M \alpha_k \psi_k(\mathbf{x}_n, \mathbf{x}_m) = \sum_{k=1}^M \alpha_k \sum_{n,m=1}^N c_n c_m \psi_k(\mathbf{x}_n, \mathbf{x}_m) \leq 0.$$

Finally, to prove the second part we take:

$$\sum_{n,m=1}^N c_n c_m \psi(\mathbf{x}_n, \mathbf{x}_m) = \sum_{n,m=1}^N c_n c_m \lim_k \psi_k(\mathbf{x}_n, \mathbf{x}_m) = \lim_k \sum_{n,m=1}^N c_n c_m \psi_k(\mathbf{x}_n, \mathbf{x}_m) \leq 0.$$

$\square$

**Lemma A.3.** Let  $X$  be a nonempty set,  $V$  be a vector space equipped with an inner product and  $T : X \rightarrow V$ . Then the function

$$\psi(\mathbf{x}, \mathbf{y}) = \|T(\mathbf{x}) - T(\mathbf{y})\|_V^2,$$

is a negative definite kernel on  $X$ .  $\diamond$

**Proof.** Consider the numbers  $c_1, \dots, c_N$  such that  $\sum_{n=1}^N c_n = 0$  and  $\mathbf{x}_1, \dots, \mathbf{x}_N \in X$ . Then

$$\begin{aligned}
 \sum_{n,m=1}^N c_n c_m \|T(\mathbf{x}_n) - T(\mathbf{x}_m)\|_V^2 &= \sum_{n,m=1}^N c_n c_m \langle T(\mathbf{x}_n) - T(\mathbf{x}_m), T(\mathbf{x}_n) - T(\mathbf{x}_m) \rangle_V \\
 &= \sum_{n,m=1}^N c_n c_m \left( \|T(\mathbf{x}_n)\|_V^2 + \|T(\mathbf{x}_m)\|_V^2 - \langle T(\mathbf{x}_n), T(\mathbf{x}_m) \rangle_V \right. \\
 &\quad \left. - \langle T(\mathbf{x}_m), T(\mathbf{x}_n) \rangle_V \right) \\
 &= \sum_{m=1}^N c_m \sum_{n=1}^N c_n \|T(\mathbf{x}_n)\|_V^2 + \sum_{n=1}^N c_n \sum_{m=1}^N c_m \|T(\mathbf{x}_m)\|_V^2 \\
 &\quad - \left\langle \sum_{n=1}^N c_n T(\mathbf{x}_n), \sum_{m=1}^N c_m T(\mathbf{x}_m) \right\rangle_V \\
 &\quad - \left\langle \sum_{m=1}^N c_m T(\mathbf{x}_m), \sum_{n=1}^N c_n T(\mathbf{x}_n) \right\rangle_V.
 \end{aligned}$$

As  $\sum_{n=1}^N c_n = 0$ , the first two terms of the summation vanish and we take:

$$\sum_{n,m=1}^N c_n c_m \|T(\mathbf{x}_n) - T(\mathbf{x}_m)\|_V^2 = -2 \left\| \sum_{n=1}^N c_n T(\mathbf{x}_n) \right\|_V^2 \leq 0.$$

Thus  $\psi$  is a negative definite kernel.  $\square$

**Lemma A.4.** Let  $\psi : X \times X \rightarrow \mathcal{R}$  be a function. Fix  $\mathbf{x}_0 \in X$  and define

$$\kappa(\mathbf{x}, \mathbf{y}) = -\psi(\mathbf{x}, \mathbf{y}) + \psi(\mathbf{x}, \mathbf{x}_0) + \psi(\mathbf{x}_0, \mathbf{y}) - \psi(\mathbf{x}_0, \mathbf{x}_0).$$

Then  $\psi$  is a negative definite kernel if and only if  $\kappa$  is a positive definite kernel.  $\diamond$

**Proof.** Let  $\mathbf{x}_1, \dots, \mathbf{x}_N \in X$ . For the if part, consider the numbers  $c_1, \dots, c_N$  such that  $\sum_{n=1}^N c_n = 0$ . Then

$$\begin{aligned}
 \sum_{n,m=1}^N c_n c_m \kappa(\mathbf{x}_n, \mathbf{x}_m) &= - \sum_{n,m=1}^N c_n c_m \psi(\mathbf{x}_n, \mathbf{x}_m) + \sum_{n,m=1}^N c_n c_m \psi(\mathbf{x}_n, \mathbf{x}_0) \\
 &\quad + \sum_{n,m=1}^N c_n c_m \psi(\mathbf{x}_0, \mathbf{x}_m) - \sum_{n,m=1}^N c_n c_m \psi(\mathbf{x}_0, \mathbf{x}_0) \\
 &= - \sum_{n,m=1}^N c_n c_m \psi(\mathbf{x}_n, \mathbf{x}_m) + \sum_{n=1}^N c_m \sum_{n=1}^N c_n \psi(\mathbf{x}_n, \mathbf{x}_0) \\
 &\quad + \sum_{n=1}^N c_n \sum_{m=1}^N c_m \psi(\mathbf{x}_0, \mathbf{x}_m) - \sum_{m=1}^N c_m \sum_{n=1}^N c_n \psi(\mathbf{x}_0, \mathbf{x}_0).
 \end{aligned}$$

As  $\sum_{n=1}^N c_n = 0$  and  $\sum_{n,m=1}^N c_n c_m \kappa(\mathbf{x}_n, \mathbf{y}_m) \geq 0$ , we take that  $\sum_{n,m=1}^N c_n c_m \psi(\mathbf{x}_n, \mathbf{y}_m) \leq 0$ . Thus  $\psi$  is a negative definite kernel.

For the converse, take  $c_1, \dots, c_N \in \mathcal{R}$  and define  $c_0 = -\sum_{n=1}^N c_n$ . By this simple trick, we generate the numbers  $c_0, c_1, \dots, c_N \in \mathcal{R}$ , which have the property  $\sum_{n=0}^N c_n = c_0 + \sum_{n=1}^N c_n = 0$ . As  $\psi$  is a negative definite kernel, we take that  $\sum_{n,m=0}^N c_n c_m \psi(\mathbf{x}_n, \mathbf{x}_m) \leq 0$ , for any  $\mathbf{x}_0 \in X$ . Thus,

$$\begin{aligned} \sum_{n,m=0}^N c_n c_m \psi(\mathbf{x}_n, \mathbf{x}_m) &= \sum_{n,m=1}^N c_n c_m \psi(\mathbf{x}_n, \mathbf{x}_m) + \sum_{m=1}^N c_0 c_m \psi(\mathbf{x}_0, \mathbf{x}_m) \\ &\quad + \sum_{n=1}^N c_0 c_n \psi(\mathbf{x}_n, \mathbf{x}_0) + c_0^2 \psi(\mathbf{x}_0, \mathbf{x}_0) \\ &= \sum_{n,m=1}^N c_n c_m \psi(\mathbf{x}_n, \mathbf{x}_m) - \sum_{n,m=1}^N c_n c_m \psi(\mathbf{x}_0, \mathbf{x}_m) \\ &\quad - \sum_{n,m=1}^N c_n c_m \psi(\mathbf{x}_n, \mathbf{x}_0) + \sum_{n,m=1}^N c_n c_m \psi(\mathbf{x}_0, \mathbf{x}_0) \\ &= \sum_{n,m=1}^N c_n c_m (\psi(\mathbf{x}_n, \mathbf{x}_m) - \psi(\mathbf{x}_0, \mathbf{x}_m) - \psi(\mathbf{x}_n, \mathbf{x}_0) + \psi(\mathbf{x}_0, \mathbf{x}_0)) \\ &= - \sum_{n,m=1}^N c_n c_m \kappa(\mathbf{x}_n, \mathbf{x}_m). \end{aligned}$$

Thus  $\sum_{n,m=1}^N c_n c_m \kappa(\mathbf{x}_n, \mathbf{x}_m) \geq 0$  and  $\kappa$  is a positive definite kernel.  $\square$

**Theorem A.5 (Schoenberg).** *Let  $X$  be a nonempty set and  $\psi : X \times X \rightarrow \mathcal{R}$ . The function  $\psi$  is a negative kernel if and only if  $\exp(-t\psi)$  is a positive definite kernel for all  $t \geq 0$ .*  $\diamond$

**Proof.** For the if part, recall that

$$\psi(\mathbf{x}, \mathbf{y}) = \lim_{t \rightarrow 0} \frac{1 - \exp(-t\psi(\mathbf{x}, \mathbf{y}))}{t}.$$

As  $\exp(-t\psi)$  is positive definite,  $-\exp(-t\psi)$  is negative definite and the result follows from Proposition A.2. It suffices to prove the converse for  $t = 1$ , as if  $\psi$  is a negative definite kernel so is  $t\psi$ , for any  $t \geq 0$ . Take  $\mathbf{x}_0 \in X$  and define the positive definite kernel  $\kappa(\mathbf{x}, \mathbf{y}) = -\psi(\mathbf{x}, \mathbf{y}) + \psi(\mathbf{x}, \mathbf{x}_0) + \psi(\mathbf{x}_0, \mathbf{y}) - \psi(\mathbf{x}_0, \mathbf{x}_0)$  (Lemma A.4). Then

$$e^{-\psi(\mathbf{x}, \mathbf{y})} = e^{-\psi(\mathbf{x}, \mathbf{x}_0)} e^{\kappa(\mathbf{x}, \mathbf{y})} e^{-\psi(\mathbf{x}_0, \mathbf{y})} e^{\kappa(\mathbf{x}_0, \mathbf{x}_0)}.$$

Let  $f(\mathbf{x}) = e^{-\psi(\mathbf{x}, \mathbf{x}_0)}$ . Then, as  $\psi$  is a negative kernel and therefore symmetric, one can readily prove that the last relation can be rewritten as

$$e^{-\psi(\mathbf{x}, \mathbf{y})} = e^{\kappa(\mathbf{x}_0, \mathbf{x}_0)} \cdot f(\mathbf{x}) e^{\kappa(\mathbf{x}, \mathbf{y})} f(\mathbf{y}).$$

Since  $e^{\kappa(x_0, x_0)}$  is a positive number, employing the properties of positive kernels given in Section 1.17.5.5, we conclude that  $e^{-\psi(x, y)}$  is a positive definite kernel.  $\square$

**Corollary A.6.** *The Gaussian radial basis function is a reproducing kernel.*

Although all properties of positive kernels do not apply to negative kernels as well (for example the product of negative kernels is not a negative kernel), there are some other operations that preserve negativity.

**Proposition A.7.** *Let  $\psi : X \times X \rightarrow \mathcal{R}$  be negative definite. In this case:*

1. *If  $\psi(x, x) \geq 0$ , for all  $x \in X$ , then  $\psi^p(x, y)$  is negative definite for any  $0 < p \leq 1$ .*
2. *If  $\psi(x, x) \geq 0$ , for all  $x \in X$ , then  $\log(1 + \psi(x, y))$  is negative definite.*
3. *If  $\psi : X \times X \rightarrow (0, +\infty)$ , then  $\log \psi(y, x)$  is negative definite.*  $\diamond$

**Proof.** We give a brief description of the proofs.

1. We use the formula:

$$\psi(x, y)^p = \frac{p}{\Gamma(1-p)} \int_0^\infty t^{-p-1} (1 - e^{-t\psi(x, y)}) dt,$$

where the Gamma function is given by  $\Gamma(z) = \int_0^\infty e^{-t} t^z dt$ . As  $e^{-t\psi(x, y)}$  is positive definite (Theorem A.5) and  $t^{-p-1}$  is a positive number, it is not difficult to prove that the expression inside the integral is negative definite for all  $t > 0$ .

2. Similarly, we use the formula:

$$\log(1 + \psi(x, y)) = \int_0^\infty \frac{e^{-t}}{t} (1 - e^{-t\psi(x, y)}) dt.$$

3. For any  $c > 0$ ,  $\log(\psi(x, y) + 1/c) = \log(1 + c\psi(x, y)) - \log(c)$ . We can prove that the second part is negative definite. Then, by taking the limit as  $c \rightarrow 0$ , one completes the proof.  $\square$

As a direct consequence, one can prove that since  $\|x - y\|^2$  is a negative kernel, so is  $\|x - y\|^{2p}$ , for any  $0 < p \leq 1$ . Thus, for any  $0 < p \leq 2$ ,  $\|x - y\|^p$  is a negative kernel and  $\exp(-t\|x - y\|^p)$  is a positive kernel for any any  $t > 0$ . Therefore, for  $p = 2$  we take another proof of the positivity of the Gaussian radial basis function. In addition, for  $p = 1$  one concludes that the Laplacian radial basis function is also a positive kernel. Moreover, for the Gaussian kernel the following important property has been proved.

**Theorem A.8 (Full rank of the Gaussian RBF Gram matrices).** *Suppose that  $x_1, \dots, x_N \subset X$  are distinct points and  $\sigma \neq 0$ . The Gram matrix given by  $K = (K_{n,m})$ , where*

$$K_{n,m} = \exp\left(-\frac{\|x_n - x_m\|^2}{2\sigma^2}\right),$$

*has full rank.*  $\diamond$

As a consequence, for any choice of discrete points  $\mathbf{x}_1, \dots, \mathbf{x}_N$ , we have that  $\sum_{m=1}^N a_m \kappa(\mathbf{x}_n, \mathbf{x}_m) = 0$ , for all  $n = 1, 2, \dots, N$ , if and only if  $a_1 = \dots = a_N = 0$ . However, observe that for any  $a_1, \dots, a_N$

$$\sum_{m=1}^N a_m \kappa(\mathbf{x}_n, \mathbf{x}_m) = \sum_{m=1}^N a_m \langle \kappa(\cdot, \mathbf{x}_m), \kappa(\cdot, \mathbf{x}_n) \rangle_{\mathcal{H}} = \left\langle \sum_{m=1}^N a_m \kappa(\cdot, \mathbf{x}_m), \kappa(\cdot, \mathbf{x}_n) \right\rangle_{\mathcal{H}} = \langle f, \kappa(\cdot, \mathbf{x}_n) \rangle_{\mathcal{H}},$$

where  $f = \sum_{m=1}^N a_m \kappa(\cdot, \mathbf{x}_m) \in \text{span}\{\kappa(\cdot, \mathbf{x}_m), m = 1, \dots, N\}$ . In addition, if for an  $f \in \text{span}\{\kappa(\cdot, \mathbf{x}_m), m = 1, \dots, N\}$  we have that  $\langle f, \kappa(\cdot, \mathbf{x}_n) \rangle_{\mathcal{H}} = 0$  for all  $n = 1, \dots, N$ , if and only if  $f = 0$ . Hence, if  $f$  is orthogonal to all  $\Phi(\mathbf{x}_n)$ , then  $f = 0$ . We conclude that  $f = \sum_{m=1}^N a_m \kappa(\cdot, \mathbf{x}_m) = 0$  if and only if  $a_1 = \dots = a_N = 0$ . Therefore, the points  $\Phi(\mathbf{x}_m) = \kappa(\cdot, \mathbf{x}_m)$ ,  $m = 1, \dots, N$ , are linearly independent, provided that no two  $\mathbf{x}_m$  are the same. *Hence, a Gaussian kernel defined on a domain of infinite cardinality, produces a feature space of infinite dimension.* Moreover, the Gram matrices defined by Gaussian kernels are always strictly positive definite and invertible.

In addition, for every  $\mathbf{x}, \mathbf{y} \in X$  we have that  $\kappa(\mathbf{x}, \mathbf{x}) = 1$  and  $\kappa(\mathbf{x}, \mathbf{y}) \geq 0$ . This means that all  $\mathbf{x} \in X$  are mapped through the feature map  $\Phi$  to points lying in the surface of the unit sphere of the RKHS  $\mathcal{H}$  and that the angle between any two mapped points  $\Phi(\mathbf{x})$  and  $\Phi(\mathbf{y})$  is between  $0^\circ$  and  $90^\circ$  degrees. We conclude this section with the following two important formulas, which hold for the case of the RKHS induced by the Gaussian kernel. For the norm of  $f \in \mathcal{H}$ , one can prove that:

$$\|f\|_{\mathcal{H}}^2 = \int_X \sum_n \frac{\sigma^{2n}}{n! 2^n} (O^n f(\mathbf{x}))^2 d\mathbf{x}, \quad (17.103)$$

with  $O^{2n} = \Delta^n$  and  $O^{2n+1} = \nabla \Delta^n$ ,  $\Delta$  being the Laplacian and  $\nabla$  the gradient operator. The implication of this is that a regularization term of the form  $\|f\|_{\mathcal{H}}^2$  (which is usually adopted in practice) "penalizes" the derivatives of the minimizer. This results to a very smooth solution of the regularized risk minimization problem. Finally, the Fourier transform of the Gaussian kernel  $\kappa_\sigma$  is given by

$$F[\kappa](\omega) = |\sigma| \exp\left(-\frac{\sigma^2 \omega^2}{2}\right). \quad (17.104)$$

## B Proof of Proposition 60

First, let us define the stage of discussion. For the sake of convenience, we bind  $f$ s and  $\beta$ s together. To this end, define the Cartesian product

$$\mathsf{H} := \mathcal{H} \times \mathcal{R} := \{(f, \beta) : f \in \mathcal{H}, \beta \in \mathcal{R}\}.$$

To save space, let us denote every  $(f, \beta) \in \mathsf{H}$  by  $\mathbf{f}$ . Further, to equip  $\mathsf{H}$  with an inner product, define  $\forall \mathbf{f}_1 := (f, \beta), \forall \mathbf{f}_2 := (g, \gamma) \in \mathsf{H}$ ,

$$\langle \mathbf{f}_1, \mathbf{f}_2 \rangle_{\mathsf{H}} = \langle (f, \beta), (g, \gamma) \rangle_{\mathsf{H}} := \langle f, g \rangle + \beta \gamma.$$

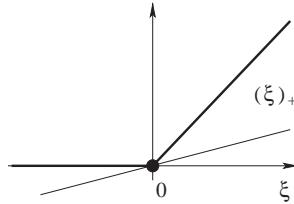

FIGURE 17.33

The positive part of a real number is not a differentiable function.

Under this definition, the task (17.93) obtains the following equivalent formulation:

$$\text{find } f \in H \text{ such that } \begin{cases} \langle f, k_{x_i} \rangle_H \geq 0, & \forall i \in \{1, 2, \dots, N_1\}, \\ \langle f, k_{\xi_j} \rangle_H \leq 0, & \forall j \in \{1, 2, \dots, N_2\}, \end{cases} \quad (17.105)$$

where we have defined  $k_{x_i} := (\kappa(x_i, \cdot), 1) \in H$  and  $k_{\xi_j} := (\kappa(\xi_j, \cdot), 1) \in H$ .

Let us develop this formulation a little further. Given a parameter vector  $k_z \in H$ , define the following closed convex set, namely, the *closed halfspace*:

$$H_{k_z}^- := \{f \in H : \langle f, k_z \rangle_H \leq 0\}.$$

Under this setting, (17.105) takes the following equivalent form:

$$\text{find } f \in \left( \bigcap_{i=1}^{N_1} H_{-k_{x_i}}^- \right) \cap \left( \bigcap_{j=1}^{N_2} H_{k_{\xi_j}}^- \right). \quad (17.106)$$

Now, let us define our *perceptron loss/penalty function*  $\mathcal{L} : H \rightarrow \mathcal{R}$  as follows:

$$\mathcal{L}(f) := \sum_{i=1}^{N_1} (\langle f, -k_{x_i} \rangle_H)_+ + \sum_{j=1}^{N_2} (\langle f, k_{\xi_j} \rangle_H)_+, \quad (17.107)$$

where the function  $(\cdot)_+$  stands for the *positive part* of a real number; see Figure 17.33.

The reasoning behind the definition of (17.107) is based on the following rationale. Since our goal is to compute an  $f$  which satisfies (17.106), we have to penalize somehow those  $f$  that do not. To this end, and without any loss of generality, assume an  $f$  and an  $i_0$  such that  $f \notin H_{-k_{x_{i_0}}}^-$ . By the definition of  $H_{-k_{x_{i_0}}}^-$ , we have  $\langle f, -k_{x_{i_0}} \rangle_H > 0$ . In such a way, the loss function  $\mathcal{L}$  scores a penalty, and the term  $\langle f, -k_{x_{i_0}} \rangle_H$  appears in (17.107). Moreover, the more  $f$  lies further from  $H_{-k_{x_{i_0}}}^-$ , i.e., the larger the quantity  $\langle f, -k_{x_{i_0}} \rangle_H$  is, the larger the penalty becomes. On the contrary, in the case where  $f \in H_{-k_{x_{i_0}}}^-$ , i.e.,  $\langle f, -k_{x_{i_0}} \rangle_H \leq 0$ , there is no penalty in (17.107) with respect to  $H_{-k_{x_{i_0}}}^-$ .

It can be easily seen by Figure 17.33 that the function  $l(\cdot) := (\cdot)_+$  is convex, with the following subdifferential:

$$\partial l(\theta) = \begin{cases} \{0\}, & \text{if } \theta < 0, \\ [0, 1], & \text{if } \theta = 0, \\ \{1\}, & \text{if } \theta > 0. \end{cases} \quad (17.108)$$

If we also define the *linear mapping*  $A_{k_z} : \mathcal{H} \rightarrow \mathcal{R} : f \mapsto A_{k_z}(f) := \langle f, k_z \rangle_{\mathcal{H}}$ , where  $k_z$  is a parameter vector, then we can readily verify that (17.107) can be given by the following equivalent form:

$$\mathcal{L}(f) := \sum_{i=1}^{N_1} l\left(A_{-k_{x_i}}(f)\right) + \sum_{j=1}^{N_2} l\left(A_{k_{y_j}}(f)\right),$$

i.e.,  $\mathcal{L}$  is the sum of a number of compositions of the convex function  $l(\cdot)$  with the linear mappings  $A_{-k_{x_i}}, A_{k_{y_j}}$ ; hence it is convex. An inspection of (17.107) shows that

$$\text{lev}_{\leq 0}(\mathcal{L}) = \left( \bigcap_{i=1}^{N_1} H_{-k_{x_i}}^- \right) \cap \left( \bigcap_{j=1}^{N_2} H_{k_{y_j}}^- \right).$$

In the sequel, we will show that Algorithm 57 solves the task (17.93), when the function  $\mathcal{L}$  is chosen as previously. To this end, let us recall here the definition of the interior of a set; a point  $g \in \text{int}(\text{lev}_{\leq 0}(\mathcal{L}))$  iff there exists a positive  $\delta > 0$  such that the open ball centered at  $g$  with a radius  $\delta$  belongs to  $\text{lev}_{\leq 0}(\mathcal{L})$ , i.e.,  $B(g, \delta) := \{f \in \mathcal{H} : \|g - f\| < \delta\} \subset \text{lev}_{\leq 0}(\mathcal{L})$ . Since the boundaries of the closed halfspaces  $H_{-k_{x_i}}^-$  and  $H_{k_{y_j}}^-$  are all those  $f$  such that  $\langle f, -k_{x_i} \rangle = 0$  and  $\langle f, k_{y_j} \rangle = 0$ , respectively, the assumption of Proposition 60 is equivalent to

$$\text{int}(\text{lev}_{\leq 0}(\mathcal{L})) \neq \emptyset. \quad (17.109)$$

Based on the definition of  $\mathcal{L}$ , we also have that

$$\mathcal{L}(f) = \sum_{i: f \notin H_{-k_{x_i}}^-} \langle f, -k_{x_i} \rangle_{\mathcal{H}} + \sum_{j: f \notin H_{k_{y_j}}^-} \langle f, k_{y_j} \rangle_{\mathcal{H}}, \quad \forall f \notin \text{lev}_{\leq 0}(\mathcal{L}).$$

Clearly, in such a case, the function is differentiable:

$$\mathcal{L}'(f) = - \sum_{i: f \notin H_{-k_{x_i}}^-} k_{x_i} + \sum_{j: f \notin H_{k_{y_j}}^-} k_{y_j}, \quad \forall f \notin \text{lev}_{\leq 0}(\mathcal{L}). \quad (17.110)$$

Hence,

$$\begin{aligned} \|\mathcal{L}'(f)\|_{\mathcal{H}} &\leq \sum_{i: f \notin H_{-k_{x_i}}^-} \|k_{x_i}\|_{\mathcal{H}} + \sum_{j: f \notin H_{k_{y_j}}^-} \|k_{y_j}\|_{\mathcal{H}} \\ &\leq \sum_{i=1}^{N_1} \|k_{x_i}\|_{\mathcal{H}} + \sum_{j=1}^{N_2} \|k_{y_j}\|_{\mathcal{H}} := K, \quad \forall f \notin \text{lev}_{\leq 0}(\mathcal{L}). \end{aligned} \quad (17.111)$$

Let us apply, now, the PSMa Algorithm 57 to the loss function of (17.107). Notice that in this case, the minimization task is unconstrained, i.e.,  $C := \mathbb{H}$ . In what follows, we assume that  $\mathbf{f}_{n-1} \notin \text{lev}_{\leq 0}(\mathcal{L})$ , since otherwise, the PSMa Algorithm 57 stalls to a point which is the solution of (17.106). Under the previous setting, for any initial point  $\mathbf{f}_0$ , for any  $\mathbf{f}_* \in \text{int}(\text{lev}_{\leq 0}(\mathcal{L}))$ , and for any iteration index  $n$ , we have:

$$\begin{aligned}\|\mathbf{f}_n - \mathbf{f}_*\|_{\mathbb{H}}^2 &= \|\mathbf{f}_{n-1} - \mu_n \mathcal{L}'(\mathbf{f}_{n-1}) - \mathbf{f}_*\|_{\mathbb{H}}^2 \\ &= \|\mathbf{f}_{n-1} - \mathbf{f}_*\|_{\mathbb{H}}^2 + \mu_n^2 \|\mathcal{L}'(\mathbf{f}_{n-1})\|_{\mathbb{H}}^2 - 2\mu_n \langle \mathbf{f}_{n-1} - \mathbf{f}_*, \mathcal{L}'(\mathbf{f}_{n-1}) \rangle_{\mathbb{H}} \\ &= \|\mathbf{f}_{n-1} - \mathbf{f}_*\|_{\mathbb{H}}^2 + \mu_n^2 \|\mathcal{L}'(\mathbf{f}_{n-1})\|_{\mathbb{H}}^2 - 2\mu_n \langle \mathbf{f}_{n-1}, \mathcal{L}'(\mathbf{f}_{n-1}) \rangle_{\mathbb{H}} \\ &\quad + 2\mu_n \langle \mathbf{f}_*, \mathcal{L}'(\mathbf{f}_{n-1}) \rangle_{\mathbb{H}}.\end{aligned}$$

Notice, now, by (17.110) and the fact that  $\mathbf{f}_{n-1} \notin \text{lev}_{\leq 0}(\mathcal{L})$  that

$$\langle \mathbf{f}_{n-1}, \mathcal{L}'(\mathbf{f}_{n-1}) \rangle_{\mathbb{H}} = \sum_{i: \mathbf{f}_{n-1} \notin H_{-\mathbf{k}_{\mathbf{x}_i}}^-} \langle \mathbf{f}_{n-1}, -\mathbf{k}_{\mathbf{x}_i} \rangle_{\mathbb{H}} + \sum_{j: \mathbf{f}_{n-1} \notin H_{\mathbf{k}_{\mathbf{\xi}_j}}^-} \langle \mathbf{f}_{n-1}, \mathbf{k}_{\mathbf{\xi}_j} \rangle_{\mathbb{H}}, \quad (17.112a)$$

$$\langle \mathbf{f}_*, \mathcal{L}'(\mathbf{f}_{n-1}) \rangle_{\mathbb{H}} = \sum_{i: \mathbf{f}_{n-1} \notin H_{-\mathbf{k}_{\mathbf{x}_i}}^-} \langle \mathbf{f}_*, -\mathbf{k}_{\mathbf{x}_i} \rangle_{\mathbb{H}} + \sum_{j: \mathbf{f}_{n-1} \notin H_{\mathbf{k}_{\mathbf{\xi}_j}}^-} \langle \mathbf{f}_*, \mathbf{k}_{\mathbf{\xi}_j} \rangle_{\mathbb{H}}. \quad (17.112b)$$

It can be readily verified by (17.112a) that  $\langle \mathbf{f}_{n-1}, \mathcal{L}'(\mathbf{f}_{n-1}) \rangle_{\mathbb{H}} > 0$ , so that

$$\|\mathbf{f}_n - \mathbf{f}_*\|_{\mathbb{H}}^2 \leq \|\mathbf{f}_{n-1} - \mathbf{f}_*\|_{\mathbb{H}}^2 + \mu_n^2 \|\mathcal{L}'(\mathbf{f}_{n-1})\|_{\mathbb{H}}^2 + 2\mu_n \langle \mathbf{f}_*, \mathcal{L}'(\mathbf{f}_{n-1}) \rangle_{\mathbb{H}}.$$

Now, let us focus on the term  $\langle \mathbf{f}_*, \mathcal{L}'(\mathbf{f}_{n-1}) \rangle_{\mathbb{H}}$ . Due to assumption (17.109), there exists an  $\epsilon > 0$  such that

$$\begin{aligned}\forall i = 1, 2, \dots, N_1, \quad \langle \mathbf{f}_*, -\mathbf{k}_{\mathbf{x}_i} \rangle_{\mathbb{H}} &\leq -\epsilon < 0, \\ \forall j = 1, 2, \dots, N_2, \quad \langle \mathbf{f}_*, \mathbf{k}_{\mathbf{\xi}_j} \rangle_{\mathbb{H}} &\leq -\epsilon < 0.\end{aligned}$$

It becomes clear, then, by (17.112b) that

$$\langle \mathbf{f}_*, \mathcal{L}'(\mathbf{f}_{n-1}) \rangle_{\mathbb{H}} \leq -\epsilon < 0.$$

For this reason, we end up in

$$\begin{aligned}\|\mathbf{f}_n - \mathbf{f}_*\|_{\mathbb{H}}^2 &\leq \|\mathbf{f}_{n-1} - \mathbf{f}_*\|_{\mathbb{H}}^2 + \mu_n^2 \|\mathcal{L}'(\mathbf{f}_{n-1})\|_{\mathbb{H}}^2 - 2\epsilon\mu_n \\ &= \|\mathbf{f}_{n-1} - \mathbf{f}_*\|_{\mathbb{H}}^2 + \frac{\mu_n^2 \|\mathcal{L}'(\mathbf{f}_{n-1})\|_{\mathbb{H}}^2}{\max^2 \{1, \|\mathcal{L}'(\mathbf{f}_{n-1})\|_{\mathbb{H}}\}} - \frac{2\mu_n\epsilon}{\max \{1, \|\mathcal{L}'(\mathbf{f}_{n-1})\|_{\mathbb{H}}\}} \\ &\leq \|\mathbf{f}_{n-1} - \mathbf{f}_*\|_{\mathbb{H}}^2 + \frac{\mu_n^2 \|\mathcal{L}'(\mathbf{f}_{n-1})\|_{\mathbb{H}}^2}{\|\mathcal{L}'(\mathbf{f}_{n-1})\|_{\mathbb{H}}^2} - \frac{2\mu_n\epsilon}{\max \{1, \|\mathcal{L}'(\mathbf{f}_{n-1})\|_{\mathbb{H}}\}} \\ &\leq \|\mathbf{f}_{n-1} - \mathbf{f}_*\|_{\mathbb{H}}^2 + \mu_n^2 - \frac{2\mu_n\epsilon}{\max \{1, \|\mathcal{L}'(\mathbf{f}_{n-1})\|_{\mathbb{H}}\}},\end{aligned} \quad (17.113)$$

where we used the definition of  $\mu_n$  and the quantity  $K$  introduced in (17.111). A repetition of the telescoping (17.113) gives the following:

$$\begin{aligned}\|f_n - f_*\|_H^2 &\leq \|f_0 - f_*\|_H^2 + \sum_{k=1}^n \mu_k^2 - \frac{2\epsilon}{\max\{1, K\}} \sum_{k=1}^n \mu_k \\ &\leq \|f_0 - f_*\|_H^2 + \sum_{n=1}^{\infty} \mu_n^2 - \frac{2\epsilon}{\max\{1, K\}} \sum_{k=1}^n \mu_k.\end{aligned}\quad (17.114)$$

Since  $\sum_{n=1}^{\infty} \mu_n = \infty$ , there exists an  $n_0 \in \mathcal{N}_*$  such that  $\forall n \geq n_0$ ,

$$\sum_{k=1}^n \mu_k \geq \frac{\max\{1, K\}}{2\epsilon} \left( \|f_0 - f_*\|_H^2 + \sum_{n=1}^{\infty} \mu_n^2 \right).$$

This result and (17.114) imply that  $\forall n \geq n_0$ ,

$$0 \leq \|f_n - f_*\|_H^2 \leq 0,$$

i.e.,  $\forall n \geq n_0$ ,  $f_n = f_*$ . This completes the proof.

## C Proof of convergence for algorithm 61

Since the set of all minimizers,  $C_{\mathcal{L}_*}$ , of (17.84) is nonempty, let us choose any  $f_* \in C_{\mathcal{L}_*}$ . Then, if we let  $v_n := \mu_n \frac{\mathcal{L}(f_{n-1}) - \mathcal{L}_*}{\|\mathcal{L}'(f_{n-1})\|^2}$ , we observe that

$$\begin{aligned}\|f_n - f_*\|^2 &= \|P_C(f_{n-1} - v_n \mathcal{L}'(f_{n-1})) - P_C(f_*)\|^2 \leq \|f_{n-1} - f_* - v_n \mathcal{L}'(f_{n-1})\|^2 \\ &= \|f_{n-1} - f_*\|^2 + v_n^2 \|\mathcal{L}'(f_{n-1})\|^2 - 2v_n \langle f_{n-1} - f_*, \mathcal{L}'(f_{n-1}) \rangle \\ &\leq \|f_{n-1} - f_*\|^2 + v_n^2 \|\mathcal{L}'(f_{n-1})\|^2 - 2v_n (\mathcal{L}(f_{n-1}) - \mathcal{L}(f_*)) \\ &= \|f_{n-1} - f_*\|^2 + \mu_n^2 \frac{(\mathcal{L}(f_{n-1}) - \mathcal{L}_*)^2}{\|\mathcal{L}'(f_{n-1})\|^2} - 2\mu_n \frac{(\mathcal{L}(f_{n-1}) - \mathcal{L}_*)^2}{\|\mathcal{L}'(f_{n-1})\|^2} \\ &= \|f_{n-1} - f_*\|^2 - \mu_n(2 - \mu_n) \frac{(\mathcal{L}(f_{n-1}) - \mathcal{L}_*)^2}{\|\mathcal{L}'(f_{n-1})\|^2} \\ &\leq \|f_{n-1} - f_*\|^2 - \epsilon^2 \frac{(\mathcal{L}(f_{n-1}) - \mathcal{L}_*)^2}{\|\mathcal{L}'(f_{n-1})\|^2},\end{aligned}$$

or in other words,

$$\epsilon^2 \frac{(\mathcal{L}(f_{n-1}) - \mathcal{L}_*)^2}{\|\mathcal{L}'(f_{n-1})\|^2} \leq \|f_{n-1} - f_*\|^2 - \|f_n - f_*\|^2. \quad (17.115)$$

Hence,  $\|f_n - f_*\| \leq \|f_{n-1} - f_*\|$ , which implies that the  $\lim_{n \rightarrow \infty} \|f_n - f_*\|^2$  exists. Since the previous analysis was conducted for any point  $f_* \in C_{\mathcal{L}_*}$ , we obtain that given any  $f_* \in C_{\mathcal{L}_*}$ , there exists a  $\delta_{f_*} \geq 0$  such that

$$\lim_{n \rightarrow \infty} \|f_n - f_*\| = \delta_{f_*}. \quad (17.116)$$

Due to the fact that  $(\|f_n - f_*\|^2)_{n \in \mathcal{N}}$  is convergent, it is also a Cauchy sequence, which suggests, in turn, that

$$\lim_{n \rightarrow \infty} (\|f_{n-1} - f_*\|^2 - \|f_n - f_*\|^2) = 0. \quad (17.117)$$

Moreover, due to the monotonicity of the sequence  $(\|f_n - f_*\|^2)_{n \in \mathcal{N}}$ , we observe that  $\|f_n - f_*\| \leq \|f_0 - f_*\|$ , or in other words,  $f_n \in B[f_*, \|f_0 - f_*\|] \cap C$ , and hence  $\|\mathcal{L}'(f_n)\| \leq c, \forall n$ . Based on this observation, we have by (17.115) that

$$\frac{\epsilon^2}{c^2} (\mathcal{L}(f_{n-1}) - \mathcal{L}_*)^2 \leq \|f_{n-1} - f_*\|^2 - \|f_n - f_*\|^2.$$

Hence, by (17.117),  $\lim_{n \rightarrow \infty} \mathcal{L}(f_n) = \mathcal{L}_* = \min_{f \in C} \mathcal{L}(f)$ .

Since  $(\|f_n - f_*\|)_{n \in \mathcal{N}}$  is bounded, so is  $(f_n)_{n \in \mathcal{N}}$ . Thus,  $(f_n)_{n \in \mathcal{N}}$  is weakly compact [65], and necessarily possesses at least one sequentially weak cluster point. Moreover,  $(f_n)_{n \in \mathcal{N}}$  lies in  $C$ , which is closed and convex, and thus weakly closed, which implies that the cluster point  $\tilde{f}_*$  belongs to  $C$ . Since  $\mathcal{L}$  is weakly lower semicontinuous [65], we finally obtain that

$$\mathcal{L}_* \leq \mathcal{L}(\tilde{f}_*) \leq \liminf_{k \rightarrow \infty} \mathcal{L}(f_{n_k}) = \lim_{k \rightarrow \infty} \mathcal{L}(f_{n_k}) = \lim_{n \rightarrow \infty} \mathcal{L}(f_n) = \mathcal{L}_*,$$

i.e.,  $\tilde{f}_* \in C_{\mathcal{L}_*}$ .

Let us show, now, that the sequence  $(f_n)_{n \in \mathcal{N}}$  converges weakly to a point in  $C_{\mathcal{L}_*}$ . We have already shown previously that the set of sequentially weak cluster points  $\mathcal{W}((f_n)_{n \in \mathcal{N}})$  of  $(f_n)_{n \in \mathcal{N}}$  is non-empty, and that  $\mathcal{W}((f_n)_{n \in \mathcal{N}}) \subset C_{\mathcal{L}_*}$ . To derive a contradiction, let two points  $\tilde{f}_{*1}, \tilde{f}_{*2} \in \mathcal{W}((f_n)_{n \in \mathcal{N}})$  such that  $\tilde{f}_{*1} \neq \tilde{f}_{*2}$ . Since both of  $\tilde{f}_{*1}, \tilde{f}_{*2}$  are sequentially weak cluster points, there exist two subsequences  $(f_{n_k})_{k \in \mathcal{N}}$  and  $(f_{m_k})_{k \in \mathcal{N}}$  such that  $f_{n_k} \rightharpoonup \tilde{f}_{*1}$  and  $f_{m_k} \rightharpoonup \tilde{f}_{*2}$ . By (17.116),

$$\lim_{n \rightarrow \infty} \|f_n - \tilde{f}_{*1}\| = \delta_{\tilde{f}_{*1}}, \quad \lim_{n \rightarrow \infty} \|f_n - \tilde{f}_{*2}\| = \delta_{\tilde{f}_{*2}}.$$

Without any loss of generality, assume that  $\delta_{\tilde{f}_{*1}} \leq \delta_{\tilde{f}_{*2}}$ . Then, notice that

$$\begin{aligned} \delta_{\tilde{f}_{*2}}^2 &= \lim_{n \rightarrow \infty} \|f_n - \tilde{f}_{*2}\|^2 = \lim_{k \rightarrow \infty} \|f_{m_k} - \tilde{f}_{*2}\|^2 = \lim_{k \rightarrow \infty} \|f_{m_k} - \tilde{f}_{*1} + \tilde{f}_{*1} - \tilde{f}_{*2}\|^2 \\ &= \lim_{k \rightarrow \infty} \left( \|f_{m_k} - \tilde{f}_{*1}\|^2 + \|\tilde{f}_{*1} - \tilde{f}_{*2}\|^2 + 2 \langle f_{m_k} - \tilde{f}_{*1}, \tilde{f}_{*1} - \tilde{f}_{*2} \rangle \right) \\ &= \delta_{\tilde{f}_{*1}}^2 + \|\tilde{f}_{*1} - \tilde{f}_{*2}\|^2 + 2 \langle \tilde{f}_{*2} - \tilde{f}_{*1}, \tilde{f}_{*1} - \tilde{f}_{*2} \rangle \\ &= \delta_{\tilde{f}_{*1}}^2 + \|\tilde{f}_{*1} - \tilde{f}_{*2}\|^2 - 2 \|\tilde{f}_{*1} - \tilde{f}_{*2}\|^2 = \delta_{\tilde{f}_{*1}}^2 - \|\tilde{f}_{*1} - \tilde{f}_{*2}\|^2 < \delta_{\tilde{f}_{*1}}^2 \leq \delta_{\tilde{f}_{*2}}^2, \end{aligned}$$

which is evidently a contradiction. Hence, there is only one sequentially weak cluster point of  $(f_n)_{n \in \mathcal{N}}$ , which implies that  $(f_n)_{n \in \mathcal{N}}$  converges weakly to that point. This completes the proof.

## Nomenclature

$X, Y, Z, Q, C$	Random variable (RV)
$x, y, z, q, w, c$	Instantiation of random variable
$\mathbf{X}, \mathbf{Y}, \mathbf{Z}, \mathbf{A}, \mathbf{B}, \mathbf{D}, \mathbf{O}, \mathbf{Q}, \mathbf{H}$	Set of random variables
$\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{o}, \mathbf{q}, \mathbf{h}, \mathbf{w}$	Set of instantiations of random variables
$\mathbf{val}(X)$	Set of values (states) of random variable $X$
$\mathbf{sp}(X) =  \mathbf{val}(X) $	Number of states of random variable $X$
$P_X(x)$	Probability density function (PDF) of a continuous random variable $X$
$P_X(x) = P(X = x)$	Probability mass function (PMF) of a discrete random variable $X$
$P(X, Y)$	Joint probability distribution of random variable $X$ and $Y$
$P(X Y)$	Conditional probability distribution (CPD) of $X$ conditioned on $Y$
$\Omega$	Outcome space composed of a set of events
$\omega_i$	Elementary event
$\Sigma$	Event space
$\theta$	Parameters
$\boldsymbol{\theta}, \Theta$	Set of parameters
$\mathbb{R}$	Set of real numbers
$\mathbb{R}_+$	Set of nonnegative real numbers
$\mathbb{E}[X]$	Expected value of random variable $X$
$\mathbb{1}_{\{A\}}$	Indicator function; equals 1 if statement $A$ is true and 0 otherwise
$\mathcal{N}(\cdot   \mu; \sigma^2)$	Gaussian distribution with mean $\mu$ and variance $\sigma^2$
$\mathcal{B}$	Bayesian network (BN)
$\mathcal{M}$	Markov network (MN)
$\mathcal{F}$	Factor graph (FG)
$\mathcal{D}$	Set of i.i.d. samples
$\mathcal{C}$	Class of models, e.g., Bayesian networks

$\mathcal{L}(\cdot; \cdot)$	Likelihood function (LH)
$\ell(\cdot, \cdot)$	Log-likelihood function
$\text{KL}(P_A    P_B)$	Kullback-Leibler (KL) divergence between distribution $P_A$ and $P_B$
$L(\cdot, \cdot)$	Lagrangian function
$\nu$	Lagrangian multiplier
$\text{Dir}(\cdot; \alpha)$	Dirichlet distribution parametrized by the vector $\alpha$
$B(\alpha)$	Beta-function parametrized by the vector $\alpha$
$\text{CR}(\cdot)$	Classification rate (CR)
$\text{CLL}(\cdot; \cdot)$	Conditional log likelihood (CLL)
$\text{MM}(\cdot; \cdot)$	Margin objective function (MM)
<b>G</b>	Generator matrix of a linear block code
<b>H</b>	Parity-check matrix of a linear block code
$\mathcal{A}$	Finite alphabet of a code
$\mathcal{G}$	Directed or undirected graph
<b>E</b>	Set of edges
$\text{Pa}_{\mathcal{G}}(X)$	Set of all parents of $X$ in graph $\mathcal{G}$
$\text{Ch}_{\mathcal{G}}(X)$	Set of all children of $X$ in graph $\mathcal{G}$
$\text{Nb}_{\mathcal{G}}(X)$	Set of neighbors of $X$ in graph $\mathcal{G}$
$\text{Anc}_{\mathcal{G}}(X)$	Set of ancestors of $X$ in graph $\mathcal{G}$
$\text{Desc}_{\mathcal{G}}(X)$	Set of descendants of $X$ in graph $\mathcal{G}$
$\text{NonDesc}_{\mathcal{G}}(X)$	Set of nondescendants of $X$ in graph $\mathcal{G}$
<b>C</b>	Clique
<b>S</b>	Separator set
$\Psi_{\mathbf{C}}$	Nonnegative potential functions over the maximal cliques <b>C</b>
$f_i$	Positive function of a factor graph $\mathcal{F}$
<b>F</b>	Set of factor nodes
$\mu_{X \rightarrow Y}(y)$	Message from node $X$ to node $Y$
$\alpha(\cdot)$	Forward probabilities
$\beta(\cdot)$	Backward probabilities

---

### 1.18.1 Introduction

Machine learning and pattern recognition are elementary building blocks of *intelligent systems*. The aim is to capture relevant phenomena hidden in empirical data using computational and statistical methods. Hence, the task is to automatically recognize and identify complex patterns in data which are further cast into a model. A prerequisite is that the learned model generalizes well in order to provide useful information for new data samples. To account for this, machine learning relies on many fields in science such as statistics and probability calculus, optimization methods, cognitive science, computer science, et cetera.

Learning can be divided into supervised, unsupervised, and reinforcement learning problems. For supervised learning the training data comprises of feature vectors which contain an abstract description of the object and their corresponding target or class label. If the desired target value is continuous, then this is referred to as *regression*. In the case where the input vector is assigned to a finite number of categories this is called *classification*. In unsupervised learning, the training data consists of a set of feature vectors without corresponding target value. The aim is to discover groups/clusters within the data or to model the distribution of the data, i.e., representations of the data are modeled. In *reinforcement* learning, an agent should perform actions in an environment so that it maximizes a long-term reward. The learning algorithm cannot access a finite set of labeled samples for training as in supervised classification. It must discover which actions of the agent result in an optimal long-term reward. Typically, the actions do not only affect an immediate reward but also have impact on future actions, i.e., taking the best reward at each time step is insufficient for the global optimal solution.

Probabilistic graphical models (PGMs) [1] are important in all three learning problems and have turned out to be the method of choice for modeling uncertainty in many areas such as computer vision, speech processing, time-series and sequential data modeling, cognitive science, bioinformatics, probabilistic robotics, signal processing, communications and error-correcting coding theory, and in the area of artificial intelligence in general. One reason is that this common modeling framework allows to transfer concepts and ideas among different application areas. Another reason stated in [2] is that *common-sense reasoning is naturally embedded within the syntax of probability calculus*. PGMs combine probability theory and graph theory. They offer a compact graph-based representation of joint probability distributions exploiting conditional independencies among the random variables. Conditional independence assumptions alleviate the computational burden for model learning and inference. Hence, graphical models provide techniques to deal with two inherent problems throughout applied mathematics and engineering, namely, uncertainty and complexity [3]. Many well-known statistical models, e.g., (dynamic) Bayesian networks, mixture models, factor analysis, hidden Markov models (HMMs), factorial HMMs, Kalman filters, Boltzmann machines, the Ising model, amongst others, can be represented by graphical models. The framework of graphical models provides techniques for inference (e.g., *sum product algorithm*, also known as *belief propagation or message passing*) [2] and learning [1].<sup>1</sup> In this article, three popular representations of graphical models are presented: Markov networks (MNs) (also known as undirected graphical models (UGMs) or Markov random fields (MRFs)), Bayesian networks (BNs) (also known as directed graphical models (DGMs) or belief networks) and factor graphs (FGs).

The research in PGMs has focused on two major fields which both are tightly connected to advanced optimization methods:

1. *Learning of graphical models*: Recent advances in structure learning are in finding structures satisfying some optimality conditions. This is in contrast to search heuristics which in general do not provide any guarantees. Current research in learning the parameters goes beyond classical maximum likelihood parameter learning which belongs to *generative learning*. Popular objectives are the conditional likelihood or a probabilistic formulation of the margin. Optimizing these objectives can lead to better classification performance, particularly when the class conditional distributions

---

<sup>1</sup>In Bayesian statistics, learning and inference are the same, i.e., learning is inference of the parameters and structure.

poorly approximate the true distribution [4]. This is often referred to as *discriminative learning* with the aim of optimizing the model for one inference scenario, namely classification.

2. *Efficient inference:* Inference means answering queries using the PGM. In more technical language, inference deals with determining the marginal or most likely configuration of random variables given observed variables using the joint distribution modeled as PGM. Generally, exact inference is not tractable in large and dense graphical models and, therefore, approximate inference techniques are needed. Over the past decades, tractable approximate inference has been one of the most challenging and active research fields.

This tutorial is organized as follows: In Section 1.18.3 we present three types of representations, namely BNs, MNs, and FGs. Then in Sections 1.18.4 and 1.18.5 different learning approaches and inference methods are discussed. In Section 1.18.6, we present typical examples for each of the three graphical model representations. Sections 1.18.7 and 1.18.8 provide references to implementations and data sets. Finally, Section 1.18.9 concludes the tutorial providing a brief perspective on advanced methods and future trends.

In this tutorial article we presume that the reader is familiar with elementary probability calculus and fundamental linear algebra concepts. This introduction to probabilistic graphical models is necessarily incomplete due to the vast amount of methods developed over the last decades. Nevertheless, we hope to provide the reader with an easily accessible and interesting introduction to the field of PGMs. For additional details on any of the covered subjects the interested reader is referred to the cited literature.

## 1.18.2 Preliminaries

In this section we introduce parts of the notation used throughout this tutorial. Further, we review the basics of probability theory and present elementary definitions from graph theory.

### 1.18.2.1 Probability theory

In this section we present a short review of the most important concepts from probability theory. For a more detailed introduction we refer the reader to [1,5,6]. We start with some basic definitions.

**Definition 1 (Outcome Space, Elementary Events).** An *outcome space*  $\Omega$  is a non-empty set. The elements of  $\Omega$  are called *elementary events*.

**Example 1 (Outcome Space, Elementary Events).** We can define an outcome space of a die game according to  $\Omega = \{\omega_1, \omega_2, \omega_3, \omega_4, \omega_5, \omega_6\}$ . The elementary event  $\omega_i$  denotes the outcome “die shows number  $i$ .”

We further define the notion of an event space.

**Definition 2 (Event Space, Events).** Given an outcome space  $\Omega$ , an *event space*  $\Sigma$  over  $\Omega$  is a set of subsets of  $\Omega$ , satisfying the following properties:

- $\emptyset \in \Sigma$  and  $\Omega \in \Sigma$ .
- If  $\sigma_1 \in \Sigma$  and  $\sigma_2 \in \Sigma$ , then also  $\sigma_1 \cup \sigma_2 \in \Sigma$ .

- If  $\sigma \in \Sigma$ , then also  $\Omega \setminus \sigma \in \Sigma$ .

The elements of  $\Sigma$  are called *events*.  $\Omega$  is called the *certain event* and  $\emptyset$  is the *impossible event*.

**Example 2 (Event Space, Events).** Given the outcome space of the die game  $\Omega = \{\omega_1, \omega_2, \omega_3, \omega_4, \omega_5, \omega_6\}$  of Example 1, we give three examples of possible event spaces:

- The event space  $\Sigma_1 = \{\emptyset, \{\omega_1, \omega_3, \omega_5\}, \{\omega_2, \omega_4, \omega_6\}, \Omega\}$  contains the impossible event, the certain event, and the two events “outcome is odd” and “outcome is even.”
- The event space  $\Sigma_2 = \{\emptyset, \{\omega_1, \omega_2, \omega_3\}, \{\omega_4, \omega_5, \omega_6\}, \Omega\}$  contains the impossible event, the certain event, and the two events “outcome is smaller or equal 3” and “outcome is larger than 3.”
- The event space  $\Sigma_3 = 2^\Omega$ , where  $2^\Omega$  is the power set of  $\Omega$ , contains all subsets of  $\Omega$ , i.e., all possible combinations of elementary events.

We are now ready to define probability distributions.

**Definition 3 (Probability Distribution, Probability Space).** Let  $\Omega$  be an outcome space and  $\Sigma$  an event space over  $\Omega$ . A *probability distribution* over  $(\Omega, \Sigma)$  is a function  $P : \Sigma \mapsto \mathbb{R}$  satisfying the following properties:

- $P(\sigma) \geq 0, \forall \sigma \in \Sigma$ .
- $P(\Omega) = 1$ .
- If  $\sigma_i \cap \sigma_j = \emptyset$ , then  $P(\sigma_i \cup \sigma_j) = P(\sigma_i) + P(\sigma_j), \forall \sigma_i, \sigma_j \in \Sigma, i \neq j$ .

The triplet  $(\Omega, \Sigma, P)$  is called a *probability space*.

**Example 3 (Probability Distribution).** Let  $\Sigma_3 = 2^\Omega$  be the event space from Example 2. We can define a probability distribution by setting  $P(\omega_1) = P(\omega_2) = P(\omega_3) = P(\omega_4) = P(\omega_5) = P(\omega_6) = \frac{1}{6}$ , i.e., we assume a fair die. Since  $P$  has to be a probability distribution, it follows that  $P(\sigma) = \frac{|\sigma|}{6}, \forall \sigma \in \Sigma_3$ , where  $|\sigma|$  denotes the cardinality of  $\sigma$ .

Throughout the article, we use events and probability distributions defined via random variables, which are characterized by their cumulative distribution functions.

**Definition 4 (Random Variable, Cumulative Distribution Function (CDF)).** Let  $(\Omega, \Sigma, P)$  be a probability space and  $\mathbb{S}$  a measurable space (in this tutorial we assume  $\mathbb{S} = \mathbb{R}$ ). A *random variable* (RV)  $X$  is a function  $X : \Omega \mapsto \mathbb{S}$ , where “ $X \leq x$ ” =  $\{\omega \in \Omega : X(\omega) \leq x\}$  is an event for every  $x \in \mathbb{S}$ , and for the events “ $X = -\infty$ ” =  $\{\omega \in \Omega : X(\omega) = -\infty\}$  and “ $X = \infty$ ” =  $\{\omega \in \Omega : X(\omega) = \infty\}$  it must hold that  $P(X = -\infty) = P(X = \infty) = 0$ . The probability of the event “ $X \leq x$ ” is the cumulative distribution function (CDF)

$$F_X(x) = P(X \leq x). \quad (18.1)$$

More generally, let  $\mathbf{X} = \{X_1, X_2, \dots, X_N\}$  be an ordered set of  $N$  RVs and  $\mathbf{x}$  a corresponding set of  $N$  values from  $\mathbb{S}$ . The *joint CDF* of  $\mathbf{X}$  is defined as

$$F_{\mathbf{X}}(\mathbf{x}) = P(X_1 \leq x_1 \cap X_2 \leq x_2 \cap \dots \cap X_N \leq x_N). \quad (18.2)$$

The image of an RV  $X$  is denoted as  $\text{val}(X) = \{x \in \mathbb{S} | \exists \omega \in \Omega : X(\omega) = x\}$ . We say that  $X$  takes values out of  $\text{val}(X)$ . Similarly, the set of values which can be assumed by a set of random variables  $\mathbf{X}$  is denoted as  $\text{val}(\mathbf{X})$ .

When we are only interested in events connected with RVs, the CDF fully characterizes the underlying probability distribution. If the CDF of an RV  $X$  is continuous, then we say that  $X$  is a *continuous* RV. For continuous RVs we define the probability density function.

**Definition 5 (Probability Density Function (PDF)).** Let  $F_X(x)$  be the CDF of a continuous RV  $X$ . The *probability density function* (PDF) of  $X$  is defined as

$$P_X(x) = \frac{dF_X(x)}{dx}. \quad (18.3)$$

If  $P_X(x)$  exists, then the CDF of  $X$  is given as

$$F_X(x) = \int_{-\infty}^x P_X(x) dx. \quad (18.4)$$

More generally, let  $F_{\mathbf{X}}(\mathbf{x})$  be the CDF of a set of continuous RVs  $\mathbf{X}$ . The *joint* PDF of  $\mathbf{X}$  is defined as

$$P_{\mathbf{X}}(\mathbf{x}) = \frac{\partial^N F_{\mathbf{X}}(\mathbf{x})}{\partial x_1 \dots \partial x_N}. \quad (18.5)$$

If  $P_{\mathbf{X}}(\mathbf{x})$  exists, then the CDF of  $\mathbf{X}$  is given as

$$F_{\mathbf{X}}(\mathbf{x}) = \int_{-\infty}^{x_1} \dots \int_{-\infty}^{x_N} P_{\mathbf{X}}(\mathbf{x}) dx_1 \dots dx_N. \quad (18.6)$$

The PDF, if it exists, is an equivalent representation of the CDF, i.e., the PDF also represents the underlying probability distribution. It follows from the definition of probability distributions, that a PDF is nonnegative and integrates to one, i.e.,  $P_{\mathbf{X}}(\mathbf{x}) \geq 0, \forall \mathbf{x}$ , and  $\int P_{\mathbf{X}}(\mathbf{x}) d\mathbf{x} = 1$ .

A RV is called *discrete* when the CDF of  $X$  is piecewise constant and has a finite number of discontinuities. For discrete RVs we define the probability mass function.

**Definition 6 (Probability Mass Function (PMF)).** Let  $X$  be a discrete RV. The probability mass function (PMF) of  $X$  is a function  $P_X : \text{val}(X) \mapsto \mathbb{R}$  and defined as

$$P_X(x) = P(X = x), x \in \text{val}(X). \quad (18.7)$$

More generally, let  $\mathbf{X}$  be a set of discrete RVs. The *joint* PMF of  $\mathbf{X}$  is a function  $P_{\mathbf{X}} : \text{val}(\mathbf{X}) \mapsto \mathbb{R}$  and defined as

$$P_{\mathbf{X}}(\mathbf{x}) = P(X_1 = x_1 \cap X_2 = x_2 \cap \dots \cap X_N = x_N), \mathbf{x} = \{x_1, x_2, \dots, x_N\} \in \text{val}(\mathbf{X}). \quad (18.8)$$

It follows from the definition of probability distributions, that a PMF is nonnegative and sums to one, i.e.,  $P_{\mathbf{X}}(\mathbf{x}) \geq 0, \forall \mathbf{x} \in \text{val}(\mathbf{X})$ , and  $\sum_{\mathbf{x} \in \text{val}(\mathbf{X})} P_{\mathbf{X}}(\mathbf{x}) = 1$ . Unlike the PDF, a PMF always exists in the case of discrete RVs.

We use the same symbol  $P_{\mathbf{X}}(\mathbf{x})$  to denote PDFs and PMFs throughout the manuscript, since most of the discussion holds for both objects. From now on, we assume that  $P_{\mathbf{X}}(\mathbf{x})$  exists and fully represents the underlying probability distribution, and with slight abuse of notation, we refer to  $P_{\mathbf{X}}(\mathbf{x})$  itself as

distribution. Usually we omit the subscripts of PDFs/PMFs, i.e., we use the shorthand  $P(\mathbf{x}) = P_{\mathbf{X}}(\mathbf{x})$ . Furthermore, we use the notation  $P(\mathbf{X})$  for RVs,  $P(\mathbf{x})$  for instantiations  $\mathbf{x}$  of RVs  $\mathbf{X}$ ,  $P(\mathbf{X} \cup \mathbf{Y}) = P(\mathbf{X}, \mathbf{Y})$ , and  $P(\{X\} \cup \mathbf{Y}) = P(X, \mathbf{Y})$ . Throughout this tutorial, we assume that  $\mathbf{X} = \{X_1, \dots, X_N\}$ . Unless stated otherwise, the variables  $X_1, \dots, X_N$  are assumed to be discrete and the number of possible states of variable  $X_i$  is denoted as  $\text{sp}(X_i) = |\text{val}(X_i)|$ . Similarly, for a set of RVs  $\mathbf{X}$ , the total number of possible assignments is given as

$$\text{sp}(\mathbf{X}) = \prod_{i=1}^N \text{sp}(X_i). \quad (18.9)$$

When  $\mathbf{Y}$  is a subset of  $\mathbf{X}$ , and  $\mathbf{x}$  is a set of values for  $\mathbf{X}$ , then  $\mathbf{x}(\mathbf{Y})$  denotes the set of values corresponding to  $\mathbf{Y}$ .

An important quantity of RVs is the expected value.

**Definition 7 (Expected Value).** Let  $X$  be an RV with distribution  $P(X)$ . The expected value of  $X$  is defined as

$$\mathbb{E}[X] = \begin{cases} \sum_{x \in \text{val}(X)} x P(x) & \text{if } X \text{ is discrete,} \\ \int_{\text{val}(X)} x P(x) dx & \text{if } X \text{ is continuous.} \end{cases} \quad (18.10)$$

More generally, the expected value of a function  $f : \text{val}(X) \mapsto \mathbb{R}$  is defined as

$$\mathbb{E}[f(X)] = \begin{cases} \sum_{x \in \text{val}(X)} f(x) P(x) & \text{if } X \text{ is discrete,} \\ \int_{\text{val}(X)} f(x) P(x) dx & \text{if } X \text{ is continuous.} \end{cases} \quad (18.11)$$

Similarly, we can define expectations over sets of RVs.

When the joint distribution  $P(\mathbf{X})$  is given, one is often interested in the distribution  $P(\mathbf{Y})$  of a subset  $\mathbf{Y} \subseteq \mathbf{X}$  of RVs. Also, one often considers the distributions of subsets  $\mathbf{Y} \subseteq \mathbf{X}$ , conditioned on the values of the remaining variables  $\mathbf{Z} = \mathbf{X} \setminus \mathbf{Y}$ .

**Definition 8 (Marginal Distribution, Conditional Distribution).** Let  $P(\mathbf{X})$  be a distribution over a set of RVs  $\mathbf{X}$ . Further let  $\mathbf{Y} \subseteq \mathbf{X}$ , and  $\mathbf{Z} = \mathbf{X} \setminus \mathbf{Y}$ , i.e.,  $\mathbf{X} = \mathbf{Y} \cup \mathbf{Z}$  and  $P(\mathbf{X}) = P(\mathbf{Y}, \mathbf{Z})$ . Assuming discrete RVs, the *marginal distribution*  $P(\mathbf{Y})$  over  $\mathbf{Y}$  is given as

$$P(\mathbf{Y}) = \sum_{\mathbf{z} \in \text{val}(\mathbf{Z})} P(\mathbf{Y}, \mathbf{Z} = \mathbf{z}) = \sum_{\mathbf{z} \in \text{val}(\mathbf{Z})} P(\mathbf{Y}, \mathbf{z}), \quad (18.12)$$

and the *conditional distribution*  $P(\mathbf{Y}|\mathbf{Z})$  over  $\mathbf{Y}$ , conditioned on  $\mathbf{Z}$ , is given as

$$P(\mathbf{Y}|\mathbf{Z}) = \frac{P(\mathbf{Y}, \mathbf{Z})}{P(\mathbf{Z})} = \frac{P(\mathbf{Y}, \mathbf{Z})}{\sum_{\mathbf{y} \in \text{val}(\mathbf{Y})} P(\mathbf{y}, \mathbf{Z})}. \quad (18.13)$$

In the case of continuous RVs, summations are replaced by integration in a straightforward manner.

The definition of the marginal and conditional distribution leads to an important rule, which allows to invert the “direction of conditioning.” Using (18.13), it is easily seen that for two sets of discrete RVs

$\mathbf{Y}$  and  $\mathbf{Z}$  the following holds:

$$P(\mathbf{Y}, \mathbf{Z}) = P(\mathbf{Y}, \mathbf{Z}), \quad (18.14)$$

$$P(\mathbf{Y}|\mathbf{Z})P(\mathbf{Z}) = P(\mathbf{Z}|\mathbf{Y})P(\mathbf{Y}), \quad (18.15)$$

$$P(\mathbf{Y}|\mathbf{Z}) = \frac{P(\mathbf{Z}|\mathbf{Y})P(\mathbf{Y})}{P(\mathbf{Z})} = \frac{P(\mathbf{Z}|\mathbf{Y})P(\mathbf{Y})}{\sum_{\mathbf{y} \in \text{val}(\mathbf{Y})} P(\mathbf{Z}|\mathbf{y})P(\mathbf{y})}. \quad (18.16)$$

Equation (18.16) is known as the *Bayes' rule* or the rule of *inverse probability*. For continuous RVs, the summation is replaced by an integral.

From the conditional distribution follows the concept of statistical independence. Informally, two RVs  $X$  and  $Y$  are independent, if knowing the state of one variable, i.e., conditioning on this variable, does not change the distribution over the other variable. Formally, statistical independence and conditional statistical independence are defined as follows.

**Definition 9 (Statistical Independence, Conditional Statistical Independence).** Let  $\mathbf{X}$ ,  $\mathbf{Y}$ , and  $\mathbf{Z}$  be mutually disjoint sets of RVs.  $\mathbf{X}$  and  $\mathbf{Y}$  are *conditionally statistically independent* given  $\mathbf{Z}$ , annotated as  $\mathbf{X} \perp \mathbf{Y}|\mathbf{Z}$ , if and only if the following equivalent conditions hold:

- $P(\mathbf{X}|\mathbf{Y}, \mathbf{Z}) = P(\mathbf{X}|\mathbf{Z})$ .
- $P(\mathbf{Y}|\mathbf{X}, \mathbf{Z}) = P(\mathbf{Y}|\mathbf{Z})$ .
- $P(\mathbf{X}, \mathbf{Y}|\mathbf{Z}) = P(\mathbf{X}|\mathbf{Z})P(\mathbf{Y}|\mathbf{Z})$ .

For the special case  $\mathbf{Z} = \emptyset$ , we say that  $\mathbf{X}$  and  $\mathbf{Y}$  are *statistically independent*, annotated as  $\mathbf{X} \perp \mathbf{Y}$ .

Furthermore, using conditional distributions, there are many ways to factorize an arbitrary joint distribution  $P(\mathbf{X})$ , i.e., any joint probability over  $\mathbf{X} = \{X_1, \dots, X_N\}$  can be written as

$$P(\mathbf{X}) = P(X_N|X_{N-1}, X_{N-2}, \dots, X_1)P(X_{N-1}|X_{N-2}, \dots, X_1) \dots P(X_2|X_1)P(X_1) \quad (18.17)$$

$$= P(X_1) \prod_{i=2}^N P(X_i|X_{i-1}, \dots, X_1). \quad (18.18)$$

This is called the *chain rule of probability*. The chain rule holds for any permutation of the indexes of the RVs  $\mathbf{X}$ .

### 1.18.2.2 Graph theory

In the context of PGMs *graphs* are used to represent probability distributions in an intuitive and easily readable way. Formally, a graph is defined as follows:

**Definition 10 (Graph, Vertex, Edge).** A graph  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  is a tuple consisting of a set of *vertices*, also denoted as *nodes*,  $\mathbf{X}$  and a set of *edges*  $\mathbf{E}$ .

In PGMs each RV corresponds to exactly one node, and vice versa. That is, there is a one-to-one relationship between RVs and nodes. Therefore, we use these terms equivalently.

The edges of the graph define specific relationships between these variables. Any two nodes  $X_i$  and  $X_j$ ,  $i \neq j$ , in a graph can be connected by either a *directed* or an *undirected* edge. An undirected edge between node  $i$  and  $j$  is denoted as  $(X_i - X_j)$ , and a directed edge from node  $X_i$  to  $X_j$  as  $(X_i \rightarrow X_j)$ .

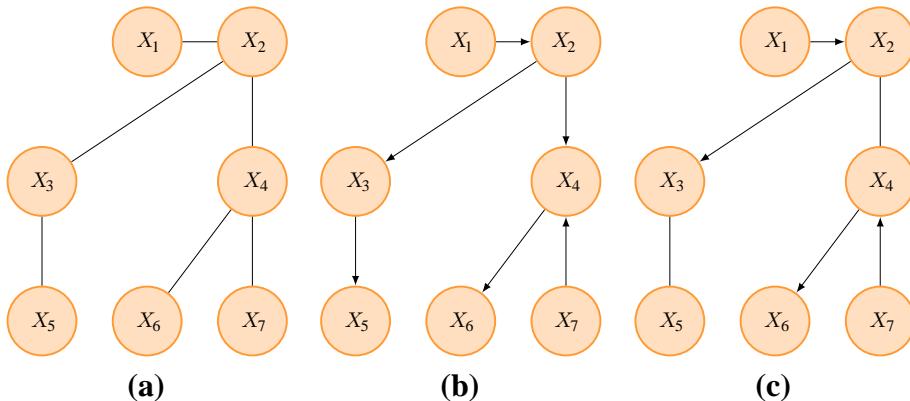

FIGURE 18.1

Graphical representation of different graph types. (a) Undirected graph. (b) Directed graph. (c) Mixed graph.

While an undirected edge is a symmetric relationship, i.e., the edge  $(X_i - X_j)$  is the same as the edge  $(X_j - X_i)$ , a directed edge represents an asymmetric relationship. Note that we do not allow these two types of edges to exist between any pair of nodes simultaneously and that there must not be an edge connecting some node with itself.

Depending on the types of edges in a graph we define the following three graph types:

**Definition 11 (Directed, Undirected, and Mixed Graph).** A graph  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  is *directed (undirected)* if all edges  $e \in \mathbf{E}$  are directed (undirected). Further, a graph is said to be a *mixed graph* if the set of edges contains undirected and directed edges.

At this point we want to introduce a graphical representation of PGMs; every node is represented by a circle and edges are depicted as lines, in the case of undirected edges, or as arrows, in the case of directed edges, connecting the corresponding nodes.

**Example 4 (Graphical representation of graphs).** Consider Figure 18.1. For all shown graphs  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  the set of nodes is  $\mathbf{X} = \{X_1, \dots, X_7\}$ . The corresponding edge sets are

- a.  $\mathbf{E} = \{(X_1 - X_2), (X_2 - X_3), (X_2 - X_4), (X_3 - X_5), (X_4 - X_6), (X_4 - X_7)\}$ ,
- b.  $\mathbf{E} = \{(X_1 \rightarrow X_2), (X_2 \rightarrow X_3), (X_2 \rightarrow X_4), (X_3 \rightarrow X_5), (X_4 \rightarrow X_6), (X_7 \rightarrow X_4)\}$ , and
- c.  $\mathbf{E} = \{(X_1 \rightarrow X_2), (X_2 \rightarrow X_3), (X_2 - X_4), (X_3 - X_5), (X_4 \rightarrow X_6), (X_7 \rightarrow X_4)\}$ .

In graphs we can define relationships between variables. In directed and mixed graphs we introduce a parent–child relationship:

**Definition 12 (Parent and Child).** Let  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  be a directed or mixed graph and  $X_i, X_j \in \mathbf{X}$ ,  $i \neq j$ . If  $(X_i \rightarrow X_j) \in \mathbf{E}$ , then  $X_i$  is a *parent* of  $X_j$  and  $X_j$  is a *child* of  $X_i$ . The set  $\mathbf{Pa}_{\mathcal{G}}(X_j)$  consists of all parents of  $X_j$  and the set  $\mathbf{Ch}_{\mathcal{G}}(X_i)$  contains all children of  $X_i$ .

**Example 5 (Parents and Children).** In Figure 18.1b  $X_3$  is a child of  $X_2$  and  $X_2$  is a parent of  $X_3$ . Further, the set  $\text{Pa}_{\mathcal{G}}(X_3) = \{X_2\}$ , as the only parent of  $X_3$  is  $X_2$ . The set of all children of  $X_2$  is  $\text{Ch}_{\mathcal{G}}(X_2) = \{X_3, X_4\}$ .

For undirected and mixed graphs we define the notion of neighborhood:

**Definition 13 (Neighbor).** Let  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  be an undirected or mixed graph and  $X_i, X_j \in \mathbf{X}, i \neq j$ . If  $(X_i - X_j) \in \mathbf{E}$ , then  $X_i$  is said to be a neighbor of  $X_j$ . The set of all neighbors of  $X_i$  is denoted as  $\text{Nb}_{\mathcal{G}}(X_i)$ , i.e.,

$$\text{Nb}_{\mathcal{G}}(X_i) = \{X_j : (X_i - X_j) \in \mathbf{E}, X_j \in \mathbf{X}\}. \quad (18.19)$$

**Example 6 (Neighborhood).** In Figure 18.1a  $X_1, X_3$  and  $X_4$  are neighbors of  $X_2$ . As these are all neighbors of  $X_2$  in the graph,

$$\text{Nb}_{\mathcal{G}}(X_2) = \{X_1, X_3, X_4\}. \quad (18.20)$$

While edges represent *direct* relationships between two nodes, the notion of *paths* and *trails* describes *indirect* relationships across several nodes:

**Definition 14 (Path, Directed Path, Trail).** Let  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  be a graph. A sequence of nodes  $Q = (X_1, \dots, X_n)$ , with  $X_1, \dots, X_n \in \mathbf{X}$  is a *path* from  $X_1$  to  $X_n$  if

$$\forall i \in \{1, \dots, n-1\} : (X_i \rightarrow X_{i+1}) \in \mathbf{E} \vee (X_i - X_{i+1}) \in \mathbf{E}. \quad (18.21)$$

A path is *directed* if

$$\exists i \in \{1, \dots, n-1\} : (X_i \rightarrow X_{i+1}) \in \mathbf{E}, \quad (18.22)$$

i.e., if there is at least one directed edge on the path.

The sequence of nodes  $Q$  is a *trail* if

$$\forall i \in \{1, \dots, n-1\} : (X_i \rightarrow X_{i+1}) \in \mathbf{E} \vee (X_{i+1} \rightarrow X_i) \in \mathbf{E} \vee (X_i - X_{i+1}) \in \mathbf{E}, \quad (18.23)$$

i.e., if  $Q$  is a path from  $X_1$  to  $X_n$  replacing all directed edges by undirected edges.

**Example 7 (Paths).** Again, consider Figure 18.1.

- a. In Figure 18.1a, the sequence  $(X_2, X_4, X_6)$  is a path from  $X_2$  to  $X_6$ , and there exists a path between all pairs of distinct nodes.
- b. In Figure 18.1b,  $(X_1, X_2, X_4)$  is a directed path from  $X_1$  to  $X_4$ , but there does not exist a path from  $X_6$  to  $X_7$  because of the directed edges. But,  $X_6$  and  $X_7$  are connected by the trail  $(X_6, X_4, X_7)$ .
- c. In Figure 18.1c, the sequence of nodes  $(X_7, X_4, X_2)$  is a directed path, but again, there does not exist a path from  $X_6$  to  $X_7$ .

An important class of undirected graphs are *trees*:

**Definition 15 (Tree).** An undirected graph  $\mathcal{G}$  is a *tree* if any two distinct nodes are connected by exactly one path.

**Example 8 (Tree).** Figure 18.1a represents a tree.

In directed graphs we can identify parts of the graph that appear *before* and *after* a certain node:

**Definition 16 (Ancestor, Descendant).** In a directed graph  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  with  $X_i, X_j \in \mathbf{X}$ ,  $i \neq j$ , the node  $X_i$  is an *ancestor* of  $X_j$  if there exists a directed path from  $X_i$  to  $X_j$ . In this case,  $X_j$  is also denoted as a *descendant* of  $X_i$ .

The set of all ancestors of some node  $X_j \in \mathbf{X}$  is denoted as  $\text{Anc}_{\mathcal{G}}(X_j)$ , i.e.,

$$\text{Anc}_{\mathcal{G}}(X_j) = \{X_i | X_i \text{ is an ancestor of } X_j\}. \quad (18.24)$$

Similarly, the set of all descendants of some node  $X_i \in \mathbf{X}$  is denoted as  $\text{Desc}_{\mathcal{G}}(X_i)$ , i.e.,

$$\text{Desc}_{\mathcal{G}}(X_i) = \{X_j | X_j \text{ is a descendant of } X_i\}. \quad (18.25)$$

We further define the nondescendants of  $X_i$  as

$$\text{NonDesc}_{\mathcal{G}}(X_i) = \mathbf{X} \setminus (\text{Desc}_{\mathcal{G}}(X_i) \cup \{X_i\} \cup \text{Pa}_{\mathcal{G}}(X_i)), \quad (18.26)$$

i.e., the nondescendants of  $X_i$  are all nodes in the graph that are neither descendants of  $X_i$ , nor the node  $X_i$  itself or the parents  $\text{Pa}_{\mathcal{G}}(X_i)$  of this node.

A special type of paths are *directed cycles*:

**Definition 17 (Directed cycle).** Let  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  be a graph,  $X_i \in \mathbf{X}$ , and let  $P$  be a directed path from  $X_i$  to  $X_i$ . Then  $P$  is denoted as a *directed cycle*.

Using these notion, we can define an important type of directed graphs:

**Definition 18 (Directed acyclic graphs).** A graph  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  is a *directed acyclic graph* (DAG) if it contains no directed cycles.

**Example 9 (DAG).** An example of a DAG is given in Figure 18.1b.

Sometimes, we will consider graphs that are *contained* in a *larger* graph:

**Definition 19 (Subgraph, Supergraph).** The graph  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  is a *subgraph* of  $\mathcal{G}' = (\mathbf{X}', \mathbf{E}')$ , if and only if  $\mathbf{X} \subseteq \mathbf{X}'$  and  $\mathbf{E} \subseteq \mathbf{E}'$ . Further,  $\mathcal{G}'$  is a *supergraph* of  $\mathcal{G}$  if and only if  $\mathcal{G}$  is a subgraph of  $\mathcal{G}'$ .

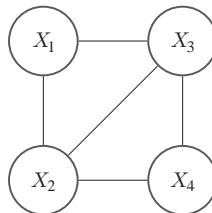

For some of our considerations we need to identify special subsets of the nodes of an undirected graph:

**Definition 20 (Clique, Maximal Clique).** In an undirected graph  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  a set of nodes  $\mathbf{C} \subseteq \mathbf{X}$  is a *clique* if there exists an edge between all pairs of nodes in the subset  $\mathbf{C}$ , i.e., if

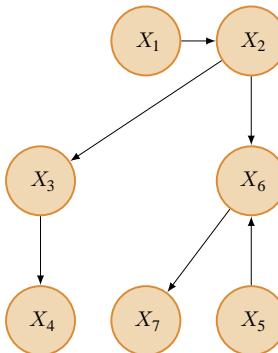

$$\forall C_i, C_j \in \mathbf{C}, i \neq j : (C_i - C_j) \in \mathbf{E}. \quad (18.27)$$

The clique  $\mathbf{C}$  is a *maximal clique* if adding any node  $X \in \mathbf{X} \setminus \mathbf{C}$  makes it no longer a clique.

**Example 10 (Cliques, Maximal Cliques).** Consider Figure 18.2. The set of nodes  $\{X_2, X_3, X_4\}$  is a maximal clique as  $\{X_1, X_2, X_3, X_4\}$  is no clique. The set  $\{X_1, X_3\}$  is a clique that is not maximal as  $\{X_1, X_2, X_3\}$  is also a clique.

**FIGURE 18.2**

Clique and maximal clique.

**FIGURE 18.3**

Topologically ordered graph.

The notion of cliques is closely related to that of *complete* (sub) graphs:

**Definition 21 (Complete Graph).** The undirected graph  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  is *complete* if every pair of distinct nodes is connected by an edge, i.e., if

$$\forall X_i, X_j \in \mathbf{X}, i \neq j : (X_i - X_j) \in \mathbf{E}. \quad (18.28)$$

The set  $\mathbf{C} \subseteq \mathbf{X}$  is a clique if the *induced* graph  $\mathcal{G}' = (\mathbf{C}, \mathbf{E}')$  is complete, where

$$\mathbf{E}' = \{(X_i - X_j) \in \mathbf{E} : X_i, X_j \in \mathbf{C}, i \neq j\}. \quad (18.29)$$

At the end of this section, we introduce the notion of a topological ordering of the nodes in a directed graph:

**Definition 22 (Topological Ordering).** Let  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  be a directed graph and  $\mathbf{X} = \{X_1, \dots, X_N\}$ . The nodes  $\mathbf{X}$  are *topologically ordered* if for any edge  $(X_i \rightarrow X_j) \in \mathbf{E}$  also  $i \leq j$ .

**Example 11.** The nodes of the graph in Figure 18.3 are topologically ordered, while the nodes of the graph in Figure 18.1b are not.

### 1.18.3 Representations

In this section we introduce three types of PGMs, namely *Bayesian networks* in Section 1.18.3.1, *Markov networks* in Section 1.18.3.2 and *factor graphs* in Section 1.18.3.3. Each type has its specific advantages and disadvantages, captures different aspects of probabilistic models, and is preferred in a certain application domain. Finally, we conclude the section by an example demonstrating how Markov chains can be represented in each of the three types of PGMs.

#### 1.18.3.1 Bayesian networks (BNs)

Bayesian networks are directed graphical models. A *dynamic BN* is a BN unrolled over time. This essentially means that at each time slice the BN has the same structure [7]. There are two equivalent ways to define BNs, namely (a) by *factorization properties*, or by *conditional independencies*. We introduce BNs by their factorization properties and show that this is equivalent to a set of conditional independence assumptions in Section 1.18.3.1.2.

##### 1.18.3.1.1 Definition and factorization properties

A BN is defined as follows:

**Definition 23 (Bayesian Network).** A *Bayesian network*  $\mathcal{B}$  is a tuple  $(\mathcal{G}, \{P_{X_1}, \dots, P_{X_N}\})$ , where  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  is a DAG, each node  $X_i$  corresponds to an RV, and  $P_{X_1}, \dots, P_{X_N}$  are conditional probability distributions (CPDs) associated with the nodes of the graph. Each of these CPDs has the form

$$P_{X_i}(X_i | \mathbf{Pa}_{\mathcal{G}}(X_i)). \quad (18.30)$$

The BN  $\mathcal{B}$  defines the joint probability distribution  $P_{\mathcal{B}}(X_1, \dots, X_N)$  according to

$$P_{\mathcal{B}}(X_1, \dots, X_N) = \prod_{i=1}^N P_{X_i}(X_i | \mathbf{Pa}_{\mathcal{G}}(X_i)). \quad (18.31)$$

We will use the shorthand notation  $P(X_i | \mathbf{Pa}_{\mathcal{G}}(X_i))$  for  $P_{X_i}(X_i | \mathbf{Pa}_{\mathcal{G}}(X_i))$  when the meaning is clear from the context. Usually each conditional probability distribution  $P_{X_i}$  is specified by a parameter set  $\theta^i$ , and we collect all the parameters into the set  $\Theta = \{\theta^1, \dots, \theta^N\}$  and use the terms  $\mathcal{B} = (\mathcal{G}, \{P_{X_1}, \dots, P_{X_N}\})$  and  $\mathcal{B} = (\mathcal{G}, \Theta)$  equivalently. Similarly, in the case of parameterized distributions, we write  $P(X_i | \mathbf{Pa}_{\mathcal{G}}(X_i), \theta^i)$  for  $P_{X_i}(X_i | \mathbf{Pa}_{\mathcal{G}}(X_i))$ .

**Example 12.** Consider the BN in Figure 18.3. The joint probability distribution  $P_{\mathcal{B}}(X_1, \dots, X_7)$  factorizes according to the graph structure as

$$P_{\mathcal{B}}(X_1, \dots, X_7) = \prod_{i=1}^7 P(X_i | \mathbf{Pa}_{\mathcal{G}}(X_i)) \quad (18.32)$$

$$= P(X_1)P(X_2|X_1)P(X_3|X_2)P(X_4|X_3)P(X_5)P(X_6|X_2, X_5)P(X_7|X_6) \quad (18.33)$$

Assuming discrete RVs with  $r = \text{sp}(X_i)$  states, a total of  $(r - 1) + (r - 1)r + (r - 1)r + (r - 1)r + (r - 1) + (r - 1)r^2 + (r - 1)r = 2(r - 1) + 4(r - 1)r + (r - 1)r^2$  parameters are required to represent  $P_{\mathcal{B}}(X_1, \dots, X_7)$ . In contrast, a non-factored representation of  $P_{\mathcal{B}}(X_1, \dots, X_7)$  requires  $r^7 - 1$  parameters. Hence, the representation of a joint probability distribution as BN can dramatically reduce the number of parameters. This is true particularly when the factorization of the joint distribution implies conditional independencies among the variables. The number of parameters for the conditional probability of  $X_i$  given its parents increases exponentially with the number of parents, i.e.,  $(\text{sp}(X_i) - 1)\text{sp}(\text{Pa}_{\mathcal{G}}(X_i))$ . The factorization of the joint probability distribution is beneficial for learning and inference as shown in Section 1.18.4 and Section 1.18.5, respectively.

In the sequel, we give two commonly used examples of parametric BNs, one with discrete nodes, and one with conditional Gaussian probabilities.

**Example 13 (Discrete Variables).** Assume a BN  $\mathcal{B}$  with discrete variables  $X_1, \dots, X_N$ , where each  $X_i$  takes one out of a finite set of states. For simplicity, we identify the states of  $X_i$  with natural numbers in  $\{1, \dots, \text{sp}(X_i)\}$ . In this case, the conditional distributions  $P(X_i | \text{Pa}_{\mathcal{G}}(X_i), \theta^i)$  are PMFs, parameterized by  $\theta^i$  such that

$$P(X_i = j | \text{Pa}_{\mathcal{G}}(X_i) = \mathbf{h}, \theta^i) = \theta_{j|\mathbf{h}}^i, \quad (18.34)$$

where  $\mathbf{h}$  is the instantiation of the parent variables  $\text{Pa}_{\mathcal{G}}(X_i)$  and  $j$  the instantiation of  $X_i$ . Note that the parameters  $\theta^i$  must satisfy

$$\theta_{j|\mathbf{h}}^i \geq 0, \quad \forall j \in \text{val}(X_i), \mathbf{h} \in \text{val}(\text{Pa}_{\mathcal{G}}(X_i)) \text{ and} \quad (18.35)$$

$$\sum_{j=1}^{\text{sp}(X_i)} \theta_{j|\mathbf{h}}^i = 1, \quad \forall \mathbf{h} \in \text{val}(\text{Pa}_{\mathcal{G}}(X_i)), \quad (18.36)$$

in order to specify valid probability distributions. Therefore, the CPDs corresponding to the  $i$ th variable can be stored in a table with  $(\text{sp}(X_i) - 1) \cdot \text{sp}(\text{Pa}_{\mathcal{G}}(X_i))$  entries.

The BN distribution in Eq. (18.31) becomes

$$P_{\mathcal{B}}(\mathbf{X} = \mathbf{x}) = \prod_{i=1}^N \prod_{j=1}^{\text{sp}(X_i)} \prod_{\mathbf{h} \in \text{val}(\text{Pa}_{\mathcal{G}}(X_i))} \left( \theta_{j|\mathbf{h}}^i \right)^{u_{j|\mathbf{h}}^i}, \quad (18.37)$$

where  $u_{j|\mathbf{h}}^i = \mathbb{1}_{\{x_i=j \text{ and } \mathbf{x}(\text{Pa}_{\mathcal{G}}(X_i))=\mathbf{h}\}}$ . The symbol  $\mathbb{1}_{\{A\}}$  denotes the indicator function which equals 1 if the statement  $A$  is true and 0 otherwise.

**Example 14 (Conditional Gaussian Variables).** In this example we assume that the variables of a BN  $\mathcal{B}$  are real-valued and that the CPDs are specified by Gaussian distributions, with the mean depending linearly on the value of the parents, and shared variance  $\sigma^2$ . That is, the CPD of node  $X_i$ , is given as

$$P(X_i | \text{Pa}_{\mathcal{G}}(X_i), \theta^i) = \mathcal{N} \left( X_i \left| \sum_{X_k \in \text{Pa}_{\mathcal{G}}(X_i)} \alpha_{i,k} x_k + \beta_i; \sigma^2 \right. \right), \quad (18.38)$$

where

$$\mathcal{N}(X|\mu; \sigma^2) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(X-\mu)^2}{2\sigma^2}\right) \quad (18.39)$$

denotes the Gaussian distribution with mean  $\mu$  and variance  $\sigma^2$ . Here, the parameter set  $\boldsymbol{\theta}^i = \{\boldsymbol{\alpha}_i, \beta_i\}$  contains the linear weights  $\boldsymbol{\alpha}_i = (\alpha_{i,1}, \dots, \alpha_{i,|\text{Pa}_{\mathcal{G}}(X_i)|})$  and the bias  $\beta_i$ . It can be shown that in this case the BN distribution in Eq. (18.31) is a multivariate Gaussian distribution, with mean vector  $\boldsymbol{\mu} = (\mu_1, \mu_2, \dots, \mu_N)$  and covariance matrix  $\boldsymbol{\Sigma}$ , which are recursively given as [4]:

$$\mu_i = \mathbb{E}[X_i] = \sum_{X_k \in \text{Pa}_{\mathcal{G}}(X_i)} \alpha_{i,k} \mu_k + \beta_i, \quad (18.40)$$

$$\begin{aligned} \Sigma_{i,j} &= \mathbb{E}[(X_i - \mathbb{E}[X_i])(X_j - \mathbb{E}[X_j])^T] \\ &= \sum_{X_k \in \text{Pa}_{\mathcal{G}}(X_j)} \alpha_{j,k} \Sigma_{i,k} + I_{i,j} \sigma^2, \end{aligned} \quad (18.41)$$

where  $I$  denotes the identity matrix,  $\Sigma_{i,j}$  the entry in  $\boldsymbol{\Sigma}$  in the  $i$ th row and  $j$ th column.

### 1.18.3.1.2 Conditional independence properties

BNs provide means for representing conditional independence properties of a probability distribution. Exploiting conditional independencies among variables supports efficient inference and reduces complexity. The factorization properties of the joint distribution of BNs as given in the last section imply a set of conditional independencies [1]:

**Theorem 1 (Local Conditional Independencies).** *Let  $\mathcal{B} = (\mathcal{G}, \{P_{X_1}, \dots, P_{X_N}\})$  be a BN and  $P_{\mathcal{B}}$  the joint probability defined by  $\mathcal{B}$ . Then,  $P_{\mathcal{B}}$  satisfies the local independencies*

$$X_i \perp \text{NonDesc}_{\mathcal{G}}(X_i) | \text{Pa}_{\mathcal{G}}(X_i) \quad \forall i, \quad (18.42)$$

i.e., any variable  $X_i$  is conditional independent of its nondescendants given its parents.

**Proof.** To prove the stated conditional independence property, it suffices to show that

$$P_{\mathcal{B}}(X_i | \text{NonDesc}_{\mathcal{G}}(X_i), \text{Pa}_{\mathcal{G}}(X_i)) = P_{\mathcal{B}}(X_i | \text{Pa}_{\mathcal{G}}(X_i)). \quad (18.43)$$

The conditional distribution  $P_{\mathcal{B}}(X_i | \text{NonDesc}_{\mathcal{G}}(X_i), \text{Pa}_{\mathcal{G}}(X_i))$  can be written as

$$P_{\mathcal{B}}(X_i | \text{NonDesc}_{\mathcal{G}}(X_i), \text{Pa}_{\mathcal{G}}(X_i)) = \frac{P_{\mathcal{B}}(X_i, \text{NonDesc}_{\mathcal{G}}(X_i), \text{Pa}_{\mathcal{G}}(X_i))}{P_{\mathcal{B}}(\text{NonDesc}_{\mathcal{G}}(X_i), \text{Pa}_{\mathcal{G}}(X_i))}. \quad (18.44)$$

The numerator is

$$P_{\mathcal{B}}(X_i, \text{NonDesc}_{\mathcal{G}}(X_i), \text{Pa}_{\mathcal{G}}(X_i)) = \sum_{\text{Desc}_{\mathcal{G}}(X_i)} P_{\mathcal{B}}(X_i, \text{NonDesc}_{\mathcal{G}}(X_i), \text{Pa}_{\mathcal{G}}(X_i), \text{Desc}_{\mathcal{G}}(X_i)) \quad (18.45)$$

$$= \sum_{\text{Desc}_{\mathcal{G}}(X_i)} P_{\mathcal{B}}(X_i | \text{Pa}_{\mathcal{G}}(X_i)) \prod_{X_j \in \text{Desc}_{\mathcal{G}}(X_i)} P_{\mathcal{B}}(X_j | \text{Pa}_{\mathcal{G}}(X_j)) \cdot \\ \prod_{X_k \in \text{NonDesc}_{\mathcal{G}}(X_i) \cup \text{Pa}_{\mathcal{G}}(X_i)} P_{\mathcal{B}}(X_k | \text{Pa}_{\mathcal{G}}(X_k)) \quad (18.46)$$

$$= P_{\mathcal{B}}(X_i | \text{Pa}_{\mathcal{G}}(X_i)) \underbrace{\prod_{X_k \in \text{NonDesc}_{\mathcal{G}}(X_i) \cup \text{Pa}_{\mathcal{G}}(X_i)} P_{\mathcal{B}}(X_k | \text{Pa}_{\mathcal{G}}(X_k))}_{=A} \cdot \\ \underbrace{\sum_{\text{Desc}_{\mathcal{G}}(X_i)} \prod_{X_j \in \text{Desc}_{\mathcal{G}}(X_i)} P_{\mathcal{B}}(X_j | \text{Pa}_{\mathcal{G}}(X_j))}_{=1} \quad (18.47)$$

In the same way, the denominator is given as

$$P_{\mathcal{B}}(\text{NonDesc}_{\mathcal{G}}(X_i), \text{Pa}_{\mathcal{G}}(X_i)) = \underbrace{\prod_{X_k \in \text{NonDesc}_{\mathcal{G}}(X_i) \cup \text{Pa}_{\mathcal{G}}(X_i)} P_{\mathcal{B}}(X_k | \text{Pa}_{\mathcal{G}}(X_k))}_{=A} \quad (18.48)$$

Consequently, we obtain

$$P_{\mathcal{B}}(X_i | \text{NonDesc}_{\mathcal{G}}(X_i), \text{Pa}_{\mathcal{G}}(X_i)) = P_{\mathcal{B}}(X_i | \text{Pa}_{\mathcal{G}}(X_i)) \quad (18.49)$$

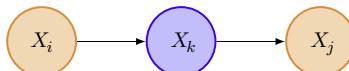

and the desired statement follows.  $\square$

Theorem 1 could have also been used as a basis for the definition of BNs, as, without proof, the local conditional independence assumptions from the Theorem imply the factorization properties of  $P_{\mathcal{B}}$  given in Eq. (18.31).

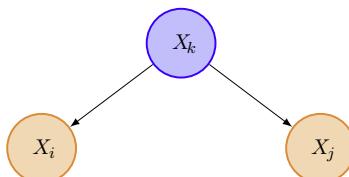

Additionally to the local conditional independencies, several other conditional independencies hold in BNs [1]. Some of them can be read off the graph by the concept of *d-separation*. Before turning to *d-separation*, we shortly introduce the notion of *context-specific independence*. In BNs with discrete variables the conditional distributions  $P(X_i | \text{Pa}_{\mathcal{G}}(X_i), \theta^i)$  are represented as conditional probability tables (CPTs). Regularities in these CPTs can render RV  $X_i$  independent of some parents conditioned on specific values of other parent variables. An example of context-specific independence is given in [1,8].

**Definition 24 (*d-separation* [2]).** Let  $\mathcal{B} = (\mathcal{G}, \{P_{X_1}, \dots, P_{X_N}\})$  be a BN,  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$ , and  $\mathbf{X} = \{X_1, \dots, X_N\}$ . Two RVs  $X_i$  and  $X_j$ ,  $i \neq j$ , are *d-separated* if for all trails between  $X_i$  and  $X_j$  there is an intermediate variable  $X_k$ ,  $i \neq k, j \neq k$ , such that

- the connection is *serial* or *diverging* and the state of  $X_k$  is observed, or

**FIGURE 18.4**

Serial connection.

**FIGURE 18.5**

Diverging connection.

- the connection is *converging* and neither the state of  $X_k$  nor the state of any descendant of  $X_k$  is observed,

where the term connection means the path corresponding to the trail.

We now introduce three simple graphs illustrating the underlying concept of the definition, i.e., the different connection types and the thereby implied conditional independencies.

*Serial connection:* A BN  $\mathcal{B}$  showing a so called *serial connection* is presented in Figure 18.4. According to Eq. (18.31) the corresponding joint distribution is given as

$$P_{\mathcal{B}}(X_i, X_k, X_j) = P(X_i)P(X_k|X_i)P(X_j|X_k). \quad (18.50)$$

We now condition the joint probability on  $X_k$ , i.e., we assume  $X_k$  to be observed. Then, by probability calculus,

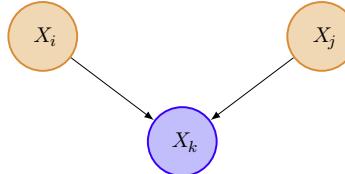

$$P_{\mathcal{B}}(X_i, X_j|X_k) = \overbrace{\frac{P(X_i)P(X_k|X_i)}{P_{\mathcal{B}}(X_k)}}^{=P_{\mathcal{B}}(X_i, X_k)} P(X_j|X_k), \quad (18.51)$$

$$= P_{\mathcal{B}}(X_i|X_k)P(X_j|X_k), \quad (18.52)$$

where  $P_{\mathcal{B}}(X_i, X_j|X_k)$ ,  $P_{\mathcal{B}}(X_i|X_k)$ , and  $P_{\mathcal{B}}(X_j|X_k)$  are conditional and marginal distributions resulting from the joint distribution  $P_{\mathcal{B}}(X_i, X_k, X_j)$ . That is,  $X_i$  and  $X_j$  are conditionally independent given  $X_k$ , i.e.,  $X_i \perp X_j|X_k$ . However, if  $X_k$  is not observed, the RVs  $X_i$  and  $X_j$  are dependent in general.

*Diverging connection:* A diverging connection is shown in Figure 18.5. Again, by exploiting the factorization properties of the BN according to (18.31), we obtain the joint probability

$$P_{\mathcal{B}}(X_i, X_k, X_j) = P(X_k)P(X_i|X_k)P(X_j|X_k). \quad (18.53)$$

**FIGURE 18.6**

Converging connection.

Conditioning this probability on  $X_k$  yields

$$P_{\mathcal{B}}(X_i, X_j | X_k) = \frac{\overbrace{P(X_k) P(X_i | X_k)}^{=P_{\mathcal{B}}(X_i, X_k)} P(X_j | X_k)}{P_{\mathcal{B}}(X_k)}, \quad (18.54)$$

$$= P_{\mathcal{B}}(X_i | X_k) P(X_j | X_k). \quad (18.55)$$

Hence,  $X_i \perp X_j | X_k$ . That is, when  $X_k$  is observed, then the variables  $X_i$  and  $X_j$  are conditionally independent given  $X_k$ , while, when  $X_k$  is not observed, they are dependent in general.

*Converging connection:* A converging connection is illustrated in Figure 18.6. The represented joint distribution is given as

$$P_{\mathcal{B}}(X_i, X_k, X_j) = P(X_i) P(X_j) P(X_k | X_i, X_j). \quad (18.56)$$

In contrast to the two cases before, the RVs  $X_i$  and  $X_j$  are a-priori independent since

$$\sum_{x_k \in \text{val}X_k} P(X_k = x_k | X_i, X_j) = 1. \quad (18.57)$$

That is

$$P_{\mathcal{B}}(X_i, X_j) = P(X_i) P(X_j), \quad (18.58)$$

which can be stated as  $X_i \perp X_j$ . To this end, consider the probability  $P_{\mathcal{B}}(X_i, X_j | X_k)$  which can be computed as

$$P_{\mathcal{B}}(X_i, X_j | X_k) = \frac{P(X_i) P(X_j) P(X_k | X_i, X_j)}{P_{\mathcal{B}}(X_k)}. \quad (18.59)$$

In general, this does not factorize in probabilities over  $X_i$  and  $X_j$ . Hence, the RVs  $X_i$  and  $X_j$  are independent if  $X_k$  is not observed but become dependent upon observation of variable  $X_k$  (or any descendant of  $X_k$ ). This is known as the *Berkson's paradox* [9] or the *explaining away phenomenon*.

Without proof, the  $d$ -separation Theorem expresses the conditional independence properties that follow from two sets of variables being  $d$ -separated (a proof is provided in [10]):

**Theorem 2 ( $d$ -separation [2]).** *Let  $\mathcal{B} = (\mathcal{G}, \{P_{X_1}, \dots, P_{X_N}\})$  be a BN and  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$ . Furthermore, let  $\mathbf{A}$ ,  $\mathbf{B}$ , and  $\mathbf{D}$  be mutually disjoint subsets of  $\mathbf{X}$ , where the variables in  $\mathbf{D}$  are observed. If every pair of nodes  $A \in \mathbf{A}$  and  $B \in \mathbf{B}$  are  $d$ -separated, then*

$$\mathbf{A} \perp \mathbf{B} | \mathbf{D}, \quad (18.60)$$

that is  $\mathbf{A}$  and  $\mathbf{B}$  are conditionally independent given  $\mathbf{D}$ .

### 1.18.3.2 Markov networks (MNs)

*Markov networks*, also known as *Markov Random Fields* (MRFs) or *undirected graphical models*, are represented by undirected graphs. As in BNs, an MN encodes certain factorization and conditional independence properties of the joint probability distribution.

#### 1.18.3.2.1 Definition and factorization properties

**Definition 25 (Markov Network).** A *Markov network* is a tuple  $\mathcal{M} = (\mathcal{G}, \{\Psi_{\mathbf{C}_1}, \dots, \Psi_{\mathbf{C}_L}\})$ , where  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  is an undirected graph with maximal cliques  $\mathbf{C}_1, \dots, \mathbf{C}_L$ . The nodes  $\mathbf{X}$  correspond to RVs and  $\Psi_{\mathbf{C}_i} : \text{val}(\mathbf{C}_i) \rightarrow \mathbb{R}_+$  are nonnegative functions, called *factors* or *potentials*, over the maximal cliques of the graph  $\mathcal{G}$ .

The MN defines a probability distribution according to

$$P_{\mathcal{M}}(X_1, \dots, X_N) = \frac{1}{Z} \prod_{l=1}^L \Psi_{\mathbf{C}_l}(\mathbf{C}_l), \quad (18.61)$$

where  $Z$  is a normalization constant given as

$$Z = \sum_{\mathbf{x} \in \text{val}(\mathbf{X})} \prod_{l=1}^L \Psi_{\mathbf{C}_l}(\mathbf{x}(\mathbf{C}_l)). \quad (18.62)$$

Often,  $Z$  is also referred to as *partition function*.

**Example 15 (Markov Network).** Consider the MN shown in Figure 18.7. The maximal cliques in this graph are surrounded by dotted boxes and are given as

$$\mathbf{C}_1 = \{X_1, X_2, X_3\}, \quad (18.63)$$

$$\mathbf{C}_2 = \{X_3, X_4\}, \quad \text{and} \quad (18.64)$$

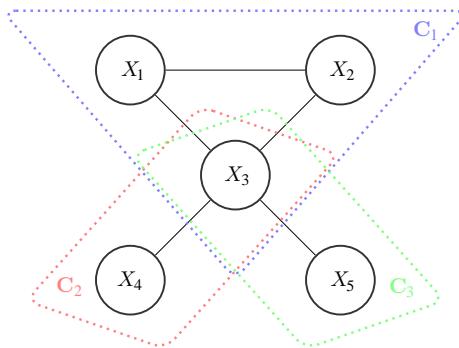

$$\mathbf{C}_3 = \{X_3, X_5\}. \quad (18.65)$$

Hence, the joint probability distribution of the represented model is

$$P_{\mathcal{M}}(X_1, \dots, X_5) = \frac{1}{Z} \Psi_{\mathbf{C}_1}(X_1, X_2, X_3) \Psi_{\mathbf{C}_2}(X_3, X_4) \Psi_{\mathbf{C}_3}(X_3, X_5). \quad (18.66)$$

#### 1.18.3.2.2 Conditional independence properties

Similarly as in BNs, MNs define a set of conditional independencies. In the following we present three conditional independence properties implied by MNs with strictly positive factors. If the factors are not strictly positive, the conditional independence properties stated below are not equivalent in general. Details regarding this are provided in [1].

**FIGURE 18.7**

Example of an MN.

The joint probability distributions represented by MNs with strictly positive factors satisfy the following equivalent conditional independencies:

- i. *Local Markov property*: Any RV  $X_i$  is conditionally independent from all other RVs given its neighbors. Formally,

$$X_i \perp (\mathbf{X} \setminus (\mathbf{Nb}_{\mathcal{G}}(X_i) \cup \{X_i\})) | \mathbf{Nb}_{\mathcal{G}}(X_i). \quad (18.67)$$

- ii. *Pairwise Markov property*: Any two non-adjacent RVs are conditionally independent given all other RVs, i.e.,

$$X_i \perp X_j | (\mathbf{X} \setminus \{X_i, X_j\}), \quad \text{if } (i - j) \notin \mathbf{E}. \quad (18.68)$$

- iii. *Global Markov property*: Let  $\mathbf{A}$ ,  $\mathbf{B}$ , and  $\mathbf{D}$  be mutually disjoint subsets of  $\mathbf{X}$ , and the variables in  $\mathbf{D}$  are observed. Then,

$$\mathbf{A} \perp \mathbf{B} | \mathbf{D}, \quad (18.69)$$

if every path from any node in  $\mathbf{A}$  to any node in  $\mathbf{B}$  passes through  $\mathbf{D}$ . In this case, the set  $\mathbf{D}$  is also denoted as *separating subset*.

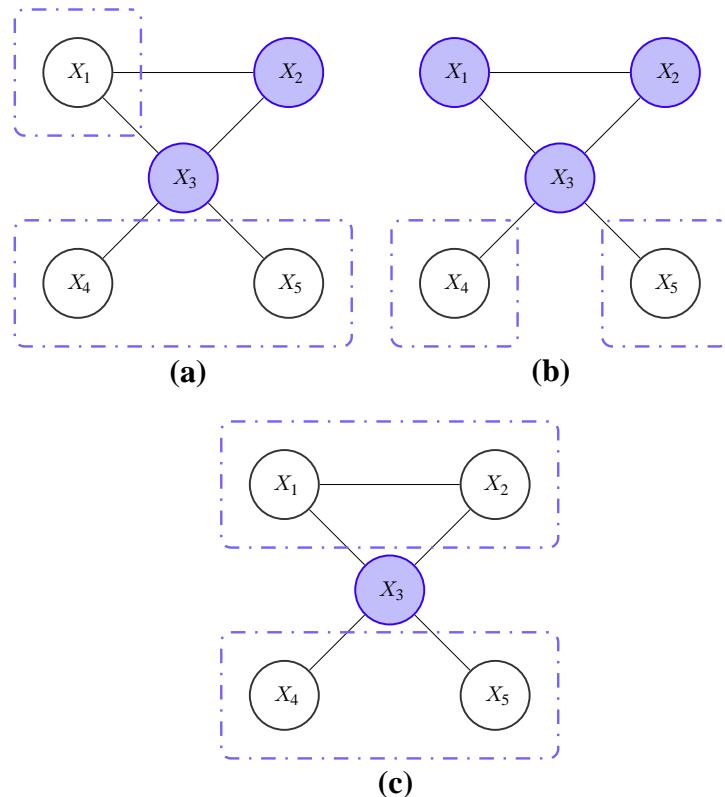

We illustrate these conditional independence statements in an example.

**Example 16 (Conditional Independencies in an MN).** Again, consider the MN shown in Figure 18.7. Then, for example,

- a. by the *local Markov property*,  $X_1$  is conditionally independent from the RVs  $X_4$  and  $X_5$  given its neighbors  $X_2$  and  $X_3$ , i.e.,

$$X_1 \perp \{X_4, X_5\} | \{X_2, X_3\}. \quad (18.70)$$

This is illustrated in Figure 18.8a.

**FIGURE 18.8**

Conditional independencies in MNs. (a) Local Markov property. (b) Pairwise Markov property. (c) Global Markov property.

- b.** by the *pairwise Markov property*,  $X_4$  and  $X_5$  are conditionally independent given  $X_1$ ,  $X_2$ , and  $X_3$ . Formally,

$$X_4 \perp X_5 | \{X_1, X_2, X_3\}. \quad (18.71)$$

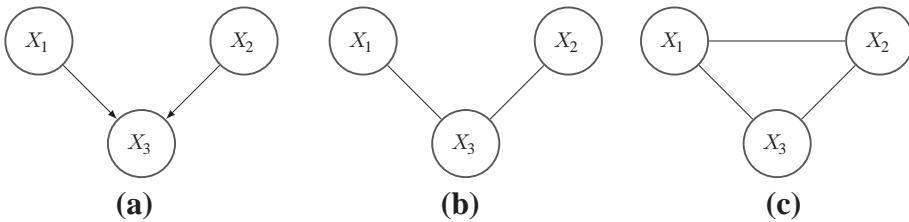

This is illustrated in Figure 18.8b.

- c.** by the *global Markov property*,  $X_1$  and  $X_2$  are conditionally independent of  $X_4$  and  $X_5$  given  $X_3$ , i.e.,

$$\{X_1, X_2\} \perp \{X_4, X_5\} | X_3. \quad (18.72)$$

This is illustrated in Figure 18.8c.

*Difference between BNs and MNs:* As introduced in the last sections, both BNs and MNs imply certain conditional independence statements. One might ask if any BN and its conditional independence

**FIGURE 18.9**

Representation of conditional independencies in BNs by MNs. (a) BN to be represented as an MN. (b) Candidate MN. (c) Another candidate MN.

properties can be represented by an MN and vice versa. Two simple examples demonstrate, that this is not the case:

**Example 17 (Conditional Independencies in BNs and MNs).** Consider the PGM with RVs \$X\_1\$, \$X\_2\$, and \$X\_3\$ represented by the BN in Figure 18.9a. We want to represent this BN by an MN that captures all the conditional independence properties of the BN:

- An appropriate MN must contain the edges \$(X\_1 - X\_3)\$ and \$(X\_2 - X\_3)\$. Otherwise, \$X\_3\$ would not depend on the state of \$X\_1\$ and \$X\_2\$ as in the BN. Such an MN is shown in Figure 18.9b. However, while in the BN in general \$X\_1 \not\perp\!\!\!\perp X\_2 | X\_3\$ the MN satisfies \$X\_1 \perp\!\!\!\perp X\_2 | X\_3\$ by the pairwise Markov property.
- Hence, we additionally need to add the edge \$(X\_1 - X\_2)\$ to the MN resulting in the MN represented in Figure 18.9c. However, now the MN does in general not satisfy that \$X\_1 \perp\!\!\!\perp X\_2\$ while the BN does.

Consequently, the conditional independencies of the BN in Figure 18.9a cannot be represented by an MN.

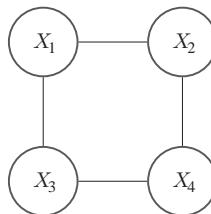

**Example 18 (Conditional Independencies in BNs and MNs).** Consider the MN in Figure 18.10. We want to represent this MN by a BN capturing all the independence properties that hold in the MN. By the pairwise Markov property \$X\_1\$ is conditionally independent from \$X\_4\$ given \$X\_2\$ and \$X\_3\$, and \$X\_2\$ is conditionally independent from \$X\_3\$ given \$X\_1\$ and \$X\_4\$, i.e.,

$$X_1 \perp\!\!\!\perp X_4 | \{X_2, X_3\}, \quad \text{and} \tag{18.73}$$

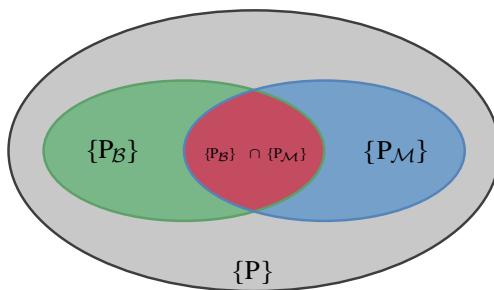

$$X_2 \perp\!\!\!\perp X_3 | \{X_1, X_4\}. \tag{18.74}$$

However, these conditional independencies cannot be encoded in a BN. The interested reader can find a proof for this in [1].

Nevertheless, there exist distributions which can be represented by both MNs and BNs. An example is the Markov chain, cf. Section 1.18.3.4. This can be illustrated graphically by the notion of *perfect maps*. A graph is a perfect map for a probability distribution if it represents all conditional independence properties of the distribution, and vice versa. Now, consider probability distributions over a given set of variables. Then, the set of probability distributions \$\{P\_B\}\$ for which some BN is a perfect map is a subset of all probability distributions \$\{P\}\$. Similarly, the set of probability distributions \$\{P\_M\}\$ for which some

**FIGURE 18.10**

Representation of conditional independencies in MNs by BNs.

**FIGURE 18.11**

Venn diagram depicting the set of all probability distributions  $\{P\}$  over a given set of variables, and the sets of probability distributions  $\{P_B\}$  and  $\{P_M\}$  for which some BN or some MN are a perfect map, respectively.

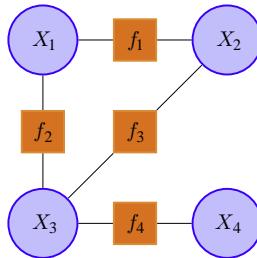

MN is a perfect map is also a subset of all probability distributions. Additionally, there are probability distributions  $\{P_B\} \cap \{P_M\}$  for which both BNs and MNs are perfect maps. This is illustrated by the Venn diagram in Figure 18.11 [4].

### 1.18.3.3 Factor graphs (FGs)

As last type of probabilistic model representation we introduce *factor graphs* (FGs) which explicitly represent the factorization properties of a function and have initially been used in the coding and image processing community.

#### 1.18.3.3.1 Definition

FGs are defined using the notion of bipartite graphs. These are graphs  $\mathcal{G} = (\mathbf{X}, \mathbf{E})$  for which the set of nodes can be divided into two disjoint subsets such that there are only edges between nodes from one subset to nodes of the other subset, as follows:

**FIGURE 18.12**

Example of an FG.

**Definition 26 (Factor Graph).** A *factor graph* is a tuple  $\mathcal{F} = (\mathcal{G}, \{f_1, \dots, f_L\})$ , where

- $\mathcal{G} = (\mathbf{V}, \mathbf{E})$  is an undirected bipartite graph such that  $\mathbf{V} = \mathbf{X} \cup \mathbf{F}$ , where  $\mathbf{X}$ , and  $\mathbf{F}$  are disjoint, and the nodes  $\mathbf{X} = \{X_1, \dots, X_N\}$  correspond to RVs. The nodes  $\mathbf{X}$  are *variable nodes*, while the nodes  $\mathbf{F}$  are *factor nodes*.
- Further,  $f_1, \dots, f_L$  are positive functions and the number of functions  $L$  equals the number of nodes in  $\mathbf{F} = \{F_1, \dots, F_L\}$ . Each node  $F_i$  is associated with the corresponding function  $f_i$  and each  $f_i$  is a function of the neighboring variables of  $F_i$ , i.e.,  $f_i = f_i(\mathbf{Nb}_{\mathcal{G}}(F_i))$ .

The factor graph  $\mathcal{F}$  defines the joint probability distribution

$$P_{\mathcal{F}}(X_1, \dots, X_N) = \frac{1}{Z} \prod_{l=1}^L f_l(\mathbf{Nb}_{\mathcal{G}}(F_l)), \quad (18.75)$$

where  $Z$  is the normalization constant given as

$$Z = \sum_{\mathbf{x} \in \text{val}(\mathbf{X})} \prod_{l=1}^L f_l(\mathbf{x}(\mathbf{Nb}_{\mathcal{G}}(F_l))). \quad (18.76)$$

As each factor node corresponds to a factor we use both terms equivalently. We illustrate the definition of FGs by the following example:

**Example 19 (Factor Graph).** Consider Figure 18.12. The given factor graph  $\mathcal{F}$  is  $\mathcal{F} = (\mathcal{G}, \{f_1, \dots, f_4\})$ , where the nodes of  $\mathcal{G}$  are the union of the set of variable nodes  $\{X_1, \dots, X_4\}$  and the set of factor nodes  $\{F_1, \dots, F_4\}$ . The functions corresponding to these factor nodes are  $f_1(X_1, X_2)$ ,  $f_2(X_1, X_3)$ ,  $f_3(X_2, X_3)$ , and  $f_4(X_3, X_4)$ . The represented joint probability density is

$$P_{\mathcal{F}}(X_1, \dots, X_4) = \frac{1}{Z} f_1(X_1, X_2) f_2(X_1, X_3) f_3(X_2, X_3) f_4(X_3, X_4), \quad (18.77)$$

where  $Z$  is the normalization constant as given in the definition of FGs.

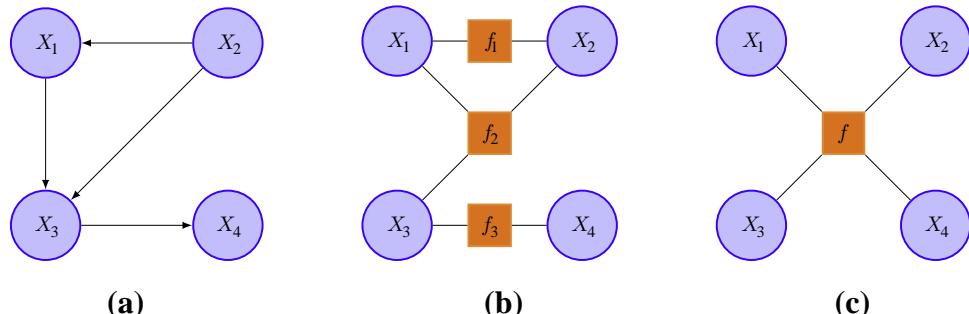

FIGURE 18.13

Conversion of a BN to an FG. (a) BN to be converted to an FG. (b) FG for representing the BN. (c) Alternative FG for representing the BN.

### **1.18.3.3.2 BNs and MNs as FGs**

FGs allow the representation of both BNs and MNs. However, note that there is in general no unique transformation from a BN/MN to an FG. We illustrate the transformation of a BN or MN to an FG in the following two examples:

**Example 20 (Conversion of a BN to an FG).** The BN shown in Figure 18.13a can be represented as the FG in Figure 18.13b where the factors  $f_1$ ,  $f_2$ ,  $f_3$  are given as

$$f_1(X_1, X_2) \equiv P_{X_2}(X_2)P_{X_1}(X_1|X_2), \quad (18.78)$$

$$f_2(X_1, X_2, X_3) \equiv P_{X_3}(X_3|X_1, X_2), \quad (18.79)$$

$$f_3(X_3, X_4) = P_{X_4}(X_4 | X_3). \quad (18.80)$$

In this way, the factor graph represents the probability distribution

$$P_{\mathcal{F}}(X_1, \dots, X_4) = f_1(X_1, X_2) f_2(X_1, X_2, X_3) f_3(X_3, X_4), \quad (18.81)$$

$$= P_{X_2}(X_2)P_{X_1}(X_1|X_2)P_{X_3}(X_3|X_1, X_2)P_{X_4}(X_4|X_3), \quad (18.82)$$

which is exactly the one given by the BN. Alternatively, the BN could also be represented by the FG shown in Figure 18.13c, where the factor  $f$  is given as

$$f(X_1, \dots, X_4) = P_{X_2}(X_2)P_{X_1}(X_1|X_2)P_{X_3}(X_3|X_1, X_2)P_{X_4}(X_4|X_3). \quad (18.83)$$

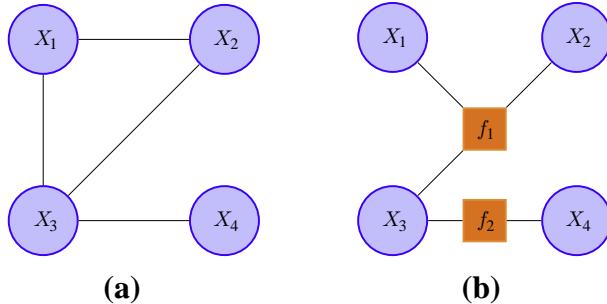

**Example 21 (Conversion of an MN to an FG).** The MN in Figure 18.14a represents the factorization

$$P_M(X_1, \dots, X_4) \equiv \Psi_{C^+}(X_1, X_2, X_3)\Psi_{C^+}(X_3, X_4). \quad (18.84)$$

where the maximal cliques are  $\mathbf{C}_1 = \{X_1, X_2, X_3\}$  and  $\mathbf{C}_2 = \{X_3, X_4\}$ , respectively. This factorization can be represented by the FG in Figure 18.14b, where

$$f_1(X_1, X_2, X_3) \equiv \Psi_{C_1}(X_1, X_2, X_3), \quad \text{and} \quad (18.85)$$

$$f_2(X_3, X_4) \equiv \Psi_{C_2}(X_3, X_4), \quad (18.86)$$

**FIGURE 18.14**

### 1.18.3.4 Markov chains

To conclude the section on PGM representations we consider Markov chains (MCs), and how they can be represented in each of the three types of PGMs. An MC is defined as follows:

**Definition 27 (Markov chain).** Let \$X\_1, \dots, X\_N\$ be a sequence of RVs. These RVs form a *Markov chain* if they satisfy

$$P(X_i | X_1, \dots, X_{i-1}) = P(X_i | X_{i-1}), \quad \forall i. \quad (18.87)$$

This is called *Markov property*.

In an MC the RVs preceding some given RV \$X\_i\$ are conditionally independent of all RVs succeeding \$X\_i\$, i.e.,

$$\{X_1, \dots, X_{i-1}\} \perp \{X_{i+1}, \dots, X_N\} | X_i. \quad (18.88)$$

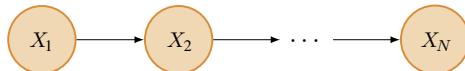

Furthermore, since any joint probability distribution \$P(X\_1, \dots, X\_N)\$ factorizes as

$$P(X_1, \dots, X_N) = \prod_{i=1}^N P(X_i | X_{i-1}, \dots, X_1), \quad (18.89)$$

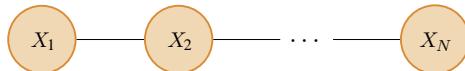

this simplifies due to the Markov property to

$$P(X_1, \dots, X_N) = \prod_{i=1}^N P(X_i | X_{i-1}). \quad (18.90)$$

We can represent MCs as BNs, MNs and FGs, as presented in the following:

**FIGURE 18.15**

BN modeling an MC.

**FIGURE 18.16**

MN modeling an MC.

- *Bayesian network:* A BN  $\mathcal{B}$  modeling an MC is shown in Figure 18.15. The represented joint distribution is

$$P_{\mathcal{B}}(X_1, \dots, X_N) = \prod_{i=1}^N P(X_i | \text{Pa}_{\mathcal{G}}(X_i)), \quad (18.91)$$

$$= P_{\mathcal{B}}(X_1, \dots, X_N) = P(X_1) \prod_{i=2}^N P(X_i | X_{i-1}), \quad (18.92)$$

where the only parent of  $X_i$  is  $X_{i-1}$ .

- *Markov network:* The MN  $\mathcal{M}$  for representing an MC in Figure 18.16 has the maximal cliques  $\mathbf{C}_i = \{X_i, X_{i+1}\}$  for  $i = 1, \dots, N - 1$ . If we define the factor  $\Psi_{\mathbf{C}_i}$  to represent the function  $P(X_{i+1}|X_i)$  for  $i = 2, \dots, N - 1$  and  $\Psi_{\mathbf{C}_1} = P(X_1)P(X_2|X_1)$ , then the MN specifies the joint probability distribution of an MC, i.e.,

$$P_{\mathcal{M}}(X_1, \dots, X_N) = \prod_{l=1}^{N-1} \Psi_{\mathbf{C}_l}(\mathbf{C}_l), \quad (18.93)$$

$$= P(X_1) \prod_{i=2}^N P(X_i | X_{i-1}). \quad (18.94)$$

- *Factor graph:* Finally, the FG  $\mathcal{F}$  in Figure 18.17 with factors  $f_1 = P(X_1)$  and  $f_i = P(X_i | X_{i-1})$  for  $i = 2, \dots, N$  specifies the distribution of an MC, i.e.,

$$P_{\mathcal{F}}(X_1, \dots, X_N) = \prod_{l=1}^N f_l(\text{Nb}_{\mathcal{G}}(F_l)), \quad (18.95)$$

$$= P(X_1) \prod_{i=2}^N P(X_i | X_{i-1}). \quad (18.96)$$

**FIGURE 18.17**

FG modeling an MC.

### 1.18.4 Learning

Our goal is now to determine a PGM which models the variables of interest. One possibility is to specify the PGM by hand. Especially BNs are suited to be specified by a domain expert, since the directed edges can be treated as causal directions and local probability tables can be elicited relatively easily. However, the more attractive approach might be to automatically determine a PGM from a set of training data. Assume we want to find a PGM for a set of random variables  $\mathbf{X} = \{X_1, \dots, X_N\}$  which are distributed according to an unknown joint distribution  $P^*(\mathbf{X})$ . Further, assume that we have a collection of  $L$  independent and identically distributed (i.i.d.) samples  $\mathcal{D} = \{\mathbf{x}^{(1)}, \mathbf{x}^{(2)}, \dots, \mathbf{x}^{(L)}\}$ , drawn from distribution  $P^*(\mathbf{X})$ . In this section we assume *complete* data, i.e., each data case  $\mathbf{x}^{(i)}$  contains values of all variables in  $\mathbf{X}$ . For incomplete data, learning becomes much harder and is typically tackled using *expectation-maximization* (EM) methods [11], or related techniques. The task of learning a PGM can be described as follows: given  $\mathcal{D}$ , return a PGM which approximates  $P^*(\mathbf{X})$  best. This type of learning is known as *generative learning*, since we aim to model the process which generated the data. Generative learning can be seen as a “multi-purpose” tool, since we directly strive for the primary object of interest: the joint distribution  $P^*(\mathbf{X})$ . All other quantities of the model which might be interesting, such as marginal distributions of single variables/sets of variables, conditional distributions, or expectations, can be derived from the joint distribution. However, it is rarely possible to exactly retrieve  $P^*(\mathbf{X})$ , especially when using a finite sample  $\mathcal{D}$ . This can be obstructive, when the ultimate goal is not to retrieve  $P^*(\mathbf{X})$ , but to use the PGM in a specialized way. An example for this is when we want to use the PGM as classifier, i.e., we want to infer the value of a class variable, given the values of the remaining variables. In the classification context we are primarily interested in minimizing the loss resulting from erroneous decisions, not in modeling the overall generative process. It can be easily shown that knowledge of  $P^*(\mathbf{X})$  leads to optimal classification, and therefore generative learning seems to be suitable to learn classifiers. However, a somewhat surprising but consistently occurring phenomenon in machine learning literature is that so-called *discriminative* learning methods, which refrain from modeling  $P^*(\mathbf{X})$ , but directly address the classification problem, often yield better classification results than the generative approach. The discriminative paradigm is discussed in Section 1.18.4.3. For now, let us focus on the generative approach.

#### 1.18.4.1 Principles of generative learning

Let us assume a specific class of models  $\mathcal{C}$ , e.g., the class of all BNs, or the class of all MNs. We define a prior distribution  $P(\mathcal{C})$  over the model class, which represents our preference for certain models. For example, if  $\mathcal{C}$  is the class of all BNs, we may prefer networks with fewer edges, and therefore define a prior which decreases with the number of edges. Furthermore, let  $\mathcal{D}$  be a set of i.i.d. training samples

drawn from the true distribution  $P^*(\mathbf{X})$ . In the generative approach, we are interested in the posterior probability distribution over the model class, conditioned on the given data. Using Bayes' law, this distribution is

$$P(\mathcal{C}|\mathcal{D}) = \frac{P(\mathcal{D}|\mathcal{C})P(\mathcal{C})}{P(\mathcal{D})} = \frac{P(\mathcal{D}|\mathcal{C})P(\mathcal{C})}{\int_{\mathcal{C}} P(\mathcal{D}|M')P(M')dM'} \propto P(\mathcal{D}|\mathcal{C})P(\mathcal{C}). \quad (18.97)$$

The data generation probability  $P(\mathcal{D}|\mathcal{C})$  is widely known as *likelihood*  $\mathcal{L}(\mathcal{C}; \mathcal{D})$ . The only difference between  $P(\mathcal{D}|\mathcal{C})$  and  $\mathcal{L}(\mathcal{C}; \mathcal{D})$  is that the likelihood is interpreted as a function of  $\mathcal{C}$ , while the data generation probability is viewed as a probability of  $\mathcal{D}$ . In (18.97) we see, that  $P(\mathcal{C}|\mathcal{D})$  is proportional to the product of prior  $P(\mathcal{C})$  and likelihood  $\mathcal{L}(\mathcal{C}; \mathcal{D})$ , i.e., the posterior  $P(\mathcal{C}|\mathcal{D})$  represents an “updated” version of the prior  $P(\mathcal{C})$ , incorporating the likelihood  $\mathcal{L}(\mathcal{C}; \mathcal{D})$ . There exist two general approaches to use the posterior distribution for learning:

- i. *Maximum a-posteriori (MAP) approach:* This approach aims to find the most probable model  $M_{\text{MAP}} \in \mathcal{C}$  for given data, i.e.,

$$M_{\text{MAP}} = \arg \max_{M \in \mathcal{C}} P(M|\mathcal{D}), \quad (18.98)$$

$$= \arg \max_{M \in \mathcal{C}} \mathcal{L}(M; \mathcal{D})P(M). \quad (18.99)$$

In the MAP approach we accept the single model  $M_{\text{MAP}}$  as best explanation for the data and consequently use it for further tasks.

- ii. *Bayesian approach:* In the Bayesian approach, we refrain to decide for a single model out of  $\mathcal{C}$ . Instead, we maintain the uncertainty about which model might be the “true” one and keep the whole model class  $\mathcal{C}$ , together with the posterior distribution  $P(\mathcal{C}|\mathcal{D})$ .

To illustrate the difference of these two approaches, let us assume we are interested in the probability of an unseen sample  $\mathbf{x}'$ , after observing  $\mathcal{D}$ . The MAP approach yields

$$P(\mathbf{X} = \mathbf{x}'|\mathcal{D}) = P(\mathbf{x}'|M_{\text{MAP}}), \quad (18.100)$$

while the Bayesian approach results in

$$P(\mathbf{X} = \mathbf{x}'|\mathcal{D}) = \int_{\mathcal{C}} P(\mathbf{x}'|M)P(M|\mathcal{D})dM. \quad (18.101)$$

The Bayesian approach proceeds more carefully and treats the uncertainty by marginalizing over all possible models. The MAP and the Bayesian approach often agree in the large sample limit, since for large  $L$  the mass of the posterior  $P(\mathcal{C}|\mathcal{D})$  is typically concentrated on a single model. For small sample sizes, the Bayesian approach typically surpasses the MAP approach. However, it is rarely possible to solve the integral in (18.101) exactly, which is the main drawback of the Bayesian approach. Typically, (18.101) has to be approximated, e.g., by integrating (or summing) over a small portion of all models.

In the special case when the prior distribution  $P(\mathcal{C})$  is flat, i.e., no model is preferred over the other, the posterior  $P(\mathcal{C}|\mathcal{D})$  is proportional to the likelihood  $\mathcal{L}(\mathcal{C}; \mathcal{D})$  and the MAP solution coincides with the *maximum-likelihood* (ML) solution, i.e.,

$$M_{\text{MAP}} = M_{\text{ML}} = \arg \max_{M \in \mathcal{C}} \mathcal{L}(M; \mathcal{D}). \quad (18.102)$$

Since the data samples in  $\mathcal{D}$  are i.i.d., the likelihood is given as

$$\mathcal{L}(\mathcal{C}; \mathcal{D}) = P(\mathcal{D}|\mathcal{C}) = \prod_{l=1}^L P(\mathbf{x}^{(l)}|\mathcal{C}). \quad (18.103)$$

In practise, it is often convenient and numerically more stable to work with the *log-likelihood*

$$\log \mathcal{L}(\mathcal{C}; \mathcal{D}) = \sum_{l=1}^L \log P(\mathbf{x}^{(l)}|\mathcal{C}). \quad (18.104)$$

Since the logarithm is an increasing function, maximizing the log-likelihood is equivalent to maximizing the likelihood. Intuitively, (log-) likelihood is a measure of “goodness of fit,” i.e., a model with maximum likelihood is considered as best explanation for the training data. Furthermore, there is an interesting connection between likelihood and information theory; For the sample  $\mathcal{D}$ , the empirical data distribution is defined as

$$P_{\mathcal{D}}(\mathbf{x}) = \frac{1}{L} \sum_{l=1}^L \mathbb{1}_{\{\mathbf{x}=\mathbf{x}^{(l)}\}}, \quad (18.105)$$

where  $\mathbb{1}_{\{\cdot\}}$  is the indicator function. It is easily shown that maximizing the likelihood is equivalent to minimize the Kullback-Leibler (KL) divergence between empirical distribution and model distribution, which is given as

$$\text{KL}(P_{\mathcal{D}}||P(\cdot|\mathcal{C})) = \sum_{\mathbf{x} \in \text{var}(\mathbf{X})} P_{\mathcal{D}}(\mathbf{x}) \log \frac{P_{\mathcal{D}}(\mathbf{x})}{P(\mathbf{x}|\mathcal{C})}. \quad (18.106)$$

The KL divergence is a dissimilarity measure of the argument distributions. In particular,  $\text{KL}(P||Q) \geq 0$  and  $\text{KL}(P||Q) = 0$  if and only if  $P(\mathbf{X})$  and  $Q(\mathbf{X})$  are identical. Furthermore,  $\text{KL}(P||Q)$  measures the minimal average coding overhead, for encoding data using the distribution  $Q(\mathbf{X})$ , while the data is actually distributed according to  $P(\mathbf{X})$  [5].

### 1.18.4.2 Generative learning of Bayesian networks

We now specify the model class  $\mathcal{C}$ , and concentrate on the problem of learning BNs from data. As discussed in Section 1.18.3.1, a BN  $\mathcal{B} = (\mathcal{G}, \Theta)$  defines a distribution over the model variables  $\mathbf{X}$  according to

$$P_{\mathcal{B}}(\mathbf{X}) = \prod_{i=1}^N P(X_i | \text{Pa}_{\mathcal{G}}(X_i), \boldsymbol{\theta}^i), \quad (18.107)$$

which is a product over local probability distributions, one for each variable  $X_i$ . Equation (18.107) highlights the two aspects of a BN: the structure  $\mathcal{G}$ , which determines the parents for each variable, and the parameters  $\Theta = \{\boldsymbol{\theta}^1, \boldsymbol{\theta}^2, \dots, \boldsymbol{\theta}^N\}$  which parameterize the local distributions. Although  $\mathcal{G}$  and  $\Theta$  are coupled, e.g., the number of parameters in  $\boldsymbol{\theta}^i$  depends on  $\mathcal{G}$ , an isolated consideration of  $\mathcal{G}$  and  $\Theta$  is possible and reasonable. This leads to the two tasks of learning BNs: parameter learning and structure learning. For parameter learning, we assume that the network structure  $\mathcal{G}$  is fixed, either

because a domain expert specified the independence relationships among the model variables, or because a structure learning algorithm found an appropriate structure. For fixed structure  $\mathcal{G}$ , we introduce the shorthand  $\mathbf{Pa}_i = \mathbf{Pa}_{\mathcal{G}}(X_i)$  and  $\mathbf{x}_{\mathbf{Pa}_i} = \mathbf{x}(\mathbf{Pa}_{\mathcal{G}}(X_i))$ . In the next section we discuss ML parameter learning, and in Section 1.18.4.2.2 we introduce a full Bayesian approach for BN parameter learning. In Section 1.18.4.2.3 we address the problem of learning also the structure  $\mathcal{G}$  from data.

### 1.18.4.2.1 Maximum likelihood parameter learning

For an i.i.d. sample  $\mathcal{D}$ , the log-likelihood of a BN model is given as

$$\log \mathcal{L}(\mathcal{B}; \mathcal{D}) = \sum_{l=1}^L \sum_{i=1}^N \log P(x_i^{(l)} | \mathbf{x}_{\mathbf{Pa}_i}^{(l)}, \boldsymbol{\theta}^i) = \sum_{i=1}^N \ell(\boldsymbol{\theta}^i, \mathcal{D}). \quad (18.108)$$

Equation (18.108) shows that the log-likelihood decomposes, i.e.,  $\log \mathcal{L}(\mathcal{B}; \mathcal{D})$  equals to a sum over local terms, one for each variable, given as

$$\ell(\boldsymbol{\theta}^i, \mathcal{D}) = \sum_{l=1}^L \log P(x_i^{(l)} | \mathbf{x}_{\mathbf{Pa}_i}^{(l)}, \boldsymbol{\theta}^i). \quad (18.109)$$

Thus the overall BN log-likelihood is maximized by maximizing the individual local terms w.r.t. the local parameters  $\boldsymbol{\theta}^i$ . This holds true as long as each local term  $\ell(\boldsymbol{\theta}^i; \mathcal{D})$  only depends on  $\boldsymbol{\theta}^i$ . If there exists a coupling between the parameters, as for instance introduced by parameter tying, we loose this decomposition property.

*Maximum likelihood parameter learning for discrete variables:* If the variables  $\mathbf{X}$  are discrete, the most general CPDs are discrete distributions (cf. Example 13):

$$P(X_i = j | \mathbf{Pa}_i = \mathbf{h}, \boldsymbol{\theta}^i) = \theta_{j|\mathbf{h}}^i. \quad (18.110)$$

In order to maximize the likelihood, we aim to individually maximize the local terms  $\ell(\boldsymbol{\theta}^i; \mathcal{D})$  (18.109), which are given as

$$\ell(\boldsymbol{\theta}^i; \mathcal{D}) = \sum_{l=1}^L \log \left( \prod_{j=1}^{\text{sp}(X_i)} \prod_{\mathbf{h} \in \text{val}(\mathbf{Pa}_i)} \theta_{j|\mathbf{h}}^i u_{j|\mathbf{h}}^{i,l} \right), \quad (18.111)$$

$$= \sum_{\mathbf{h}} \sum_{l: \mathbf{x}_l \in \mathcal{D}_{\mathbf{h}}} \sum_{j=1}^{\text{sp}(X_i)} u_{j|\mathbf{h}}^{i,l} \log \theta_{j|\mathbf{h}}^i, \quad (18.112)$$

$$= \sum_{\mathbf{h}} \log \mathcal{L}(\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i; \mathcal{D}_{\mathbf{h}}). \quad (18.113)$$

Here  $u_{j|\mathbf{h}}^{i,l} = \mathbb{1}_{\{x_i^{(l)} = j \text{ and } \mathbf{x}_{\mathbf{Pa}_i}^{(l)} = \mathbf{h}\}}$ . The data set  $\mathcal{D}_{\mathbf{h}}$  is a subset of the training data  $\mathcal{D}$ , containing those samples  $\mathbf{x}^{(l)}$  where  $\mathbf{x}_{\mathbf{Pa}_i}^{(l)} = \mathbf{h}$ . In (18.112) sums are interchanged and some terms which would be

evaluated to zero, are discarded. In (18.113) the local terms  $\ell(\boldsymbol{\theta}^i; \mathcal{D})$  decompose to a sum of local log-likelihoods

$$\log \mathcal{L}(\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i; \mathcal{D}_{\mathbf{h}}) = \sum_{l: \mathbf{x}_l \in \mathcal{D}_{\mathbf{h}}} \sum_{j=1}^{\text{sp}(X_i)} u_{j|\mathbf{h}}^{i,l} \log \theta_{j|\mathbf{h}}^i. \quad (18.114)$$

Inserting this result into (18.108), we see that the BN log-likelihood is given as a sum of local log-likelihoods:

$$\log \mathcal{L}(\mathcal{B}; \mathcal{D}) = \sum_{i=1}^N \sum_{\mathbf{h} \in \text{val}(\mathbf{Pa}_i)} \log \mathcal{L}(\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i; \mathcal{D}_{\mathbf{h}}) \quad (18.115)$$

Since each  $\theta_{\cdot|\mathbf{h}}^i$  only occurs in a single summand in (18.115), the overall log-likelihood is maximized by individually maximizing each local log-likelihood. Note that  $\theta_{\cdot|\mathbf{h}}^i$  are the parameters of  $X_i$  conditioned on a particular  $\mathbf{h}$ , i.e., they are the parameters of single dimensional discrete distributions. Finding these ML parameters is easy. For notational simplicity, we derive the ML estimate for a generic variable  $Y$  with data  $\mathcal{D}_Y = \{y^{(1)}, \dots, y^{(L)}\}$  and generic parameters  $\boldsymbol{\theta}^Y = (\theta_1^Y, \dots, \theta_{\text{sp}(Y)}^Y)$ . The ML estimate  $\hat{\boldsymbol{\theta}}^Y$  is found by solving the optimization problem:

$$\underset{\boldsymbol{\theta}^Y}{\text{maximize}} \sum_{l=1}^L \sum_{j=1}^{\text{sp}(Y)} u_j^l \log \theta_j^Y, \quad (18.116)$$

$$\text{s.t. } \sum_{j=1}^{\text{sp}(Y)} \theta_j^Y = 1. \quad (18.117)$$

Here  $u_j^l$  is the indicator function  $\mathbb{1}_{\{y^{(l)}=j\}}$ . The Lagrangian function of this problem is given as

$$L(\boldsymbol{\theta}^Y, v) = \sum_{l=1}^L \sum_{j=1}^{\text{sp}(Y)} u_j^l \log \theta_j^Y + v \left( 1 - \sum_{j=1}^{\text{sp}(Y)} \theta_j^Y \right). \quad (18.118)$$

Since the objective in (18.116) is concave and we have a linear equality constraint (18.117), stationarity of  $L(\boldsymbol{\theta}^Y, v)$  is necessary and sufficient for optimality [12], i.e., the constraint (18.117) has to hold and the partial derivatives w.r.t.  $\theta_j^Y$  have to vanish:

$$\frac{\partial L(\boldsymbol{\theta}^Y, v)}{\partial \theta_j^Y} = \sum_{l=1}^L u_j^l \frac{1}{\theta_j^Y} - v \stackrel{!}{=} 0. \quad (18.119)$$

We see that the optimal parameters have the form

$$\hat{\theta}_j^Y = \frac{\sum_{l=1}^L u_j^l}{v} = \frac{n_j}{v}, \quad (18.120)$$

where  $n_j = \sum_{l=1}^L u_j^l$  is the number of occurrences of  $Y = j$  in the data set  $\mathcal{D}_Y$ . Since (18.117) has to hold, we see that  $v$  has to be equal to  $\sum_{j=1}^{\text{sp}(Y)} n_j$ , and therefore the ML parameters are simply the relative frequency counts according to  $\mathcal{D}_Y$ :

$$\hat{\theta}_j^Y = \frac{n_j}{\sum_{j'=1}^{\text{sp}(Y)} n_{j'}}. \quad (18.121)$$

Applying this result to  $\theta_{|\mathbf{h}}^i$ , we obtain the ML parameters as

$$\hat{\theta}_{j|\mathbf{h}}^i = \frac{\sum_{l=1}^L u_{j|\mathbf{h}}^{i,l}}{\sum_{j'=1}^{\text{sp}(X_j)} \sum_{l=1}^L u_{j'|\mathbf{h}}^{i,l}}. \quad (18.122)$$

This estimate is well-defined if there is at least one sample in the subset  $\mathcal{D}_{\mathbf{h}}$ . If there is no sample in  $\mathcal{D}_{\mathbf{h}}$ , an arbitrary distribution (e.g., the uniform distribution) can be assumed, since in this case  $\theta_{|\mathbf{h}}^i$  does not contribute to the likelihood.

*Maximum likelihood parameter learning for conditional Gaussian variables:* Now let us assume that the variables are real-valued, and that the CPDs are conditional Gaussians (cf. Example 14), i.e.,

$$P(X_i|\mathbf{Pa}_i, \theta^i) = \mathcal{N}\left(X_i \mid \boldsymbol{\alpha}_i^T \mathbf{x}_{\mathbf{Pa}_i} + \beta_i; \sigma^2\right), \quad (18.123)$$

where we assume a fixed shared variance  $\sigma^2$ . Again, in order to maximize the BN likelihood, we aim to individually maximize the local terms  $\ell(\theta^i; \mathcal{D})$  in (18.109). Inserting the logarithm of (18.123) in (18.109) yields

$$\ell(\theta^i; \mathcal{D}) = \sum_{l=1}^L \left[ -\frac{1}{2} \log(2\pi\sigma^2) - \frac{(x_i^{(l)} - \boldsymbol{\alpha}_i^T \mathbf{x}_{\mathbf{Pa}_i}^{(l)} - \beta_i)^2}{2\sigma^2} \right] \quad (18.124)$$

$$\begin{aligned} &= -\frac{1}{2\sigma^2} \sum_{l=1}^L \left[ x_i^{(l)2} + \boldsymbol{\alpha}_i^T \mathbf{x}_{\mathbf{Pa}_i}^{(l)} \mathbf{x}_{\mathbf{Pa}_i}^{(l)T} \boldsymbol{\alpha}_i + \beta_i^2 - 2x_i^{(l)} \boldsymbol{\alpha}_i^T \mathbf{x}_{\mathbf{Pa}_i}^{(l)} \right. \\ &\quad \left. - 2x_i^{(l)} \beta_i + 2\boldsymbol{\alpha}_i^T \mathbf{x}_{\mathbf{Pa}_i}^{(l)} \beta_i \right] + \text{const.}, \end{aligned} \quad (18.125)$$

where additive terms which are independent of  $\boldsymbol{\alpha}_i$  and  $\beta_i$  are summarized in a constant. The overall log-likelihood of the BN is maximized by individually maximizing (18.124) w.r.t.  $\theta^i = \{\boldsymbol{\alpha}_i, \beta_i\}$ . The function  $\ell(\theta^i; \mathcal{D})$  is the negative square of an affine function and therefore concave in  $\boldsymbol{\alpha}_i$  and  $\beta_i$  [12]. Thus, a maximum can be found by setting the partial derivatives to zero. For  $\beta_i$  we get:

$$\frac{\partial \ell(\theta^i; \mathcal{D})}{\partial \beta_i} = -\frac{1}{2\sigma^2} \sum_{l=1}^L \left[ 2\beta_i - 2x_i^{(l)} + 2\mathbf{x}_{\mathbf{Pa}_i}^{(l)T} \boldsymbol{\alpha}_i \right] \stackrel{!}{=} 0. \quad (18.126)$$

Hence the ML parameter  $\hat{\beta}_i$  is given as

$$\hat{\beta}_i = \frac{1}{L} \sum_{l=1}^L \left[ x_i^{(l)} - \mathbf{x}_{\mathbf{Pa}_i}^{(l)T} \boldsymbol{\alpha}_i \right] = \hat{x}_i - \hat{\mathbf{x}}_{\mathbf{Pa}_i}^T \boldsymbol{\alpha}_i, \quad (18.127)$$

where  $\hat{x}_i$  and  $\hat{\mathbf{x}}_{\mathbf{Pa}_i}$  are the sample means of  $X_i$  and  $\mathbf{Pa}_i$ , respectively. For  $\boldsymbol{\alpha}_i$  we have

$$\nabla_{\boldsymbol{\alpha}_i} \ell(\boldsymbol{\theta}^i; \mathcal{D}) = -\frac{1}{2\sigma^2} \sum_{l=1}^L \left[ 2\mathbf{x}_{\mathbf{Pa}_i}^{(l)} \mathbf{x}_{\mathbf{Pa}_i}^{(l)T} \boldsymbol{\alpha}_i - 2x_i^{(l)} \mathbf{x}_{\mathbf{Pa}_i}^{(l)} + 2\mathbf{x}_{\mathbf{Pa}_i}^{(l)} \beta_i \right] \stackrel{!}{=} 0. \quad (18.128)$$

Using  $\hat{\beta}_i$  in (18.128), we get the ML parameters  $\hat{\boldsymbol{\alpha}}_i$  by the following chain of equations:

$$\begin{aligned} \sum_{l=1}^L \left[ \mathbf{x}_{\mathbf{Pa}_i}^{(l)} \left( \mathbf{x}_{\mathbf{Pa}_i}^{(l)T} - \hat{\mathbf{x}}_{\mathbf{Pa}_i}^T \right) \right] \hat{\boldsymbol{\alpha}}_i &= \sum_{l=1}^L \left[ \left( x_i^{(l)} - \hat{x}_i \right) \mathbf{x}_{\mathbf{Pa}_i}^{(l)} \right], \\ \sum_{l=1}^L \left[ \left( \mathbf{x}_{\mathbf{Pa}_i}^{(l)} - \hat{\mathbf{x}}_{\mathbf{Pa}_i} + \hat{\mathbf{x}}_{\mathbf{Pa}_i} \right) \left( \mathbf{x}_{\mathbf{Pa}_i}^{(l)T} - \hat{\mathbf{x}}_{\mathbf{Pa}_i}^T \right) \right] \hat{\boldsymbol{\alpha}}_i &= \sum_{l=1}^L \left[ \left( x_i^{(l)} - \hat{x}_i \right) \left( \mathbf{x}_{\mathbf{Pa}_i}^{(l)} - \hat{\mathbf{x}}_{\mathbf{Pa}_i} + \hat{\mathbf{x}}_{\mathbf{Pa}_i} \right) \right], \end{aligned} \quad (18.129)$$

$$\frac{1}{L-1} \sum_{l=1}^L \left[ \left( \mathbf{x}_{\mathbf{Pa}_i}^{(l)} - \hat{\mathbf{x}}_{\mathbf{Pa}_i} \right) \left( \mathbf{x}_{\mathbf{Pa}_i}^{(l)T} - \hat{\mathbf{x}}_{\mathbf{Pa}_i}^T \right) \right] \hat{\boldsymbol{\alpha}}_i = \frac{1}{L-1} \sum_{l=1}^L \left[ \left( x_i^{(l)} - \hat{x}_i \right) \left( \mathbf{x}_{\mathbf{Pa}_i}^{(l)} - \hat{\mathbf{x}}_{\mathbf{Pa}_i} \right) \right], \quad (18.131)$$

$$\hat{\mathbf{C}}_{\mathbf{Pa}} \hat{\boldsymbol{\alpha}}_i = \hat{\mathbf{c}}, \quad (18.132)$$

$$\hat{\boldsymbol{\alpha}}_i = \hat{\mathbf{C}}_{\mathbf{Pa}}^{-1} \hat{\mathbf{c}}. \quad (18.133)$$

Here  $\hat{\mathbf{C}}_{\mathbf{Pa}}$  is the estimated covariance matrix of the parent variables, and  $\hat{\mathbf{c}}$  is the estimated covariance vector between parents and the child. In (18.131) we used the fact that  $\sum_{l=1}^L \mathbf{v} \left( \mathbf{x}_{\mathbf{Pa}_i}^{(l)T} - \hat{\mathbf{x}}_{\mathbf{Pa}_i}^T \right) = \mathbf{0}$  and  $\sum_{l=1}^L \left( x_i^{(l)} - \hat{x}_i \right) \mathbf{v} = \mathbf{0}$ , for any vector  $\mathbf{v}$  which does not depend on  $i$ .

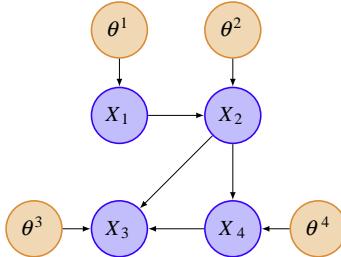

#### 1.18.4.2.2 Bayesian parameter learning

In a Bayesian approach, we do not assume that there exists a single set of “true” parameters, but maintain the uncertainty about the parameters. Therefore, we explicitly include the parameters into the model as in Figure 18.18, where a BN over variables  $X_1, \dots, X_4$  is augmented with their local CPD parameters  $\boldsymbol{\theta}^1, \dots, \boldsymbol{\theta}^4$ . Learning in the Bayesian setting means to perform inference over parameters; in the Bayesian view, there is actually no difference between learning and inference.

Note that there are no edges between any  $\boldsymbol{\theta}^i$  and  $\boldsymbol{\theta}^j$ , which means that we assume parameter independence. This kind of independence is called *global parameter independence* (as opposed to *local parameter independence*, discussed below) [1,13]. Global parameter independence, although reasonable in many cases, does not necessarily hold in every context. However, in the case of global parameter independence any prior over  $\Theta = \{\boldsymbol{\theta}^1, \dots, \boldsymbol{\theta}^N\}$  factorizes according to

$$P(\Theta) = \prod_{i=1}^N P(\boldsymbol{\theta}^i). \quad (18.134)$$

Furthermore, if all model variables  $X_1, \dots, X_N$  are observed, then the local parameters  $\boldsymbol{\theta}^1, \dots, \boldsymbol{\theta}^N$  are pairwise  $d$ -separated, and thus independent. Furthermore, the same is true for multiple i.i.d. samples,

**FIGURE 18.18**

Bayesian network over variables  $X_1, \dots, X_4$ , augmented with local CPD parameters  $\theta^1, \dots, \theta^4$ .

i.e., for complete data sets  $\mathcal{D}$ . In this case, if global (a-priori) parameter independence holds, also a-posteriori parameter independence holds, and the posterior over  $\Theta$  factorizes according to

$$P(\Theta|\mathcal{D}) = \prod_{i=1}^N P(\theta^i|\mathcal{D}). \quad (18.135)$$

Combining (18.135) with (18.107), we obtain the model posterior as

$$P_B(\mathbf{X}, \Theta|\mathcal{D}) = P_B(\mathbf{X}|\Theta)P(\Theta|\mathcal{D}), \quad (18.136)$$

$$= \left( \prod_{i=1}^N P(X_i|\mathbf{Pa}_i, \theta^i) \right) \left( \prod_{i=1}^N P(\theta^i|\mathcal{D}) \right), \quad (18.137)$$

$$= \prod_{i=1}^N P(X_i|\mathbf{Pa}_i, \theta^i)P(\theta^i|\mathcal{D}). \quad (18.138)$$

Since one is usually interested in the data posterior  $P(\mathbf{X}|\mathcal{D})$ , one has to marginalize over  $\Theta$ :

$$P(\mathbf{X}|\mathcal{D}) = \int_{\Theta} P(\mathbf{X}, \Theta|\mathcal{D})d\Theta, \quad (18.139)$$

$$= \int_{\theta^1} \int_{\theta^2} \cdots \int_{\theta^N} \left( \prod_{i=1}^N P(X_i|\mathbf{Pa}_i, \theta^i)P(\theta^i|\mathcal{D}) \right) d\theta^1 d\theta^2 \cdots d\theta^N, \quad (18.140)$$

$$= \prod_{i=1}^N \left( \int_{\theta^i} P(X_i|\mathbf{Pa}_i, \theta^i)P(\theta^i|\mathcal{D})d\theta^i \right). \quad (18.141)$$

The exchange of integrals and products in (18.141) is possible since each term in the product in (18.140) depends only on a single  $\theta^i$ . Hence, under the assumption of global parameter independence and completely observed data, the integral over the entire parameter space in (18.139) factorizes into a product of several simpler integrals (18.141).

**FIGURE 18.19**

Simple Bayesian network containing a single variable  $X$ , augmented with parameters  $\theta$ .

*Bayesian parameter learning for discrete variables:* We now return to the example, where all variables of the BN are discrete. As a basic example, and in order to introduce concepts which are required later, let us consider a simple BN with only a single variable, i.e.,  $N = 1$  and set  $X = X_1$  and  $J = \text{sp}(X)$ . The probability of  $X$  being in state  $j$  is

$$P(X = j|\theta) = \theta_j. \quad (18.142)$$

Figure 18.19 shows the corresponding BN, where  $\theta$  is explicitly included. The parameters can be represented as a vector  $\theta = (\theta_1, \dots, \theta_J)^T$  of RVs, which has to be an element of the standard simplex  $\mathcal{S} = \left\{ \theta \mid \theta_j \geq 0, \forall j, \sum_{j=1}^J \theta_j = 1 \right\}$ . We need to specify a prior distribution over  $\theta$ , where a natural choice is the Dirichlet distribution, defined as

$$\text{Dir}(\theta; \alpha) = \begin{cases} \frac{1}{B(\alpha)} \prod_{j=1}^J \theta_j^{\alpha_j - 1} & \text{if } \theta \in \mathcal{S}, \\ 0 & \text{otherwise.} \end{cases} \quad (18.143)$$

The Dirichlet distribution is parameterized by the vector  $\alpha = (\alpha_1, \dots, \alpha_J)^T$  with  $\alpha_j > 0$  for all  $j$ . The term  $\frac{1}{B(\alpha)}$  is the normalization constant of the distribution, where the *beta-function*  $B(\alpha)$  is given as

$$B(\alpha) = \int_{\mathcal{S}} \prod_{j=1}^J \theta_j^{\alpha_j - 1} d\theta = \frac{\prod_{j=1}^J \Gamma(\alpha_j)}{\Gamma\left(\sum_{j=1}^J \alpha_j\right)}. \quad (18.144)$$

Here  $\Gamma(\cdot)$  is the *gamma function*, i.e., a continuous generalization of the factorial function. In the special case that  $\alpha_j = 1, \forall j$ , the Dirichlet distribution is uniform over all  $\theta \in \mathcal{S}$ .

Assuming a Dirichlet prior over  $\theta$ , the distribution of the BN in Figure 18.19 is given as  $P(X, \theta) = P_B(X|\theta)\text{Dir}(\theta; \alpha)$ . Usually one is interested in the posterior over  $X$ , which is obtained by marginalizing over  $\theta$ :

$$P(X = j') = \int_{\theta} P(X|\theta)\text{Dir}(\theta; \alpha)d\theta, \quad (18.145)$$

$$= \int_{\mathcal{S}} \theta_{j'} \frac{1}{B(\alpha)} \prod_{j=1}^J \theta_j^{\alpha_j - 1} d\theta, \quad (18.146)$$

$$= \frac{1}{B(\boldsymbol{\alpha})} \frac{\Gamma(\alpha_{j'} + 1) \prod_{j \neq j'} \Gamma(\alpha_j)}{\Gamma\left(1 + \sum_{j=1}^J \alpha_j\right)}, \quad (18.147)$$

$$= \frac{B(\boldsymbol{\alpha})}{B(\boldsymbol{\alpha})} \frac{\alpha_{j'}}{\sum_{j=1}^J \alpha_j}, \quad (18.148)$$

$$= \frac{\alpha_{j'}}{\sum_{j=1}^J \alpha_j}. \quad (18.149)$$

The integral in (18.146) can be solved using (18.144), and (18.148) follows from the properties of the gamma function. We see that (18.148) has the form of relative frequency counts, exactly as the ML estimator in (18.122). Thus, the Dirichlet parameters  $\boldsymbol{\alpha}$  gain the interpretation of a-priori pseudo-data-counts, which represent our belief about  $\boldsymbol{\theta}$ . Now assume that we have an i.i.d. sample  $\mathcal{D} = (x^{(1)}, \dots, x^{(L)})$  of variable  $X$ . Learning in the Bayesian framework means to incorporate the information given by  $\mathcal{D}$ , i.e., to modify our belief about  $\boldsymbol{\theta}$ . Formally, we want to obtain the posterior distribution over  $\boldsymbol{\theta}$ :

$$P(\boldsymbol{\theta}|\mathcal{D}) \propto P(\mathcal{D}|\boldsymbol{\theta})P(\boldsymbol{\theta}) = \left( \prod_{l=1}^L P(x^{(l)}|\boldsymbol{\theta}) \right) \text{Dir}(\boldsymbol{\theta}; \boldsymbol{\alpha}), \quad (18.150)$$

$$= \left( \prod_{l=1}^L \prod_{j=1}^J \theta_j^{u_j^l} \right) \left( \frac{1}{B(\boldsymbol{\alpha})} \prod_{j=1}^J \theta_j^{\alpha_j - 1} \right), \quad (18.151)$$

$$= \frac{1}{B(\boldsymbol{\alpha})} \prod_{j=1}^J \theta_j^{n_j + \alpha_j - 1}, \quad (18.152)$$

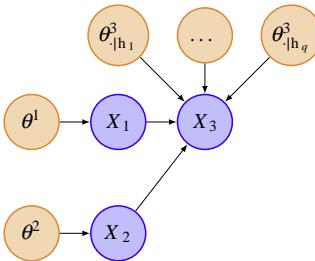

where  $u_j^l = \mathbb{1}_{\{x^{(l)}=j\}}$  and  $n_j = \sum_{l=1}^L u_j^l$ . Note that (18.152) has again the functional form of a Dirichlet distribution, although not correctly normalized. Hence, we can conclude that the posterior  $P(\boldsymbol{\theta}|\mathcal{D})$  is also a Dirichlet distribution. After normalizing, we obtain

$$P(\boldsymbol{\theta}|\mathcal{D}) = \text{Dir}(\boldsymbol{\theta}; \boldsymbol{\alpha} + \mathbf{n}), \quad (18.153)$$

where  $\mathbf{n} = (n_1, n_2, \dots, n_J)^T$ . The property that the posterior is from the same family of distributions as the prior, comes from the fact that the Dirichlet distribution is a so-called *conjugate prior* [4] for the discrete distribution. The intuitive interpretation of (18.153) is that the distribution over  $\boldsymbol{\theta}$  is updated by adding the real data counts  $\mathbf{n}$  to our a-priori pseudo-counts  $\boldsymbol{\alpha}$ . Replacing the prior  $P(\boldsymbol{\theta})$  with the posterior  $P(\boldsymbol{\theta}|\mathcal{D})$  in 18.145–18.148 yields

$$P(X = j'|\mathcal{D}) = \frac{\alpha_{j'} + n'_j}{\sum_{j=1}^J (\alpha_j + n_j)}. \quad (18.154)$$

Now we extend the discussion to general BNs. First, we interpret the CPD parameters  $\boldsymbol{\Theta} = \{\boldsymbol{\theta}^1, \boldsymbol{\theta}^2, \dots, \boldsymbol{\theta}^N\}$  as RVs, i.e., we define a prior  $P(\boldsymbol{\Theta})$ . We assume global parameter independence,

**FIGURE 18.20**

Bayesian network over variables  $X_1, X_2, X_3, X_4$ .

such that the prior takes the form  $P(\Theta) = \prod_{i=1}^N P(\theta^i)$ . Note that  $\theta^i$  can be interpreted as a matrix of RVs, containing one column  $\theta_{\cdot|\mathbf{h}}^i$  for each possible assignment  $\mathbf{h}$  of the parent variables  $\mathbf{Pa}_i$ . We can additionally assume that the columns of  $\theta^i$  are a-priori independent, i.e., that the prior over  $\theta^i$  factorizes as

$$P(\theta^i) = \prod_{\mathbf{h} \in \text{val}(\mathbf{Pa}_i)} P(\theta_{\cdot|\mathbf{h}}^i). \quad (18.155)$$

This independence assumption is called *local parameter independence*, as in contrast to global parameter independence [1, 13]. Similar, as global parameter independence, local parameter independence is often a reasonable assumption, but has to be considered with care. For a specific assignment  $\mathbf{h}$ , the vector  $\theta_{\cdot|\mathbf{h}}^i = (\theta_{1|\mathbf{h}}^i, \dots, \theta_{\text{sp}(X_i)|\mathbf{h}}^i)^T$  represents a single (conditional) discrete distribution over  $X_i$ . As in the basic example with only one variable, we can assume a Dirichlet prior for  $\theta_{\cdot|\mathbf{h}}^i$ , each with its own parameters  $\alpha_{\mathbf{h}}^i = (\alpha_{1|\mathbf{h}}^i, \dots, \alpha_{\text{sp}(X_i)|\mathbf{h}}^i)$ . Together with the assumption of global and local parameter independence, the prior over the whole parameter set  $\Theta$  is then given as

$$P(\Theta) = \prod_{i=1}^N \prod_{\mathbf{h}} \text{Dir}(\theta_{\cdot|\mathbf{h}}^i; \alpha_{\mathbf{h}}^i). \quad (18.156)$$

For global parameter independence, we observed that the parameters  $\theta^1, \dots, \theta^N$  remain independent, when conditioned on a completely observed data set (cf. (18.134) and (18.135)) since the parameters are  $d$ -separated by the observed nodes  $X_1, \dots, X_N$ . For local parameter independence, it does not happen that any two sets of parameters  $\theta_{\cdot|\mathbf{h}}^i$  and  $\theta_{\cdot|\mathbf{h}'}^j$ ,  $\mathbf{h} \neq \mathbf{h}'$ , are  $d$ -separated.

**Example 22.** Consider Figure 18.20 and let  $q = \text{sp}(X_1)\text{sp}(X_2)$  be the total number of parent configurations for node  $X_3$ . The parameter sets  $\theta_{\cdot|\mathbf{h}_1}^3, \dots, \theta_{\cdot|\mathbf{h}_q}^3$  are not  $d$ -separated, since  $X_3$  is observed.

However, note that  $d$ -separation is sufficient for conditional independence, but not necessary. This means that even if two sets of nodes are not  $d$ -separated, they still can turn out to be independent. Fortunately, this is the case here. To see this, assume that local (a-priori) parameter independence holds, and that all nodes  $X_1, \dots, X_N$  are observed. For some arbitrary node  $X_i$ , the posterior parameter distribution is

given as

$$P(\boldsymbol{\theta}^i | \mathbf{X}) = P(\boldsymbol{\theta}^i | X_i, \mathbf{Pa}_i) = \frac{P(X_i | \boldsymbol{\theta}^i, \mathbf{Pa}_i) P(\boldsymbol{\theta}^i | \mathbf{Pa}_i)}{P(X_i | \mathbf{Pa}_i)}, \quad (18.157)$$

$$= \frac{P(X_i | \boldsymbol{\theta}_{\cdot|\mathbf{Pa}_i}^i, \mathbf{Pa}_i) \prod_{\mathbf{h}} P(\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i)}{P(X_i | \mathbf{Pa}_i)}, \quad (18.158)$$

$$= \frac{\prod_{\mathbf{h}} f(\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i, \mathbf{X})}{P(X_i | \mathbf{Pa}_i)}, \quad (18.159)$$

where

$$f(\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i, \mathbf{X}) = \begin{cases} P(X_i | \boldsymbol{\theta}_{\cdot|\mathbf{h}}^i, \mathbf{Pa}_i) P(\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i) & \text{if } \mathbf{h} = \mathbf{Pa}_i, \text{ and} \\ P(\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i) & \text{otherwise.} \end{cases} \quad (18.160)$$

We see that the posterior parameter distribution factorizes over the parent configurations, i.e., that the parameters  $\boldsymbol{\theta}_{\cdot|\mathbf{h}_1}^i, \dots, \boldsymbol{\theta}_{\cdot|\mathbf{h}_q}^i, q = \text{sp}(\mathbf{Pa}_i)$ , remain independent when conditioned on  $\mathbf{X}$ . This conclusion comes from two observations in (18.158): (i) All  $\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i$  except  $\boldsymbol{\theta}_{\cdot|\mathbf{Pa}_i}^i$  are independent from  $X_i$ , when  $\mathbf{Pa}_i$  is given, and (ii)  $\boldsymbol{\theta}^i$  is a-priori independent from  $\mathbf{Pa}_i$ .

Furthermore, local a-posteriori parameter independence also holds for multiple observed i.i.d. samples  $\mathcal{D}$ , i.e.,

$$P(\boldsymbol{\theta}^i | \mathcal{D}) = \prod_{\mathbf{h}} P(\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i | \mathcal{D}). \quad (18.161)$$

Since we assumed Dirichlet priors, which are conjugate priors for discrete distributions, the posterior over  $\boldsymbol{\theta}^i$  takes the form (cf. (18.153)),

$$P(\boldsymbol{\theta}^i | \mathcal{D}) = \prod_{\mathbf{h}} \text{Dir}\left(\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i | \boldsymbol{\alpha}_{\mathbf{h}}^i + \mathbf{n}_{\mathbf{h}}^i\right), \quad (18.162)$$

where  $\mathbf{n}_{\mathbf{h}}^i = (n_{1|\mathbf{h}}^i, n_{2|\mathbf{h}}^i, \dots, n_{\text{sp}(X_i)|\mathbf{h}}^i)^T$ , and  $n_{j|\mathbf{h}}^i = \sum_{l=1}^L u_{j|\mathbf{h}}^{i,l}$ . This result can now be applied to (18.141), where we showed (under the assumption of global parameter independence), that

$$P(\mathbf{X} | \mathcal{D}) = \prod_{i=1}^N \left( \int_{\boldsymbol{\theta}^i} P(X_i | \mathbf{Pa}_i, \boldsymbol{\theta}^i) P(\boldsymbol{\theta}^i | \mathcal{D}) d\boldsymbol{\theta}^i \right). \quad (18.163)$$

Inserting (18.162) in (18.163), we obtain

$$P(\mathbf{X} = \mathbf{x} | \mathcal{D}) = \prod_{i=1}^N \left( \int_{\boldsymbol{\theta}^i} \left( \prod_{j=1}^{\text{sp}(X_i)} \prod_{\mathbf{h}} \theta_{j|\mathbf{h}}^i u_{j|\mathbf{h}}^i \right) \left( \prod_{\mathbf{h}} \text{Dir}(\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i | \boldsymbol{\alpha}_{\mathbf{h}}^i + \mathbf{n}_{\mathbf{h}}^i) \right) d\boldsymbol{\theta}^i \right), \quad (18.164)$$

$$= \prod_{i=1}^N \left( \int_{\boldsymbol{\theta}^i} \prod_{\mathbf{h}} \left[ \left( \prod_{j=1}^{\text{sp}(X_i)} \theta_{j|\mathbf{h}}^i u_{j|\mathbf{h}}^i \right) \text{Dir}(\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i | \boldsymbol{\alpha}_{\mathbf{h}}^i + \mathbf{n}_{\mathbf{h}}^i) \right] d\boldsymbol{\theta}^i \right), \quad (18.165)$$

$$= \prod_{i=1}^N \left( \int_{\boldsymbol{\theta}_{\cdot|\mathbf{h}_1}^i} \cdots \int_{\boldsymbol{\theta}_{\cdot|\mathbf{h}_{q_i}}^i} \prod_{\mathbf{h}} \left[ \left( \prod_{j=1}^{\text{sp}(X_i)} \theta_{j|\mathbf{h}}^i u_{j|\mathbf{h}}^i \right) \text{Dir}(\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i | \boldsymbol{\alpha}_{\mathbf{h}}^i + \mathbf{n}_{\mathbf{h}}^i) \right] d\boldsymbol{\theta}_{\cdot|\mathbf{h}_1}^i \cdots d\boldsymbol{\theta}_{\cdot|\mathbf{h}_{q_i}}^i \right), \quad (18.166)$$

$$= \prod_{i=1}^N \prod_{\mathbf{h}} \left( \int_{\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i} \left( \prod_{j=1}^{\text{sp}(X_i)} \theta_{j|\mathbf{h}}^i u_{j|\mathbf{h}}^i \right) \text{Dir}(\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i | \boldsymbol{\alpha}_{\mathbf{h}}^i + \mathbf{n}_{\mathbf{h}}^i) d\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i \right), \quad (18.167)$$

where  $q_i = \text{sp}(\mathbf{Pa}_i)$ . The integration over the entire parameter space factorizes into a product of many simpler integrals. Each integral in (18.167) has the same form as in (18.145) and is given as

$$\int_{\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i} \left( \prod_{j=1}^{\text{sp}(X_i)} \theta_{j|\mathbf{h}}^i u_{j|\mathbf{h}}^i \right) \text{Dir}(\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i | \boldsymbol{\alpha}_{\mathbf{h}}^i + \mathbf{n}_{\mathbf{h}}^i) d\boldsymbol{\theta}_{\cdot|\mathbf{h}}^i = \begin{cases} \frac{\alpha_{x_i|\mathbf{h}}^i + n_{x_i|\mathbf{h}}^i}{\sum_{j=1}^{\text{sp}(X_i)} (\alpha_{j|\mathbf{h}}^i + n_{j|\mathbf{h}}^i)} & \text{if } \mathbf{h} = \mathbf{x}_{\mathbf{Pa}_i}, \\ 1 & \text{otherwise.} \end{cases} \quad (18.168)$$

Therefore, under the assumptions of global and local parameter independence and using Dirichlet parameter priors, the Bayesian approach is feasible for BNs with discrete variables and reduces to a product over closed-form integrations. This result can be seen as the Bayesian analog to (18.115), where we showed that the BN likelihood is maximized by solving many independent closed-form ML problems.

#### 1.18.4.2.3 Learning the structure of Bayesian networks

So far we have discussed parameter learning techniques for BNs, i.e., we assumed that the BN structure  $\mathcal{G}$  is fixed and learned the parameters  $\boldsymbol{\Theta}$ . The goal is now to also learn the structure  $\mathcal{G}$  from data, where we restrict the discussion to discrete variables from now on. Generally there are two main approaches to structure learning:

- i. *Constraint-based approach:* In this approach, we aim to find a structure  $\mathcal{G}$  which represents the same conditional independencies as present in the data. While being theoretically sound, these methods heavily rely on statistical independence tests performed on the data, which might be inaccurate and usually render the approach unsuitable in practise. Therefore, we do not discuss constraint-based approaches here, but refer the interested reader to [1, 14, 15], and references therein.

- ii. *Scoring-based approach:* Here we aim to find a graph which represents a “suitable” distribution to represent the true distribution  $P^*(\mathbf{X})$ , where “suitability” is measured by a scoring function score  $\mathcal{G}$ . There are two key issues here: Defining an appropriate scoring function, and developing a search algorithm which finds a score-maximizing structure  $\mathcal{G}$ .

A natural choice for the scoring function would be the log-likelihood, i.e., the aim to maximize  $\log \mathcal{L}(\mathcal{B}; \mathcal{D}) = \log \mathcal{L}(\mathcal{G}, \Theta; \mathcal{D})$ , w.r.t.  $\mathcal{G}$  and  $\Theta$ . Using the ML parameter estimates  $\hat{\Theta}$  from Section 1.18.4.2.1, this problem reduces to maximize

$$\log \mathcal{L}(\mathcal{G}, \hat{\Theta}; \mathcal{D}) = \sum_{l=1}^L \log P(\mathbf{X} = \mathbf{x}^{(l)} | \mathcal{G}, \hat{\Theta}), \quad (18.169)$$

w.r.t.  $\mathcal{G}$ . However, the likelihood score in (18.169) is in general not suitable for structure learning. When  $\mathcal{G}$  is a subgraph of  $\mathcal{G}'$ , it is easy to show that a BN defined over  $\mathcal{G}'$  contains all distributions which can also be represented by a BN defined over  $\mathcal{G}$ . Consequently, the supergraph  $\mathcal{G}'$  will always have at least the same likelihood-score as  $\mathcal{G}$ , and furthermore, any fully connected graph will also be a maximizer of (18.169). We see that likelihood prefers more complex models and leads to overfitting. Note that overfitting stems from using a too flexible model class for a finite data set, and that the flexibility of a model is reflected by the number of free parameters. The number of parameters  $T(\mathcal{G})$  in a BN is given as

$$T(\mathcal{G}) = \sum_{i=1}^N (\mathbf{sp}(X_i) - 1)(\mathbf{sp}(\mathbf{Pa}_{\mathcal{G}}(X_i))), \quad (18.170)$$

which grows exponentially with the maximal number of parents. The likelihood-score merely aims to fit the training data, but is blind to model complexity.

As a remedy, we can modify the pure likelihood-score in order to account for model complexity. One way delivers the minimum description length (MDL) principle [16], which aims to find the shortest, most compact representation of the data  $\mathcal{D}$ . As discussed in Section 1.18.4.1, maximizing likelihood is equivalent to minimizing  $\text{KL}(P_{\mathcal{D}} || P(\cdot | \mathcal{C}))$ , i.e., the KL divergence between the empirical data distribution and the model distribution. The KL divergence measures the average coding overhead for encoding the data  $\mathcal{D}$  using  $P(\mathbf{X} | \mathcal{C})$  instead of  $P_{\mathcal{D}}(\mathbf{X})$ . The MDL principle additionally accounts for the description length of the model, which is measured by the number of parameters. For BNs with discrete variables, the following MDL score was derived [17, 18]:

$$\text{MDL}(\mathcal{G}) = - \sum_{l=1}^L \log P(\mathbf{x}^{(l)} | \mathcal{G}, \Theta_{\text{ML}}) + \frac{\log L}{2} T(\mathcal{G}), \quad (18.171)$$

which is a negative score, since we aim to find a graph  $\mathcal{G}$  minimizing  $\text{MDL}(\mathcal{G})$ . The MDL score is simply the negative likelihood score (18.169), plus a penalization term for the number of parameters. In typical applications, the likelihood decreases linearly with  $L$ , while the penalization term in (18.171) grows logarithmically. Therefore, for large  $L$ , the likelihood dominates the penalization term and the MDL score becomes equivalent to likelihood. However, when  $L$  is small, then the penalization term significantly influences (18.171), resulting in a preference for BNs with fewer parameters.

An alternative way to avoid overfitting is delivered by a Bayesian approach. The main problem with the likelihood score (18.169) is that it is not aware of model complexity, i.e., the number of free parameters. While with more densely connected graphs  $\mathcal{G}$  the dimensionality of the parameter space  $\Theta$  increases exponentially, nevertheless only a single point estimate is used from this space, i.e., the ML parameters  $\Theta_{\text{ML}}$ . Therefore, the ML approach can be described as overly optimistic, trusting in the single “true” parameters  $\Theta_{\text{ML}}$ . In contrast to the ML approach, the Bayesian approach (cf. Section 1.18.4.2.2) uses the parameter space in its entirety. We introduce a prior distribution  $P(\Theta)$  over the parameters, and marginalize over  $\Theta$ , leading to the Bayesian score

$$\text{Bayes}(\mathcal{G}) = P(\mathcal{D}|\mathcal{G}) = \int_{\Theta} P(\mathcal{D}|\Theta, \mathcal{G}) P(\Theta) d\Theta, \quad (18.172)$$

$$= \int_{\Theta} \prod_{l=1}^L P(\mathbf{x}^{(l)}|\Theta, \mathcal{G}) P(\Theta) d\Theta. \quad (18.173)$$

We see that this score actually represents a semi-Bayesian approach: While being Bayesian about  $\Theta$ , we still follow the ML principle for the structure  $\mathcal{G}$ . A Bayesian approach, which requires approximation techniques, is provided in [19]. Assuming global and local parameter independence, and using Dirichlet priors for the local parameters (cf. Section 1.18.4.2.2) leads to the Bayesian-Dirichlet score (BD) [20, 21]

$$\text{BD}(\mathcal{G}) = \int_{\Theta} \left( \prod_{l=1}^L \prod_{i=1}^N \prod_{j=1}^{\text{sp}(X_i)} \prod_{\mathbf{h}} \theta_{j|\mathbf{h}}^i u_{j|\mathbf{h}}^{i,l} \right) \left( \prod_{i=1}^N \prod_{\mathbf{h}} \frac{1}{B(\boldsymbol{\alpha}_{\mathbf{h}}^i)} \prod_{j=1}^{\text{sp}(X_i)} \theta_{j|\mathbf{h}}^i \alpha_{j|\mathbf{h}}^{i-1} \right) d\Theta, \quad (18.174)$$

$$= \int_{\Theta} \prod_{i=1}^N \prod_{\mathbf{h}} \frac{1}{B(\boldsymbol{\alpha}_{\mathbf{h}}^i)} \prod_{j=1}^{\text{sp}(X_i)} \theta_{j|\mathbf{h}}^i \alpha_{j|\mathbf{h}}^{i-1} n_{j|\mathbf{h}}^{i-1} d\Theta, \quad (18.175)$$

$$= \prod_{i=1}^N \prod_{\mathbf{h}} \frac{1}{B(\boldsymbol{\alpha}_{\mathbf{h}}^i)} \left( \int_{\theta_{|\mathbf{h}}^i}^{\infty} \prod_{j=1}^{\text{sp}(X_i)} \theta_{j|\mathbf{h}}^i \alpha_{j|\mathbf{h}}^{i-1} n_{j|\mathbf{h}}^{i-1} d\theta_{|\mathbf{h}}^i \right), \quad (18.176)$$

$$= \prod_{i=1}^N \prod_{\mathbf{h}} \frac{B(\boldsymbol{\alpha}_{\mathbf{h}}^i + \mathbf{n}_{\mathbf{h}}^i)}{B(\boldsymbol{\alpha}_{\mathbf{h}}^i)}, \quad (18.177)$$

$$= \prod_{i=1}^N \prod_{\mathbf{h}} \frac{\Gamma\left(\sum_{j=1}^{\text{sp}(X_i)} \alpha_{j|\mathbf{h}}^i\right)}{\Gamma\left(\sum_{j=1}^{\text{sp}(X_i)} \alpha_{j|\mathbf{h}}^i + n_{j|\mathbf{h}}^i\right)} \prod_{j=1}^{\text{sp}(X_i)} \frac{\Gamma\left(\alpha_{j|\mathbf{h}}^i + n_{j|\mathbf{h}}^i\right)}{\Gamma\left(\alpha_{j|\mathbf{h}}^i\right)}. \quad (18.178)$$

In (18.176) we can interchange integrals with products, since each term only depends on a single  $\theta_{|\mathbf{h}}^i$ . The solution of the integrals is given in (18.144). Heckerman et al. [13] pointed out that the parameters  $\boldsymbol{\alpha}_{\mathbf{h}}^i$  can not be chosen arbitrarily, when one desires a consistent, likelihood-equivalent score, meaning that the same score is assigned for two networks representing the same set of independence assumptions. They show how such parameters can be constructed, leading to the likelihood-equivalent Bayesian-Dirichlet

score (BDe). A simple choice for  $\alpha_{\mathbf{h}}^i$ , already proposed in [20], is

$$\alpha_{j|\mathbf{h}}^i = \frac{A}{\mathbf{sp}(X_i)\mathbf{sp}(\mathbf{Pa}_{\mathcal{G}}(X_i))}, \quad (18.179)$$

where  $A$  is the equivalent sample size, i.e., the number of virtual a-priori samples (a typical value would be  $A = 1$ ). These parameters result from the a-priori assumption of an uniform distribution over the state space of  $\mathbf{X}$ . Consequently, the BDe score using parameters according (18.179) is called BDe uniform score (BDeu).

Furthermore, there is a connection between the BD score and the MDL score: It can be shown [1], that for  $L \rightarrow \infty$ , the logarithm of the BD score converges to the so-called Bayesian information criterion score (BIC)

$$\text{BIC}(\mathcal{G}) = \sum_{l=1}^L \log P(\mathbf{x}^{(l)}|\mathcal{G}, \Theta_{\text{ML}}) - \frac{\log N}{2} T(\mathcal{G}) + \text{const.}, \quad (18.180)$$

which is the negative MDL score (18.171), up to some constant. Thus, although derived from two different perspectives, the MDL score and the BIC score are equivalent.

We now turn to the problem of finding a graph  $\mathcal{G}$  which maximizes a particular score. All the scores discussed so far, namely log-likelihood (18.169), MDL (18.171) and BIC (18.180), and (the logarithm of) the BD/BDe score (18.178) can be written in the form

$$\text{score}(\mathcal{G}) = \sum_{i=1}^N \text{score}_i(X_i, \mathbf{Pa}_{\mathcal{G}}(X_i)), \quad (18.181)$$

which means that the global network score decomposes into a sum of local scores, depending only on the individual variables and their parents. This property is very important to find efficient structure learning algorithms. For example, if an algorithm decides to add a parent to some variable  $X_i$ , then the overall score is affected only via the the change of a single additive term. Therefore, decomposability of the scoring function alleviates the problem of finding a score-maximizing graph  $\mathcal{G}$ . Unfortunately, even for decomposable scores the problem of finding a score-maximizing BN structure  $\mathcal{G}$  is NP-hard in general, even if the maximum number of parents is restricted to  $K \geq 2$  [22,23]. For  $K = 1$ , i.e., when the BN is constrained to be a directed tree, the Chow-Liu algorithm [24] learns the optimal network structure in polynomial time. Here the structure learning problem is reduced to a maximum spanning tree problem, where the edge weights are given by mutual information estimates. It is shown [24] that this is equivalent to maximizing the log-likelihood over the class of BNs with a directed tree structure. The class of directed trees is typically restrictive enough to avoid overfitting, i.e., the likelihood score is an appropriate choice in this case.

For learning more complicated structures, there exist a large variety of approximative techniques. One of the first general search algorithms was the K2 algorithm [21] which relies on an initial variable ordering, and greedily adds parents for each node, in order to increase the BD score. A more general scheme is hill-climbing (HC) [13,25], which does not rely on an initial variable ordering. HC starts with an unconnected graph  $\mathcal{G}$ . In each iteration, the current graph  $\mathcal{G}$  is replaced with a neighboring graph  $\mathcal{G}'$  with maximal score, if  $\text{score}(\mathcal{G}') > \text{score}(\mathcal{G})$ . Neighboring graphs are those graphs which

can be created from the current graph by single edge-insertions, edge-deletions and edge-reversals, maintaining acyclicity constraints. When no neighboring graph has higher score than the current graph, the algorithm stops. HC greedily increases the score, and will typically terminate in a local maximum. HC can be combined with tabu-search [26] in order to escape local maxima: When the algorithm is trapped in a local maximum, then the last several iterations leading to the local maximum are reverted and marked as forbidden. In this way, the algorithm is forced to use alternative iterations, possibly leading to a better local maximum. A related method is simulated annealing (SA) which randomly generates a neighbor solution in each step. If the new solution has higher score than the current one, it is immediately accepted. However, also a solution with lower score is accepted with a certain probability. While this probability is high in the beginning, leading to a large exploration over the search space, it is successively reduced according to a cooling schedule. At the end of the search process, SA only accepts score-increasing solutions. [25] applied SA for BN structure learning. While these heuristic methods perform a greedy search in the space of all DAGs, [27] proposed to greedily search over the space of equivalence classes. An equivalence class contains all BN structures which represent the same set of independence assumptions. A related approach can be found in [28], which proposes to perform a search over possible variable orderings. This approach uses the fact, as already mentioned in [21], that for a given variable ordering the optimal structure can be found in polynomial time.

Recently, several exact approaches for finding globally optimal structures have been proposed. Methods based on dynamic programming [29–31] have exponential time and memory requirements, which restricts their application to approximately 30 variables. Furthermore, there are branch-and-bound methods [32–34] which cast the combinatorial structure learning problem to a relaxed continuous problem. The relaxed continuous problem is successively divided (branched) into sub-problems, until the solutions of the relaxed sub-problems coincide with feasible structures, i.e., DAGs. The scores of the relaxed solutions provide an upper bound of the achievable score, and each feasible solution provides a lower bound of this score. Branches whose upper bound is lower than the currently best lower bound can consequently be pruned. Although branch-and-bound methods also have an exponential runtime, they provide two key advantages: (i) They maintain (after some initial time) a feasible solution, i.e., they can be prematurely terminated, returning the currently best solution. Methods based on dynamic programming do not offer this possibility; (ii) They provide upper and lower bounds on the maximal score, which represents a worst-case certificate of sub-optimality.

### 1.18.4.3 Discriminative learning in Bayesian networks

So far, we discussed generative learning of BNs, aiming to retrieve the underlying true distribution  $P^*(\mathbf{X})$  from a sample  $\mathcal{D} = (\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(L)})$ . Now, let us assume that our final goal is classification, i.e., we aim to predict the value of a class variable  $C \in \mathbf{X}$ , given the values of the features  $\mathbf{Z} = \mathbf{X} \setminus \{C\}$ . Without loss of generality, we can assume that  $C$  is  $X_1$ , and we renumber the remaining variables, such that  $\mathbf{X} = \{C, \mathbf{Z}\} = \{C, X_1, X_2, \dots, X_{N-1}\}$ . In classification, we are interested in finding a decision function  $f(\mathbf{Z})$ , which can take values in  $\{1, \dots, \text{sp}(C)\}$ , such that the expected classification rate

$$\text{CR}(f) = \mathbb{E}_{P^*}[\mathbf{1}_{\{f(\mathbf{z})=c\}}] \quad (18.182)$$

$$= \sum_{\{c, \mathbf{z}\} \in \text{val}(\{C, \mathbf{Z}\})} P^*(c, \mathbf{z}) \mathbf{1}_{\{f(\mathbf{z})=c\}} \quad (18.183)$$

is maximized. It is easily shown that a function  $f^*(\mathbf{Z})$  maximizing (18.182) is given by [35]

$$f^*(\mathbf{Z}) = \arg \max_{c \in \text{val}(\mathcal{C})} P^*(c|\mathbf{Z}) = \arg \max_{c \in \text{val}(\mathcal{C})} P^*(c, \mathbf{Z}). \quad (18.184)$$

Therefore, since the generative approach aims to retrieve  $P^*(\mathbf{X})$ , we are in principle able to learn an optimal classifier, when (i) we use a sufficiently expressive model, (ii) we have a sufficient amount of training data, and (iii) we train the model using a generative approach, such as ML. Classifiers trained this way are called *generative classifiers*. Generative classifiers are amenable to interpretation and for incorporating prior information, and are flexible to versatile inference scenarios. However, we rarely have sufficient training data, and typically we restrict the model complexity, partly to avoid overfitting (which occurs due to a lack of training data), partly due to computational reasons. Therefore, although theoretically sound, generative classifiers usually do not yield the best classification results.

Discriminative approaches, on the other hand, directly represent aspects of the model which are important for classification accuracy. For example, some approaches model the class posterior probability  $P(C|\mathbf{Z})$ , while others, such as support vector machines (SVMs) [36, 37] or neural networks [4, 38], model information about the decision function, without using a probabilistic model. In each case, a discriminative objective does not necessarily agree with accurate joint distribution estimates, but rather aims for a low classification error on the training data. Discriminative models are usually restricted to the mapping from observed input features  $\mathbf{Z}$  to the unknown class output variable  $C$ , while inference of  $\mathbf{Z}$  for given  $C$  is impossible or unreasonable. There are several reasons for using discriminative rather than generative classifiers, one of which is that the classification problem should be solved most simply and directly, and never via a more general problem such as the intermediate step of estimating the joint distribution [39]. Discriminative classifiers typically lead to better classification performance, particularly when the class conditional distributions poorly approximate the true distribution [4]. The superior performance of discriminative classifiers has been reported in many application domains.

When using PGMs for classification, both parameters and structure can be learned using either generative or discriminative objectives [40]. In the generative approach, the central object is the parameter posterior  $P(\Theta|\mathcal{D})$ , yielding the MAP, ML and the Bayesian approach. In the discriminative approach, we use alternative objective functions such as conditional log-likelihood (CLL), classification rate (CR), or margin, which can be applied for both structure learning and for parameter learning. Unfortunately, while essentially all generative scores (likelihood, MDL/BIC, BDe) decompose into a sum over the nodes, it turns out that this does not happen for discriminative scores. Therefore, although many of the structure learning algorithms discussed for the generative case can also be applied for discriminative scores, the problem becomes computationally more expensive in the discriminative case. We restrict our discussion to BN, since most of the literature for discriminative learning is concerned about this type of PGMs.

*Conditional log-likelihood (CLL):* The log-likelihood over a model class  $\mathcal{C}$  can be written as

$$\log \mathcal{L}(\mathcal{C}; \mathcal{D}) = \sum_{l=1}^L \log P(\mathbf{x}^{(l)}|\mathcal{C}), \quad (18.185)$$

$$= \sum_{l=1}^L \log P(\mathbf{c}^{(l)}|\mathbf{z}^{(l)}, \mathcal{C}) + \sum_{l=1}^L \log P(\mathbf{z}^{(l)}|\mathcal{C}), \quad (18.186)$$

$$= \text{CLL}(\mathcal{C}; \mathcal{D}) + \log \mathcal{L}(\mathcal{C}; \mathcal{D}_{\mathbf{Z}}), \quad (18.187)$$

where the log-likelihood decomposes into two terms. The term  $\log \mathcal{L}(\mathcal{C}; \mathcal{D}_{\mathbf{Z}})$  is the log-likelihood of the attributes  $\mathbf{Z}$ , where the data set  $\mathcal{D}_{\mathbf{Z}}$  contains only the samples of the features  $\mathbf{Z}$ , without the values of  $C$ . The term  $\text{CLL}(\mathcal{C}; \mathcal{D})$  is called *conditional log-likelihood*, which is the log-likelihood of the class variable  $C$ , conditioned on the respective values of  $\mathbf{Z}$ . While  $\text{CLL}(\mathcal{C}; \mathcal{D})$  reflects how well some model  $M \in \mathcal{C}$  fits the empirical conditional distribution  $P_{\mathcal{D}}(C|\mathbf{Z})$ , the term  $\mathcal{L}(\mathcal{C}; \mathcal{D}_{\mathbf{Z}})$  measures the fitness of  $M$  to represent the empirical distribution over the features  $P_{\mathcal{D}_{\mathbf{Z}}}(\mathbf{Z})$ . For discriminative learning, we are primarily interested in optimizing  $\text{CLL}(\mathcal{C}; \mathcal{D})$ , but not  $\mathcal{L}(\mathcal{C}; \mathcal{D}_{\mathbf{Z}})$ . Therefore, for discriminative learning we discard the second term in (18.187) and maximize the conditional likelihood:

$$\text{CLL}(\mathcal{C}; \mathcal{D}) = \sum_{l=1}^L \left[ \log P(c^{(l)}, \mathbf{z}^{(l)} | \mathcal{C}) - \log \sum_{c=1}^{|C|} P(c, \mathbf{z}^{(l)} | \mathcal{C}) \right]. \quad (18.188)$$

Suppose we found a model  $M^*$  maximizing the CLL, and we wish to classify a new sample  $\mathbf{z}$ . The decision function according to  $M^*$  is then

$$f_{M^*}(\mathbf{z}) = \arg \max_{c \in \text{val}(C)} P(c | \mathbf{z}, M^*). \quad (18.189)$$

However, although CLL is connected with classification rate, maximizing CLL is not the same as maximizing the classification rate on the training set. Friedman [41] shows that improving CLL even can be obstructive for classification. This can be understood in a wider context, when our goal is not to maximize the number of correct classifications, but to make an optimal decision based on the classification result. As an example given in [4], assume a system which classifies if a patient has a lethal disease, based on some medical measurements. There are 4 different combinations of the state of the patient and the system diagnosis, which have very different consequences: the scenario that a healthy patient is diagnosed as ill is not as disastrous as the scenario when an ill patient is diagnosed as healthy. For such a system it is not enough to return a 0/1-decision, but additionally a value of confidence has to be provided. These requirements are naturally met by maximum CLL learning. Generally, one can define a loss-function  $L(k, l)$  which represents the assumed loss when a sample with class  $c = k$  is classified as  $c = l$ . Maximizing CLL is tightly connected with minimizing the expected loss for a loss-function  $L(k, l)$  satisfying  $L(k, k) = 0$ , and  $L(k, l) \geq 0, k \neq l$ .

In [42], an algorithm for learning the BN parameters for a fixed structure  $\mathcal{G}$  was proposed. This algorithm uses gradient ascend to increase the CLL, while maintaining parameter feasibility, i.e., non-negativity and sum-to-one constraints. Although CLL is a concave function, these constraints are non-convex, such that the algorithm generally finds only a local maximum of the CLL. However, in [43, 44] it is shown that for certain network structures the parameter constraints can be neglected, yielding a convex optimization problem and thus a globally optimal solution. More precisely, the network structure  $\mathcal{G}$  has to fulfill the condition:

$$\forall Z \in \mathbf{Ch}_{\mathcal{G}}(C) : \exists X \in \mathbf{Pa}_{\mathcal{G}}(Z) : \mathbf{Pa}_{\mathcal{G}}(Z) \subseteq \mathbf{Pa}_{\mathcal{G}}(X) \cup \{X\}. \quad (18.190)$$

In words, every class child  $Z_i$  must have a parent  $X$ , which together with its own parents  $\mathbf{Pa}_{\mathcal{G}}(X)$  contain all parents  $\mathbf{Pa}_{\mathcal{G}}(Z_i)$ . It is shown that for structures fulfilling this condition, always a correctly

normalized BN with the same CLL objective value as for the unconstrained solution can be found. This implies that the obtained BN parameters globally maximize the CLL. In [45], a greedy hill-climbing algorithm for BN structure learning is proposed using CLL as scoring function.

*Empirical classification rate (CR):* Often one is interested in the special case of 0/1-loss, where each correctly classified sample has loss 0, while each misclassified sample causes a loss of 1. As pointed out in [41], maximum CLL training does not directly correspond to optimal 0/1-loss. An objective directly reflecting the 0/1-loss is the empirical classification rate

$$\text{CR}(\mathcal{C}; \mathcal{D}) = \frac{1}{L} \sum_{l=1}^L \mathbb{1}_{\{c^{(l)} = \arg \max_{c \in \text{val}(\mathcal{C})} P(c|\mathbf{z}^{(l)}, \mathcal{C})\}}.$$

Parameter learning using CR is hard, due to the non-differentiability and non-convexity of the function. In [40, 46], CR was used for greedy hill-climbing structure learning.

*Maximum margin (MM):* The probabilistic multi-class margin [47] for the  $l$ th sample can be expressed as

$$d_{\mathcal{C}}^{(l)} = \min_{c \neq c^{(l)}} \frac{P(c^{(l)}|\mathbf{z}^{(l)}, \mathcal{C})}{P(c|\mathbf{z}^{(l)}, \mathcal{C})} = \frac{P(c^{(l)}, \mathbf{z}^{(l)}|\mathcal{C})}{\max_{c \neq c^{(l)}} P(c, \mathbf{z}^{(l)}|\mathcal{C})}. \quad (18.191)$$

If  $d_{\mathcal{C}}^{(l)} > 1$ , then sample  $l$  is correctly classified and vice versa. The magnitude of  $d_{\mathcal{C}}^{(l)}$  is related to the confidence of the classifier about its decision. Taking the logarithm, we obtain

$$\log d_{\mathcal{C}}^{(l)} = \log P(c^{(l)}, \mathbf{z}^{(l)}|\mathcal{C}) - \max_{c \neq c^{(l)}} (\log P(c, \mathbf{z}^{(l)}|\mathcal{C})). \quad (18.192)$$

Usually, the maximum margin approach maximizes the margin of the sample with the smallest margin for a separable classification problem [37], i.e., we use the objective function

$$\text{MM}(\mathcal{C}; \mathcal{D}) = \min_{l=1, \dots, L} \log d_{\mathcal{C}}^{(l)}. \quad (18.193)$$

For non-separable problems, this is relaxed by introducing a so-called soft margin, which has been used for parameter learning [47, 48] and for structure learning [49, 50].

## 1.18.5 Inference

In the last section the basics of learning PGMs have been introduced. Now, assuming that the process of learning has already been performed, i.e., the model structure and parameterization are established, we move onto the task of *inference*. This task deals with assessing the marginal and/or most likely configuration of variables given observations. For this, the set of RVs  $\mathbf{X}$  in the PGM is partitioned into three mutually disjoint subsets  $\mathbf{O}$ ,  $\mathbf{Q}$  and  $\mathbf{H}$ , i.e.,  $\mathbf{X} = \mathbf{O} \cup \mathbf{Q} \cup \mathbf{H}$  and  $\mathbf{O} \cap \mathbf{Q} = \mathbf{O} \cap \mathbf{H} = \mathbf{Q} \cap \mathbf{H} = \emptyset$ . Here,  $\mathbf{O}$  denotes the set of *observed nodes*, i.e., the evidence variables,  $\mathbf{Q}$  denotes the set of *query variables*, and  $\mathbf{H}$  refers to the set of nodes which belong neither to  $\mathbf{O}$  or  $\mathbf{Q}$ , also known as latent or hidden variables.

There are two basic types of inference queries:

- i. *Marginalization query*: This first type of query infers the marginal distribution of the query variables conditioned on the observation  $\mathbf{O}$ , i.e., it computes

$$P(\mathbf{Q}|\mathbf{O} = \mathbf{o}) = \frac{P(\mathbf{Q}, \mathbf{O} = \mathbf{o})}{P(\mathbf{O} = \mathbf{o})}. \quad (18.194)$$

The terms  $P(\mathbf{Q}, \mathbf{O} = \mathbf{o})$  and  $P(\mathbf{O} = \mathbf{o})$  can be determined by marginalization over  $\mathbf{H}$  and  $\mathbf{H} \cup \mathbf{Q}$  of the joint probability  $P(\mathbf{X}) = P(\mathbf{O}, \mathbf{Q}, \mathbf{H})$  represented by the PGM, respectively. That is,

$$P(\mathbf{Q}, \mathbf{O} = \mathbf{o}) = \sum_{\mathbf{h} \in \text{val}(\mathbf{H})} P(\mathbf{O} = \mathbf{o}, \mathbf{Q}, \mathbf{H} = \mathbf{h}), \quad \text{and} \quad (18.195)$$

$$P(\mathbf{O} = \mathbf{o}) = \sum_{\mathbf{q} \in \text{val}(\mathbf{Q})} P(\mathbf{O} = \mathbf{o}, \mathbf{Q} = \mathbf{q}). \quad (18.196)$$

**Example 23.** Assume a PGM used by a car insurance company to calculate the insurance fees for individuals. Then, a query could ask for the probabilities of certain damage sums (this corresponds to query variables) arising for the case of a driver with age 25 and no children (this corresponds to evidence variables). Other variables in the model, such as e.g., the number of accidents in the past, are marginalized out since they are not observed.

- ii. *Maximum a posteriori query*: This query determines the most likely instantiation of the query variables given some evidence, i.e., it computes

$$\mathbf{q}^* = \arg \max_{\mathbf{q} \in \text{val}(\mathbf{Q})} P(\mathbf{Q} = \mathbf{q} | \mathbf{O} = \mathbf{o}). \quad (18.197)$$

This is equivalent to

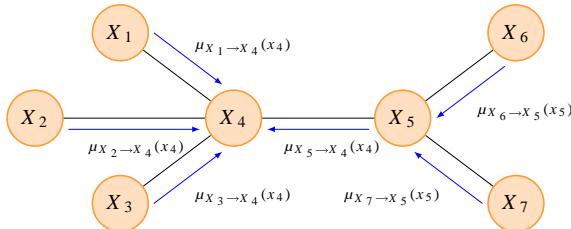

$$\mathbf{q}^* = \arg \max_{\mathbf{q} \in \text{val}(\mathbf{Q})} \sum_{\mathbf{h} \in \text{val}(\mathbf{H})} P(\mathbf{Q} = \mathbf{q}, \mathbf{H} = \mathbf{h} | \mathbf{O} = \mathbf{o}), \quad (18.198)$$

$$= \arg \max_{\mathbf{q} \in \text{val}(\mathbf{Q})} \sum_{\mathbf{h} \in \text{val}(\mathbf{H})} P(\mathbf{Q} = \mathbf{q}, \mathbf{H} = \mathbf{h}, \mathbf{O} = \mathbf{o}). \quad (18.199)$$

Note, that the most likely instantiation of the joint variables  $\mathbf{q}^*$  does in general not correspond to the states obtained by selecting the most likely instantiation for all variables in  $\mathbf{Q}$  individually. An example for this is shown in [1], Chapter 2.

**Example 24.** In hidden Markov models (HMMs) this amounts to finding the most likely state sequence  $\mathbf{q}^*$  explaining the given observation sequence. This state sequence is determined by applying the Viterbi algorithm as shown in Section 1.18.6.1.

While both inference queries can in principle be answered by directly evaluating the sums in the corresponding equations, this approach becomes intractable for PGMs with many variables. This is due to the number of summands growing exponentially with the number of variables. Therefore, more

**FIGURE 18.21**

Message passing in a tree-shaped MN  $\mathcal{M}$  to determine the marginal  $P_{\mathcal{M}}(X_4)$ .

efficient inference methods exploiting the structure of the underlying PGMs have been developed; The exact solution to (i) can be found using the *sum-product algorithm*, also known as *belief propagation* or *message passing algorithm* [2, 51], assuming tree-structured graphical models, and (ii) can be calculated by applying the *max-product* or in the log-domain the *max-sum* algorithm. In this tutorial, the focus is on marginalization queries  $P(\mathbf{Q}|\mathbf{O})$ . Details on MAP queries are provided in [1], Chapter 9.

The remainder of this section is structured as follows: In Section 1.18.5.1 the sum-product algorithm is derived and the junction tree algorithm for exact inference in arbitrary graphs is introduced. In cases, where exact inference is computationally too demanding, approximate inference techniques can be used. A short introduction to these techniques is given in Section 1.18.5.2.

### 1.18.5.1 Exact inference

Given some evidence  $\mathbf{o} \in \text{val}(\mathbf{O})$ , the direct calculation of the marginal in (18.196) of the joint probability distribution

$$P(\mathbf{O} = \mathbf{o}) = \sum_{\mathbf{q} \in \text{val}(\mathbf{Q})} \sum_{\mathbf{h} \in \text{val}(\mathbf{H})} P(\mathbf{O} = \mathbf{o}, \mathbf{Q} = \mathbf{q}, \mathbf{H} = \mathbf{h}) \quad (18.200)$$

expands to  $\prod_{i=1}^{|\mathbf{Q}|} \text{sp}(\mathbf{Q}_i) \prod_{i=1}^{|\mathbf{H}|} \text{sp}(\mathbf{H}_i)$  summations. Hence, assuming that each variable can be in one of  $k$  states the evaluation of Eq. (18.200) requires  $\mathcal{O}(k^{|\mathbf{Q}|+|\mathbf{H}|})$  summations, i.e., the evaluation of a sum with exponentially many terms in the number of variables. This renders the direct computation intractable for large values of  $k$  and many variables. Fortunately, the underlying graph structure, and the thereby introduced factorization of the joint probability, can be exploited. This is demonstrated in the following example:

**Example 25.** Consider the MN  $\mathcal{M}$  in Figure 18.21. The joint probability factorizes according to the maximal cliques  $\mathbf{C}_1 = \{X_1, X_4\}$ ,  $\mathbf{C}_2 = \{X_2, X_4\}$ ,  $\mathbf{C}_3 = \{X_3, X_4\}$ ,  $\mathbf{C}_4 = \{X_4, X_5\}$ ,  $\mathbf{C}_5 = \{X_5, X_6\}$ , and  $\mathbf{C}_6 = \{X_5, X_7\}$  as

$$P_{\mathcal{M}}(X_1, X_2, X_3, X_4, X_5, X_6, X_7) = \frac{1}{Z} \Psi_{\mathbf{C}_1}(X_1, X_4) \Psi_{\mathbf{C}_2}(X_2, X_4) \Psi_{\mathbf{C}_3}(X_3, X_4) \cdot \quad (18.201)$$

$$\Psi_{\mathbf{C}_4}(X_4, X_5) \Psi_{\mathbf{C}_5}(X_5, X_6) \Psi_{\mathbf{C}_6}(X_5, X_7). \quad (18.202)$$

Suppose, we are interested in determining the marginal probability  $P_{\mathcal{M}}(X_4)$ . Then,

$$\begin{aligned}
 P_{\mathcal{M}}(X_4) &= \sum_{x_1} \cdots \sum_{x_3} \sum_{x_5} \cdots \sum_{x_7} P_{\mathcal{M}}(X_1, X_2, X_3, X_4, X_5, X_6, X_7) \\
 &= \frac{1}{Z} \left[ \underbrace{\sum_{x_1 \in \text{val}(X_1)} \Psi_{C_1}(x_1, x_4)}_{=\mu_{X_1 \rightarrow X_4}(x_4)} \right] \left[ \underbrace{\sum_{x_2 \in \text{val}(X_2)} \Psi_{C_2}(x_2, x_4)}_{=\mu_{X_2 \rightarrow X_4}(x_4)} \right] \left[ \underbrace{\sum_{x_3 \in \text{val}(X_3)} \Psi_{C_3}(x_3, x_4)}_{=\mu_{X_3 \rightarrow X_4}(x_4)} \right] \\
 &\quad \cdot \left[ \underbrace{\sum_{x_5 \in \text{val}(X_5)} \Psi_{C_4}(x_4, x_5)}_{=\mu_{X_5 \rightarrow X_4}(x_4)} \left[ \underbrace{\sum_{x_6 \in \text{val}(X_6)} \Psi_{C_5}(x_5, x_6)}_{=\mu_{X_6 \rightarrow X_5}(x_5)} \right] \left[ \underbrace{\sum_{x_7 \in \text{val}(X_7)} \Psi_{C_6}(x_5, x_7)}_{=\mu_{X_7 \rightarrow X_5}(x_5)} \right] \right] \\
 &= \frac{1}{Z} \mu_{X_1 \rightarrow X_4}(x_4) \mu_{X_2 \rightarrow X_4}(x_4) \mu_{X_3 \rightarrow X_4}(x_4) \mu_{X_5 \rightarrow X_4}(x_4),
 \end{aligned}$$

where the terms  $\mu_{X_i \rightarrow X_j}(x_j)$  denote so-called *messages* from  $X_i$  to  $X_j$ . The grouping of the factors with the corresponding sums essentially exploits the distributive law [52] and reduces the computational burden. In this example, we require  $\mathcal{O}(k^2)$  summations and multiplications assuming that  $\text{sp}(X_i) = k$  for all variables  $X_i$ . Direct calculation of  $P_{\mathcal{M}}(X_4)$  would instead require  $\mathcal{O}(k^{N-1})$  arithmetic operations, where  $N = 7$ . The normalization constant  $Z$  can be determined by summing the product of incoming messages over  $x_4$ , i.e.,

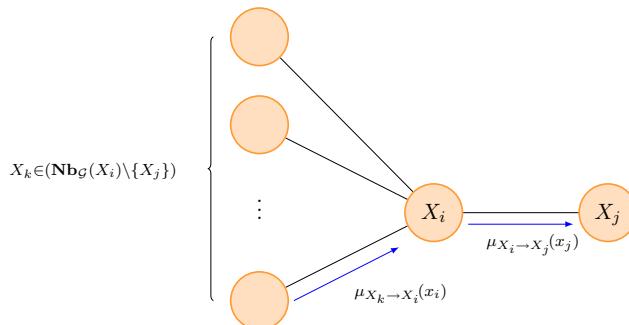

$$Z = \sum_{x_4 \in \text{val}(X_4)} \mu_{X_1 \rightarrow X_4}(x_4) \mu_{X_2 \rightarrow X_4}(x_4) \mu_{X_3 \rightarrow X_4}(x_4) \mu_{X_5 \rightarrow X_4}(x_4). \quad (18.203)$$

In the sequel, we generalize the example above to pairwise MNs, while inference in more general MNs, BNs and FGs is covered later in this section. This generalization leads to the *sum-product rule*: Messages  $\mu_{X_i \rightarrow X_j}(x_j)$  are sent on each edge  $(X_i - X_j) \in \mathbf{E}$  from  $X_i$  to  $X_j$ . These messages are updated according to

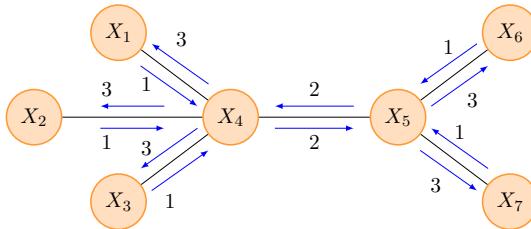

$$\mu_{X_i \rightarrow X_j}(x_j) = \sum_{x_i \in \text{val}(X_i)} \Psi_{\{X_i, X_j\}}(x_i, x_j) \prod_{X_k \in (\text{Nb}_{\mathcal{G}}(X_i) \setminus \{X_j\})} \mu_{X_k \rightarrow X_i}(x_i), \quad (18.204)$$

i.e., the new message  $\mu_{X_i \rightarrow X_j}(x_j)$  is calculated as the product of the *incoming* messages with the potential function  $\Psi_{\{X_i, X_j\}}$  and summation over all variables except  $X_j$ . This message update is sketched in Figure 18.22.

The *sum-product algorithm* schedules the messages such that an updated message is sent from  $X_i$  to  $X_j$  when  $X_i$  has received the messages from all its neighbors except  $X_j$ , i.e., from all nodes in  $\text{Nb}_{\mathcal{G}}(X_i) \setminus \{X_j\}$  [53].

**FIGURE 18.22**

Sum-product update rule.

**FIGURE 18.23**

Message update of the sum-product algorithm.

**Example 26.** This message update schedule of the sum-product algorithm for our previous example is illustrated in Figure 18.23. The sent messages are illustrated as arrows in the figure, where the numbers next to the arrows indicate the iteration count at which message updates are sent to neighboring nodes. After three iterations the updates converge for all nodes in the graph.

The sum-product algorithm is *exact* if the MN is free of cycles [2], i.e., if it is a tree. *Exact* means that the marginals  $P(X_i)$  (also called *beliefs*) obtained from the sum-product algorithm according to

$$P(X_i) = \frac{1}{Z} \prod_{X_k \in \text{Nb}_{\mathcal{G}}(X_i)} \mu_{X_k \rightarrow X_i}(x_i) \quad (18.205)$$

are guaranteed to converge to the true marginals. Again, considering the graph in Figure 18.23, each clique factor  $\Psi_C$  includes two variables. Consequently, the complexity of the sum-product algorithm is  $\mathcal{O}(k^2)$  assuming that  $\text{sp}(X_i) = k$  for all variables  $X_i$ .

So far, we are able to obtain the marginals  $P(X_i)$  for any  $X_i \in \mathbf{Q}$  for tree-shaped MNs. However, the aim is to determine the marginal distribution over the query variable  $Q_i \in \mathbf{Q}$  conditioned on the evidence  $\mathbf{O} = \mathbf{o}$ . This requires the computation of  $P(Q_i, \mathbf{o})$ , cf. Eq. (18.194) assuming only one query

variable. The evidence is introduced to each clique factor  $\Psi_C$  that depends on evidence nodes, i.e., to each  $\Psi_C$  for which there is an  $O_i \in \mathbf{C}$  that is also in  $\mathbf{O}$ . Therefore, we identify all factors  $\Psi_C$  with  $O_i \in \mathbf{C}$  for any  $O_i \in \mathbf{O}$  and determine the new factor by multiplying  $\Psi_C$  with the indicator function  $\mathbb{1}_{\{O_i=o_i\}}$ , i.e.,  $\Psi_C(\cdot)$  is modified according to  $\Psi_C(\cdot)\mathbb{1}_{\{O_i=o_i\}}$ . In other words, factors are set to zero for instantiations inconsistent with  $\mathbf{O} = \mathbf{o}$ . Interestingly, it turns out that running the sum-product algorithm on the updated factors leads to an unnormalized representation of  $P(Q_i, \mathbf{o})$ . The regular  $P(Q_i|\mathbf{o})$  is obtained by normalizing  $P(Q_i, \mathbf{o})$  by  $Z = \sum_{q_i \in \text{val}(Q_i)} P(Q_i = q_i, \mathbf{o})$  [53,54].

*Message Passing in FGs:* For FGs, the sum-product algorithm for determining the marginal distribution of the variable  $X_i$ , given all the observations can be formulated analogously [55]. The observations are absorbed into the factors instead of the clique factors. Neighboring nodes communicate with each other: whenever a node, either a variable or factor node, has received all messages except on one edge, it sends a new message to its neighbor over this edge. At the beginning, messages from variable nodes are initialized to 1. The message from variable node  $X$  to factor node  $F$  is

$$\mu_{X \rightarrow F}(x) = \prod_{F_k \in (\mathbf{Nb}_G(X) \setminus \{F\})} \mu_{F_k \rightarrow X}(x), \quad (18.206)$$

while a message from factor node  $F$  to variable node  $X$  is computed as

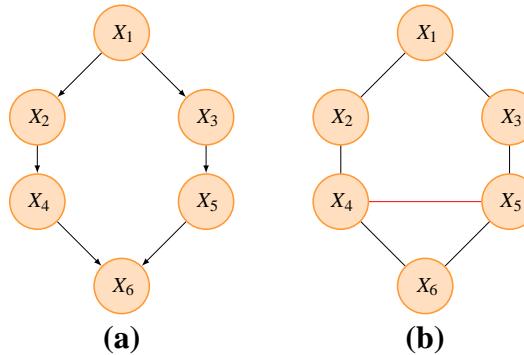

$$\mu_{F \rightarrow X}(x) = \sum_{\mathbf{Nb}_G(F) \setminus \{X\}} \left( f(\mathbf{Nb}_G(F)) \prod_{X_k \in (\mathbf{Nb}_G(F) \setminus \{X\})} \mu_{X_k \rightarrow F}(X_k) \right). \quad (18.207)$$

The marginal at each variable node can be determined as  $P(X_i) = \frac{1}{Z} \prod_{F \in \mathbf{Nb}_G(X_i)} \mu_{F \rightarrow X_i}(X_i)$ , where  $Z$  is a normalization constant.

So far, we have shown how to efficiently compute the marginals of a factorized joint probability distribution given some evidence in the case of tree-structured MNs and FGs. Generally, the sum-product algorithm is exact only if performed on a graphical model that is a tree. The remaining question is how to perform inference in BNs and arbitrarily structured BNs and MNs?

*Message passing in arbitrarily structured BNs and MNs:* Inference in BNs can be performed by first transforming the BN into an MN. Inference is then performed on this transformed model. The transformation of the model is known as *moralization*. Further, any arbitrary directed (and undirected) graphical model can be transformed into an undirected tree (*junction tree* or *clique tree*) where each node in the tree corresponds to a subset of variables (cliques) [3,53,54,56–59]. This is done with the goal of performing inference on this tree, exploiting that inference on trees is exact. The transformation of an arbitrary graph to a junction tree involves the following three steps, where the first step is only required when transforming a BN to an MN:

- i. *Moralization:* In the case of a directed graphical model, undirected edges are added between all pairs of parents  $\mathbf{Pa}_G(X_i)$  having a common child  $X_i$  for all  $X_i \in \mathbf{X}$ . This is known as moralization [54]. The *moral graph* is then obtained by dropping the directions of the edges. Moralization essentially results in a loss of conditional independence statements represented by the original graph. However, this is necessary for representing the original factorization by the undirected graph.

**FIGURE 18.24**

Moralization example. (a) BN to be transformed to an MN. (b) Moral graph; the added edge is red.

**Example 27 (Moralization).** The joint probability of the BN  $\mathcal{B}$  in Figure 18.24a is

$$P_{\mathcal{B}}(X_1, \dots, X_6) = P_{X_1}(X_1)P_{X_2}(X_2|X_1)P_{X_3}(X_3|X_1)P_{X_4}(X_4|X_2)P_{X_5}(X_5|X_3)P_{X_6}(X_6|X_4, X_5). \quad (18.208)$$

The corresponding moral graph is shown in Figure 18.24b. It factorizes as a product of the factors of the maximal cliques  $\mathbf{C}_1 = \{X_1, X_2\}$ ,  $\mathbf{C}_2 = \{X_1, X_3\}$ ,  $\mathbf{C}_3 = \{X_2, X_4\}$ ,  $\mathbf{C}_4 = \{X_3, X_5\}$ , and  $\mathbf{C}_5 = \{X_4, X_5, X_6\}$  as

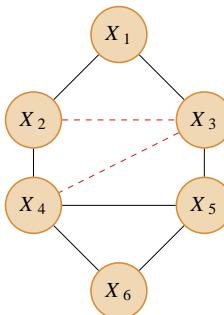

$$P_{\mathcal{M}}(X_1, \dots, X_6) = \Psi_{\mathbf{C}_1}(X_1, X_2)\Psi_{\mathbf{C}_2}(X_1, X_3)\Psi_{\mathbf{C}_3}(X_2, X_4)\Psi_{\mathbf{C}_4}(X_3, X_5)\Psi_{\mathbf{C}_5}(X_4, X_5, X_6). \quad (18.209)$$

Each CPD  $P_{X_i}(X_i|\mathbf{Pa}_{\mathcal{G}}(X_i))$  of the BN is mapped into the factor of exactly one clique, i.e., each clique factor is initialized to one and then each  $P_{X_i}(X_i|\mathbf{Pa}_{\mathcal{G}}(X_i))$  is multiplied into a clique factor which contains  $\{X_i\} \cup \mathbf{Pa}_{\mathcal{G}}(X_i)$ . In this example, this results in the following factors:  $\Psi_{\mathbf{C}_1}(X_1, X_2) = P_{X_1}(X_1)P_{X_2}(X_2|X_1)$ ,  $\Psi_{\mathbf{C}_2}(X_1, X_3) = P_{X_3}(X_3|X_1)$ ,  $\Psi_{\mathbf{C}_3}(X_2, X_4) = P_{X_4}(X_4|X_2)$ ,  $\Psi_{\mathbf{C}_4}(X_3, X_5) = P_{X_5}(X_5|X_3)$ , and  $\Psi_{\mathbf{C}_5}(X_4, X_5, X_6) = P_{X_6}(X_6|X_4, X_5)$ . The normalization factor of  $P_{\mathcal{M}}(X_1, \dots, X_6)$  in this case is  $Z = 1$ .

- ii. *Triangulation:* The next step in converting an arbitrary MN into a junction tree is the triangulation of the moral graph. The *triangulated graph* is sometimes called *chordal graph*.

**Definition 28 (Triangulation [54]).** A graph  $\mathcal{G}$  is *triangulated* if there is no cycle of length  $\geq 4$  without an edge joining two non-neighboring nodes.

The triangulated graph can be found by the *elimination algorithm* [1] that eliminates one variable from the graph in each iteration: Assuming a given *elimination order* of the variables the first node from the ordering is selected and in the moral graph all pairs of neighbors of that node are connected. The resulting graph is collected in a set of graphs  $\mathcal{G}_e$ . Afterwards, this node and all its edges are removed from the graph. Then, the next node in the elimination ordering is selected for elimination. We proceed in the same way as above until all nodes have been eliminated. The graph resulting from the union

**FIGURE 18.25**

Triangulated graph; added edges are dashed.

of all the graphs in  $\mathcal{G}_e$  is triangulated. Depending on the ordering, there typically exist many different triangulations. For efficient inference, we would like to choose a ordering such that e.g., the state-space size of the largest clique is minimal. Finding the optimal elimination ordering is NP-hard [1]. Greedy algorithms for determining an ordering so that the induced graph is close to optimal are summarized in [1], Chapter 9.

**Example 28 (Triangulation).** An example of a triangulated graph obtained from Figure 18.24b with elimination ordering  $X_6, X_5, X_4, X_3, X_2, X_1$  is shown in Figure 18.25. The elimination of node  $X_5$  and  $X_4$  introduces the edges  $(X_3 - X_4)$  and  $(X_2 - X_3)$ , respectively. The dashed edges are added to triangulate the moral graph.

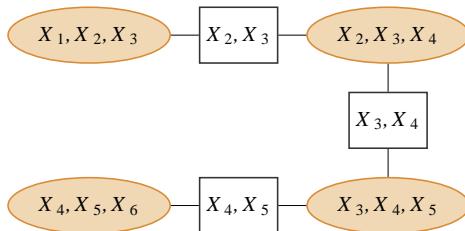

Each maximal clique of the moral graph is contained in the triangulated graph  $\mathcal{G}_t$ . Using a similar mechanism as in Example 27, we can map the factors of the moral graph to the factors of the triangulated graph. The cliques in  $\mathcal{G}_t$  are maximal cliques and

$$P_{\mathcal{M}}(\mathbf{X}) = \frac{1}{Z} \prod_{\mathbf{C} \in \mathcal{G}_t} \Psi_{\mathbf{C}}(\mathbf{C}). \quad (18.210)$$

For efficiency, the cliques of the triangulated graph can be identified during variable elimination; A node which is eliminated from the moral graph forms a clique with all neighboring nodes, when connecting all pairs of neighbors. If this clique is not contained in a previously determined maximal clique, it is a maximal clique in  $\mathcal{G}_t$ .

**Example 29.** The maximal cliques of the triangulated graph in Figure 18.25 are  $\{X_4, X_5, X_6\}$ ,  $\{X_3, X_4, X_5\}$ ,  $\{X_2, X_3, X_4\}$ , and  $\{X_1, X_2, X_3\}$ .

- iii. *Building a junction tree:* In the last step, the maximal cliques are treated as nodes and are connected to form a tree. The junction tree has to satisfy the *running intersection property*, i.e., an RV  $X_i$  present in two different cliques  $\mathbf{C}_i$  and  $\mathbf{C}_j$ ,  $i \neq j$ , has to be also in each clique on the path

**FIGURE 18.26**

Junction tree.

connecting these two cliques.<sup>2</sup> The cliques in the junction tree are connected by a *separator set*  $\mathbf{S} = \mathbf{C}_i \cap \mathbf{C}_j$ . The number of variables in  $\mathbf{S}$  determines the edge weight for joining these two cliques in the junction tree. These weights can be used to find the junction tree using the *maximum spanning tree* algorithm [60]. The tree with maximal sum of the weights is guaranteed to be a junction tree satisfying the running intersection property.<sup>3</sup>

**Example 30 (Junction Tree).** A junction tree of the example in Figure 18.25 with separators (square nodes) is shown in Figure 18.26.

Once the junction tree is determined, message passing between the cliques is performed for inference. This essentially amounts to the sum-product algorithm. First, the potential of a separator  $\Psi_{\mathbf{S}}(\mathbf{S})$  is initialized to unity. The clique potential of neighboring cliques  $\mathbf{C}_i$  and  $\mathbf{C}_j$  is  $\Psi_{\mathbf{C}_i}(\mathbf{C}_i)$  and  $\Psi_{\mathbf{C}_j}(\mathbf{C}_j)$ , respectively. The message passed from  $\mathbf{C}_i$  to  $\mathbf{C}_j$  is determined as

$$\begin{aligned}\tilde{\Psi}_{\mathbf{S}}(\mathbf{S}) &\leftarrow \sum_{\mathbf{C}_i \setminus \mathbf{S}} \Psi_{\mathbf{C}_i}(\mathbf{C}_i), \quad \text{and} \\ \Psi_{\mathbf{C}_j}(\mathbf{C}_j) &\leftarrow \frac{\tilde{\Psi}_{\mathbf{S}}(\mathbf{S})}{\Psi_{\mathbf{S}}(\mathbf{S})} \Psi_{\mathbf{C}_j}(\mathbf{C}_j),\end{aligned}$$

where the sum is over all variables in  $\mathbf{C}_i$  which are not in  $\mathbf{S}$ .

The message passing schedule is similar as for tree-structured models, i.e., a clique sends a message to a neighbor after receiving all the messages from its other neighbors. Furthermore, the introduction of evidence in the junction tree can be performed likewise as above. After each node has sent and received a message, the junction tree is *consistent* and the marginals  $P(Q_i, \mathbf{o})$  can be computed by identifying the clique potential  $\Psi_{\mathbf{C}_i}(\mathbf{C}_i)$  which contains  $Q_i$  and summing over  $\mathbf{C}_i \setminus \{Q_i\}$  as

$$P(Q_i, \mathbf{o}) = \sum_{\mathbf{C}_i \setminus \{Q_i\}} \Psi_{\mathbf{C}_i}(\mathbf{C}_i).$$

<sup>2</sup>This property is important for the message passing algorithm to achieve local consistency between cliques. Local consistency means that  $\Psi_{\mathbf{S}}(\mathbf{S}) = \sum_{\mathbf{C}_i \setminus \mathbf{S}} \Psi_{\mathbf{C}_i}(\mathbf{C}_i)$  for any  $\mathbf{C}_i$  and neighboring separator set  $\mathbf{S}$ . Because of this property, local consistency implies global consistency [1].

<sup>3</sup>A proof of this result is provided in [61].

The computational complexity of exact inference in discrete networks is exponential in the size of the largest clique (the width of the tree<sup>4</sup>). Hence, there is much interest in finding an optimal triangulation. Nevertheless, exact inference is intractable in large and dense PGMs and approximation algorithms are necessary.

### 1.18.5.2 Approximate inference

In the past decade, the research in PGMs has focused on the development of efficient *approximate inference* algorithms. While exact inference algorithms provide a satisfactory solution to many inference and learning problems, there are large-scale problems where a recourse to approximate inference is inevitable. In the following, we provide a brief overview of the most popular approximate inference methods. Details can be found in [1, 4, 62].

#### 1.18.5.2.1 Variational methods

The underlying idea in variational methods [4, 62–65] is the approximation of the posterior probability distribution  $P(\mathbf{Q}|\mathbf{O})$ , assuming  $\mathbf{H} = \emptyset$ , by a tractable surrogate distribution  $g(\mathbf{Q})$ , where we assume that the evaluation of  $P(\mathbf{Q}, \mathbf{O})$  is computational less expensive than that of  $P(\mathbf{Q}|\mathbf{O})$  and  $P(\mathbf{O})$ . The logarithm of  $P(\mathbf{O})$  can be decomposed as

$$\ln P(\mathbf{O}) = \underbrace{\sum_{\mathbf{q}} g(\mathbf{q}) \ln \left[ \frac{P(\mathbf{O}, \mathbf{q})}{g(\mathbf{q})} \right]}_{\text{LB}(g)} + \underbrace{\left\{ - \sum_{\mathbf{q}} g(\mathbf{q}) \ln \left[ \frac{P(\mathbf{q}|\mathbf{O})}{g(\mathbf{q})} \right] \right\}}_{\text{KL}(g||P)},$$

where the term  $\text{LB}(g)$  denotes a lower bound for  $\ln P(\mathbf{O})$ , i.e.,  $\text{LB}(g) \leq \ln P(\mathbf{O})$ , and  $\text{KL}(g||P)$  denotes the Kullback-Leibler divergence between  $g(\mathbf{Q})$  and  $P(\mathbf{Q}|\mathbf{O})$ . Since  $\ln P(\mathbf{O})$  does not depend on  $g(\mathbf{q})$ , and  $\text{LB}(g)$  and  $\text{KL}(g||P)$  are non-negative, maximizing  $\text{LB}(g)$  amounts to minimizing  $\text{KL}(g||P)$ . Hence, maximizing  $\text{LB}(g)$  with respect to  $g(\mathbf{q})$  results in the best approximation of the posterior  $P(\mathbf{Q}|\mathbf{O})$ .

Alternatively, the lower bound can be determined as

$$\ln P(\mathbf{O}) = \ln \sum_{\mathbf{q}} P(\mathbf{q}, \mathbf{O}) = \ln \sum_{\mathbf{q}} g(\mathbf{q}) \frac{P(\mathbf{q}, \mathbf{O})}{g(\mathbf{q})} \geq \sum_{\mathbf{q}} g(\mathbf{q}) \ln \left[ \frac{P(\mathbf{O}, \mathbf{q})}{g(\mathbf{q})} \right] = \text{LB}(g), \quad (18.211)$$

where we applied Jensen's inequality [5]. Furthermore, the lower bound  $\text{LB}(g)$  can be derived by using convex duality theory [65].

In variational approaches,  $g(\mathbf{Q})$  is restricted to simple tractable distributions. The simplest possibility, also called *mean-field approximation*, assumes that  $g(\mathbf{Q})$  factorizes as

$$g(\mathbf{Q}) = \prod_{i=1}^{|\mathbf{Q}|} g_i(Q_i). \quad (18.212)$$

---

<sup>4</sup>The tree-width of a graph is defined as the size (i.e., number of variables) of the largest clique of the moralized and triangulated directed graph minus one.

The variational inference approach can be combined with exact inference applied on parts of the graph. In particular, exact inference is performed on tractable substructures. This is called *structured variational approximation* [63], where much of the structure of the original graph is preserved.

### 1.18.5.2.2 Loopy message passing

While message passing algorithms can be shown to be exact on PGMs with tree structure, convergence of these algorithms on arbitrary graphs with cycles (loops) is not guaranteed. Moreover, even after convergence, the resulting solution might be only an approximation of the exact solution. Surprisingly, message passing on *loopy graphs* often converges to stable posterior/marginal probabilities. The most significant breakthrough came with the insight that for certain graph structures the fixed points of the message passing algorithm are actually the stationary points of the Bethe free energy [66]. This clarified the nature of message passing and led to more efficient algorithms. Further, this established a bond to a large body of physics literature and generalized belief propagation (GBP) algorithms [67] were developed. The GBP algorithms operate on regions of nodes and messages are passed between these regions. In contrast to GBP, Yuille [68] proposes a concave-convex procedure to directly optimize the Bethe free energy. Experiments on spin class configurations show that this method is stable, converges rapidly, and leads to even better solutions than message passing and GBP in some cases.

Convergence of loopy message passing has been experimentally confirmed for many applications (the maybe most popular being “turbo codes” [69, 70]). There has also been a lot of theoretical work investigating convergence properties of loopy message passing [67, 71–73]. Recently, theoretical conditions guaranteeing convergence of loopy message passing to a unique fixed point have been proposed in [74]. Minka [75] showed that many of the proposed approximate inference approaches, such as variational message passing, loopy message passing, expectation propagation amongst others can be viewed as instances of minimizing particular information divergences.

### 1.18.5.2.3 Sampling Methods

Sampling methods are computational tractable methods aiming at computing the quantities of interest by means of Monte Carlo procedures. One of the simplest of such methods is known as *importance sampling* and *sampling importance resampling* [76] for estimating expectations of functions. There are severe limitations of importance sampling in high dimensional sample spaces. However, Markov Chain Monte Carlo methods scale well with the dimensionality. Special cases are Gibbs sampling and the *Metropolis-Hastings* algorithm (see, e.g., [77, 78] for an introduction). One of the most prominent application of Monte Carlo methods (i.e., sequential importance sampling) are *particle filters* [79, 80] for online, non-linear and non-Gaussian tracking, where the posterior distribution is represented by a finite set of particles (samples). Particle filters generalize traditional Kalman filters which assume that the evolution of the state space is linear and that probability densities are Gaussian. Classical particle filters solve the inference task of computing the posterior  $P(\mathbf{Q}|\mathbf{O} = \mathbf{o})$  for a limited family of graph structures such as Kalman filters. Recently, Koller et al., Sudderth et al., and Ihler and McAllester [81–83] extended particle methods to solve inference problems defined on general graphical model structures.

## 1.18.6 Applications

PGMs have a long tradition in modeling uncertainty in intelligent systems and are important in many application areas such as computer vision [84–87], speech processing [88, 89], time-series and sequential modeling [90], cognitive science [91], bioinformatics [92], probabilistic robotics [93], signal processing, communications and error-correcting coding theory [55, 70, 76, 94], and in the area of artificial intelligence.

In this tutorial, we restrict ourselves to present some typical applications for each of the three PGM representations, namely for BNs, MNs and FGs. The first application is about dynamic BNs for time-series modeling of speech signals, followed by BNs for expert systems. Then, we present MRFs for image analysis, and FGs for decoding error-correcting codes.

### 1.18.6.1 Dynamic BNs for speech processing and time-series modeling

Speech recognition is the task of retrieving the sequence of words from a speech recording. The main components of an automatic speech recognition (ASR) system are:

1. *Feature extraction*: A feature sequence  $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_T)$  is determined by extracting  $T$  feature vectors from the audio signal. Commonly, mel-cepstral coefficients, delta, and double delta features [89] are derived from overlapping windows of  $\sim 25$  ms length of the speech signal.
2. *Recognition*: Based on the extracted features, a sequence of  $N$  words  $\mathbf{w} = (w_1, \dots, w_N)$  is determined.

The most likely word sequence  $\mathbf{w}^*$  given some sequence of feature vectors can be determined by the posterior probability  $P(\mathbf{w}|\mathbf{X})$  as

$$\mathbf{w}^* = \arg \max_{\mathbf{w} \in \mathcal{W}} P(\mathbf{w}|\mathbf{X}), \quad (18.213)$$

$$= \arg \max_{\mathbf{w} \in \mathcal{W}} \frac{P(\mathbf{X}|\mathbf{w}) P(\mathbf{w})}{P(\mathbf{X})}, \quad (18.214)$$

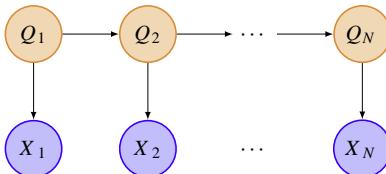

$$= \arg \max_{\mathbf{w} \in \mathcal{W}} P(\mathbf{X}|\mathbf{w}) P(\mathbf{w}), \quad (18.215)$$

where  $\mathcal{W}$  denotes the set of all possible word sequences. The *acoustic model* probability  $P(\mathbf{X}|\mathbf{w})$  for an utterance  $\mathbf{w}$  can be modeled as the concatenation of HMMs representing acoustic units such as words. In practice, it might even be beneficial to model subunits of words, e.g., bi- or triphones<sup>5</sup> or syllable units.

An HMM is a (hidden) Markov chain over states  $\{Q_1, \dots, Q_N\}$  and observations  $\{X_1, \dots, X_N\}$ . The states generate the observations such that observation  $X_i$  stochastically depends only on state  $Q_i$ , i.e.,

$$P(X_i|Q_1, \dots, Q_N, X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_N) = P(X_i|Q_i). \quad (18.216)$$

<sup>5</sup>In linguistics, a biphone (triphone) is a sequence of two (three) phonemes.

**FIGURE 18.27**

Hidden Markov Model.

The number of states of  $Q_i$  and  $X_i$  (considering discrete observations) is the same for each  $i \in \{1, \dots, N\}$ . An HMM can be represented as *dynamic BN* shown in Figure 18.27. In the case of Gaussian distributed state variables and observation probabilities  $P(X_i|Q_i)$ , this model structure is known as *Kalman filter*.

In the context of HMMs, we usually have to deal with three fundamental problems: (i) Evaluation problem; (ii) Decoding problem; and (iii) Learning (estimation) problem. Approaches to each of these problems for discrete observation variables are discussed in the following. The observations  $\{X_1, \dots, X_N\}$  are collected in  $\mathbf{X}$  and the states  $\{Q_1, \dots, Q_N\}$  in  $\mathbf{Q}$ .

- i. *Evaluation problem:* The aim is to determine the likelihood  $P(\mathbf{X}|\Theta)$  for an observation sequence  $\mathbf{X}$  given the model parameters  $\Theta$ . This likelihood is typically used in sequence classification tasks. The joint probability distribution<sup>6</sup> of the HMM in Figure 18.27 is

$$P_B(\mathbf{X}, \mathbf{Q}|\Theta) = P(Q_1|\theta^1)P(X_1|Q_1, \theta^3)\prod_{i=2}^N P(Q_i|Q_{i-1}, \theta^2)P(X_i|Q_i, \theta^3), \quad (18.217)$$

where  $\theta^1$ ,  $\theta^2$ , and  $\theta^3$  are known as prior, transition, and observation (emission) probabilities, respectively. The parameters  $\theta^2$  and  $\theta^3$  are assumed to be constant for all  $i$ . The likelihood  $P(\mathbf{X}|\Theta)$  can be obtained by marginalizing over all possible state sequences according to

$$P(\mathbf{X}|\Theta) = \sum_{\mathbf{q} \in \text{val}(\mathbf{Q})} P_B(\mathbf{X}, \mathbf{Q} = \mathbf{q}|\Theta), \quad (18.218)$$

i.e., determining  $P(\mathbf{X}|\Theta)$  is a simple marginalization query. A naive summation over all state sequences would be exponential in the length of the sequence  $N$ . Fortunately, the HMM has a tree structure which can be exploited to compute the likelihood  $P(\mathbf{X}|\Theta)$  efficiently. Similar as in Example 25, we can rearrange the sums to the relevant terms in  $P_B(\mathbf{X}, \mathbf{Q}|\Theta)$ , i.e., we can determine  $P(\mathbf{X}|\Theta)$  recursively. Hence, neglecting the parameters  $\Theta$ , we have

---

<sup>6</sup>In implementations on computers the joint probability distribution is usually computed in the log-domain where the products turn into sums. This alleviates numerical problems.

$$P(\mathbf{X}|\Theta) = \sum_{q_1 \in \text{val}(\mathcal{Q}_1)} P(q_1) P(X_1|q_1) \sum_{q_2 \in \text{val}(\mathcal{Q}_2)} P(q_2|q_1) P(X_2|q_2) \cdot \\ \sum_{q_3 \in \text{val}(\mathcal{Q}_3)} P(q_3|q_2) P(X_3|q_3) \cdots \quad (18.219)$$

$$\cdots \sum_{q_{N-1} \in \text{val}(\mathcal{Q}_{N-1})} P(q_{N-1}|q_{N-2}) P(X_{N-1}|q_{N-1}) \underbrace{\sum_{q_N \in \text{val}(\mathcal{Q}_N)} P(q_N|q_{N-1}) P(X_N|q_N)}_{= \sum_{q_N \in \text{val}(\mathcal{Q}_N)} P(q_N, X_N|q_{N-1}) = P(X_N|q_{N-1}) = \beta(q_{N-1})} \\ = \underbrace{\sum_{q_{N-1} \in \text{val}(\mathcal{Q}_{N-1})} P(q_{N-1}, X_{N-1}|q_{N-2}) \beta(q_{N-1}) = P(X_{N-1}, X_N|q_{N-2}) = \beta(q_{N-2})}_{(18.220)}$$

where we defined the *backward* probability recursively as

$$\beta(Q_i = q_i) = P(X_{i+1}, \dots, X_N | Q_i = q_i), \quad (18.221)$$

$$= \sum_{q_{i+1} \in \text{val}(Q_{i+1})} \beta(Q_{i+1} = q_{i+1}) \cdot$$

$$P(Q_{i+1} = q_{i+1} | Q_i = q_i) P(X_{i+1} | Q_{i+1} = q_{i+1}). \quad (18.222)$$

The recursion for computing  $\beta(Q_{N-1})$  backwards to  $\beta(Q_1)$  is initialized with  $\beta(Q_N) = 1$ . The likelihood  $P(\mathbf{X}|\Theta)$  can be determined from  $\beta(Q_1 = q_1)$  according to

$$P(\mathbf{X}|\Theta) = \sum_{q_1 \in \text{val}(\mathcal{Q}_1)} P(Q_1 = q_1) P(X_1 | Q_1 = q_1) \beta(Q_1 = q_1), \quad (18.223)$$

$$= \sum_{q_1 \in \text{val}(\mathcal{Q}_1)} P(Q_1 = q_1) P(X_1 | Q_1 = q_1) P(X_2, \dots, X_N | Q_1 = q_1), \quad (18.224)$$

$$= \sum_{q_1 \in \text{val}(\mathcal{Q}_1)} P(Q_1 = q_1, X_1, \dots, X_N). \quad (18.225)$$

This recursive algorithm reduces the computational complexity from  $\mathcal{O}(N \cdot \text{sp}(\mathcal{Q})^N)$  to  $\mathcal{O}(N \cdot \text{sp}(\mathcal{Q})^2)$ .

In a similar manner, *forward* probabilities  $\alpha(Q_i = q_i)$  can be defined recursively as

$$\alpha(Q_i = q_i) = P(X_1, \dots, X_i, Q_i = q_i), \quad (18.226)$$

$$= \sum_{q_{i-1} \in \text{val}(Q_{i-1})} \alpha(Q_{i-1} = q_{i-1}) \cdot$$

$$P(Q_i = q_i | Q_{i-1} = q_{i-1}) P(X_i | Q_i = q_i), \quad (18.227)$$

$$= \sum_{q_{i-1} \in \text{val}(Q_{i-1})} P(X_1, \dots, X_{i-1}, Q_{i-1} = q_{i-1}) \cdot$$

$$P(Q_i = q_i | Q_{i-1} = q_{i-1}) P(X_i | Q_i = q_i), \quad (18.228)$$

$$= \sum_{q_{i-1} \in \text{val}(Q_{i-1})} P(X_1, \dots, X_i, Q_{i-1} = q_{i-1}, Q_i = q_i). \quad (18.229)$$

After initializing  $\alpha(Q_1)$  to  $\alpha(Q_1) = P(Q_1)P(X_1|Q_1)$  the forward probabilities can be computed for  $i = 2, \dots, N$  and the likelihood  $P(\mathbf{X}|\Theta)$  is determined as

$$P(\mathbf{X}|\Theta) = \sum_{q_N \in \text{val}(Q_N)} \alpha(Q_N = q_N) = \sum_{q_N \in \text{val}(Q_N)} P(X_1, \dots, X_N, Q_N = q_N). \quad (18.230)$$

Interestingly,  $P(\mathbf{X}|\Theta)$  can be determined as

$$P(\mathbf{X}|\Theta) = \sum_{q_i \in \text{val}(Q_i)} \alpha(Q_i = q_i) \beta(Q_i = q_i), \quad (18.231)$$

$$= \sum_{q_i \in \text{val}(Q_i)} P(X_1, \dots, X_i, Q_i = q_i) P(X_{i+1}, \dots, X_N | Q_i = q_i), \quad (18.232)$$

$$= \sum_{q_i \in \text{val}(Q_i)} P(\mathbf{X}, Q_i = q_i). \quad (18.233)$$

Computing  $P(\mathbf{X}|\Theta)$  using  $\alpha(Q_i)$  and/or  $\beta(Q_i)$  is computationally efficient and is known as *forward/backward algorithm* [89]. Both algorithms are an instance of the more general sum-product algorithm.

- ii. *Decoding problem:* Decoding is concerned with finding the state sequence which best explains a given observation sequence  $\mathbf{X}$  in model  $\Theta$ . This relates decoding to the maximum a posteriori query, cf. Section 1.18.5. In other words, we are interested in the most likely instantiation of  $\mathbf{Q}$  given  $\mathbf{X}$  and the model  $\Theta$ , i.e.,

$$\mathbf{q}^* = \arg \max_{\mathbf{q} \in \text{val}(\mathbf{Q})} P(\mathbf{Q} = \mathbf{q} | \mathbf{X}, \Theta) = \arg \max_{\mathbf{q} \in \text{val}(\mathbf{Q})} \frac{P(\mathbf{Q} = \mathbf{q}, \mathbf{X} | \Theta)}{P(\mathbf{X} | \Theta)}. \quad (18.234)$$

Since  $P(\mathbf{X}|\Theta)$  is the same for every state sequences, we obtain

$$\mathbf{q}^* = \arg \max_{\mathbf{q} \in \text{val}(\mathbf{Q})} P(\mathbf{Q} = \mathbf{q}, \mathbf{X} | \Theta). \quad (18.235)$$

The Viterbi algorithm is an efficient approach for determining  $\mathbf{q}^*$  in HMMs. Similarly as the forward probabilities, we define  $\delta(Q_i = q)$  as

$$\delta(Q_i = q_i) = \max_{q_1 \in \text{val}(Q_1), \dots, q_{i-1} \in \text{val}(Q_{i-1})} P(Q_1 = q_1, \dots, Q_{i-1} = q_{i-1}, Q_i = q_i, X_1, \dots, X_i | \Theta). \quad (18.236)$$

This term describes the largest probability for the partial observation sequence  $X_1, \dots, X_i$  in model  $\Theta$  along a single state sequence which ends at variable  $Q_i$  in state  $q_i$ . Similar observations as for the evaluation problem apply and we can express the computation of  $\delta(Q_i = q_i)$  recursively as

$$\delta(Q_i = q_i) = \max_{\tilde{q} \in \text{val}(Q_{i-1})} [\delta(Q_{i-1} = \tilde{q}) P(Q_i = q_i | Q_{i-1} = \tilde{q})] P(X_i | Q_i = q_i). \quad (18.237)$$

This equation is closely related to the computation of  $\alpha(Q_i)$  in (18.227), i.e., the sum over all states in  $Q_{i-1}$  is replaced by the maximum operator. At the end of the recursion  $\delta(Q_N = q_N)$  gives the

largest probability along a single state sequence for  $\mathbf{X}$  and  $\Theta$ . Since we are interested in the most likely state sequence  $\mathbf{q}^*$ , we have to memorize for each  $q_i$  the best previous state  $q_{i-1}$  in  $\phi(Q_i = q)$  according to

$$\phi(Q_i = q_i) = \arg \max_{\tilde{q} \in \text{val}(Q_{i-1})} [\delta(Q_{i-1} = \tilde{q}) P(Q_i = q_i | Q_{i-1} = \tilde{q})]. \quad (18.238)$$

This enables to extract  $\mathbf{q}^*$  once  $\delta(Q_i = q_i)$  and  $\phi(Q_i = q_i)$  have been determined for  $1 \leq i \leq N$ . The Viterbi algorithm consists of the following steps:

(a) *Initialization:*

$$\delta(Q_1 = q) = P(Q_1 = q) P(X_1 | Q_1 = q) \quad \forall q \in \text{val}(Q), \quad (18.239)$$

$$\phi(Q_1 = q) = 0 \quad \forall q \in \text{val}(Q). \quad (18.240)$$

(b) *Recursion:*

$$\begin{aligned} \delta(Q_i = q) &= \max_{\tilde{q} \in \text{val}(Q_{i-1})} [\delta(Q_{i-1} = \tilde{q}) P(Q_i = q | Q_{i-1} = \tilde{q})] \cdot \\ &\quad P(X_i | Q_i = q), \quad \forall q \in \text{val}(Q), i = 2, \dots, N, \end{aligned} \quad (18.241)$$

$$\begin{aligned} \phi(Q_i = q) &= \arg \max_{\tilde{q} \in \text{val}(Q_{i-1})} [\delta(Q_{i-1} = \tilde{q}) P(Q_i = q | Q_{i-1} = \tilde{q})], \\ &\quad \forall q \in \text{val}(Q), i = 2, \dots, N. \end{aligned} \quad (18.242)$$

(c) *Termination:*

$$P(\mathbf{X}, \mathbf{Q} = \mathbf{q}^* | \Theta) = \max_{q \in \text{val}(Q_N)} \delta(Q_N = q), \quad (18.243)$$

$$q_N^* = \arg \max_{q \in \text{val}(Q_N)} \delta(Q_N = q). \quad (18.244)$$

(d) *Backtracking:*

$$q_i^* = \phi(Q_{i+1} = q_{i+1}^*) \quad i = N - 1, \dots, 1. \quad (18.245)$$

iii. *Learning problem:* The focus of learning is determining the parameters  $\Theta$  of an HMM given observation sequences  $\mathbf{X}^{(l)}$ . Usually, there is a set of  $L$  training sequences  $\mathcal{D} = \{\mathbf{X}^{(1)}, \dots, \mathbf{X}^{(L)}\}$ , where  $\mathbf{X}^{(l)} = \{x_1^{(l)}, \dots, x_{N_l}^{(l)}\}$ . The parameters  $\Theta$  in HMMs are determined by maximum likelihood estimation, i.e.,

$$\Theta_{\text{ML}} = \arg \max_{\Theta} \log \mathcal{L}(\Theta; \mathcal{D}), \quad (18.246)$$

where

$$\log \mathcal{L}(\Theta; \mathcal{D}) = \log \sum_{\mathbf{q} \in \text{val}(\mathbf{Q})} P_{\mathcal{B}}(\mathbf{X}, \mathbf{Q} = \mathbf{q} | \Theta), \quad (18.247)$$

$$= \log \sum_{\mathbf{q} \in \text{val}(\mathbf{Q})} P(Q_1 = q_1 | \theta^1) P(X_1 | Q_1 = q_1, \theta^3). \quad (18.248)$$

$$\prod_{i=2}^N P(Q_i = q_i | Q_{i-1} = q_{i-1}, \theta^2) P(X_i | Q_i = q_i, \theta^3). \quad (18.248)$$

So the aim is to maximize the log-likelihood  $\log \mathcal{L}(\Theta; \mathcal{D})$  with respect to  $\Theta$  given  $\mathcal{D}$ .

In HMMs we have to determine the parameters

$$P(Q_1 = q | \theta^1) = \theta_q^1 \quad \forall q \in \text{val}(Q), \quad (18.249)$$

$$P(Q_i = q | Q_{i-1} = \tilde{q}, \theta^2) = \theta_{q|\tilde{q}}^2 \quad \forall q, \tilde{q} \in \text{val}(Q), \quad (18.250)$$

$$P(X_i = j | Q_i = q, \theta^3) = \theta_{j|q}^3 \quad \forall j \in \text{val}(X), q \in \text{val}(Q). \quad (18.251)$$

ML parameter learning for discrete variables derived in Section 1.18.4.2.1 essentially amounts to counting and normalizing. In particular, we have

$$\hat{\theta}_q^1 = \frac{\sum_{l=1}^L u_q^{1,l}}{\sum_{j=1}^{\text{sp}(Q)} \sum_{l=1}^L u_j^{1,l}}, \quad (18.252)$$

$$\hat{\theta}_{q|\tilde{q}}^2 = \frac{\sum_{l=1}^L \sum_{i=2}^{N_l} u_{q|\tilde{q}}^{i,l}}{\sum_{j=1}^{\text{sp}(Q)} \sum_{l=1}^L \sum_{i=2}^{N_l} u_{j|\tilde{q}}^{i,l}}, \quad (18.253)$$

$$\hat{\theta}_{j|q}^3 = \frac{\sum_{l=1}^L \sum_{i=2}^{N_l} u_{j|q}^{i,l}}{\sum_{j'=1}^{\text{sp}(X)} \sum_{l=1}^L \sum_{i=2}^{N_l} u_{j'|q}^{i,l}}, \quad (18.254)$$

where  $\sum_{l=1}^L u_q^{1,l}$  is the number of occurrences of  $Q_1 = q$ ,  $\sum_{l=1}^L \sum_{i=2}^{N_l} u_{q|\tilde{q}}^{i,l}$  denotes the number of transitions from state  $\tilde{q}$  to  $q$ , and  $\sum_{l=1}^L \sum_{i=2}^{N_l} u_{j|q}^{i,l}$  is the number of observing  $X_i = j$  in state  $Q_i = q$ . Unfortunately, these counts cannot be determined directly from  $\mathcal{D}$  since we only observe the variables  $\mathbf{X}$  but not  $\mathbf{Q}$ . The variables  $\mathbf{Q}$  are hidden. Hence, the data  $\mathcal{D}$  are incomplete and parameter learning is solved by using the *EM*-algorithm [11]<sup>7</sup>. The *EM*-algorithm consists of an inference step (*E*-step) for estimating the values of the unobserved variables. Subsequently, the maximization step (*M*-step) uses this knowledge in (18.252), (18.253), and (18.254) to update the estimate. The *EM*-algorithm iterates between both steps until convergence of  $\log \mathcal{L}(\Theta; \mathcal{D})$ . In [11], it is proven that the log likelihood increases in each iteration. In (18.252) we replace  $u_q^{1,l}$  by the probability of  $Q_1 = q$  given  $\mathbf{X}^{(l)}$  obtained in the *E*-step as

$$u_q^{1,l} = P(Q_1 = q | \mathbf{X}^{(l)}), \quad (18.255)$$

$$= \frac{P(Q_1 = q, \mathbf{X}^{(l)})}{P(\mathbf{X}^{(l)})}, \quad (18.256)$$

$$= \frac{\alpha^{(l)}(Q_1 = q) \beta^{(l)}(Q_1 = q)}{\sum_{Q_i} \alpha^{(l)}(Q_i) \beta^{(l)}(Q_i)}. \quad (18.257)$$

---

<sup>7</sup>In the context of HMMs the *EM*-algorithm is also known as Baum-Welch algorithm.

Similarly, for estimating the transition probabilities

$$u_{q|\tilde{q}}^{i,l} = P(Q_i = q, Q_{i-1} = \tilde{q} | \mathbf{X}^{(l)}), \quad (18.258)$$

$$= \frac{P(Q_i = q, Q_{i-1} = \tilde{q}, \mathbf{X}^{(l)})}{P(\mathbf{X}^{(l)})}, \quad (18.259)$$

$$= \frac{P(X_1^{(l)}, \dots, X_{i-1}^{(l)}, Q_{i-1} = \tilde{q}) P(Q_i = q | Q_{i-1} = \tilde{q}) P(X_i^{(l)} | Q_i = q) P(X_{i+1}^{(l)}, \dots, X_N^{(l)} | Q_i = q)}{P(\mathbf{X}^{(l)})}, \quad (18.260)$$

$$= \frac{\alpha^{(l)}(Q_{i-1}) P(Q_i = q | Q_{i-1} = \tilde{q}) P(X_i^{(l)} | Q_i = q) \beta^{(l)}(Q_i)}{\sum_{Q_i} \alpha^{(l)}(Q_i) \beta^{(l)}(Q_i)} \quad (18.261)$$

and for the observation probabilities

$$u_{j|q}^{i,l} = P(Q_i = q | \mathbf{X}^{(l)}) \mathbb{1}_{\{X_i = j\}}, \quad (18.262)$$

$$= \frac{\alpha^{(l)}(Q_i = q) \beta^{(l)}(Q_i = q)}{\sum_{Q_i} \alpha^{(l)}(Q_i) \beta^{(l)}(Q_i)} \mathbb{1}_{\{X_i = j\}}. \quad (18.263)$$

The  $\alpha(Q_i)$  and  $\beta(Q_i)$  probabilities from the recursive forward/backward algorithm are determined in the E-step to facilitate the parameter estimation in (18.252), (18.253), and (18.254) of the M-Step. At the beginning of the EM-Algorithm, the parameters  $\Theta$  have to be initialized to reasonable values. Details are provided in [89].

We continue with the natural language processing model for the term  $P(\mathbf{w})$  in Eq. (18.215). For instance, stochastic language models [95] such as *n-grams* decompose the probability of a sequence of words as

$$P(w_1, \dots, w_N) = \prod_{i=1}^N P(w_i | w_1, \dots, w_{i-1}) \approx \prod_{i=1}^N P(w_i | w_{i-(n-1)}, \dots, w_{i-1}). \quad (18.264)$$

A bigram model (2-gram), which basically is a first order Markov chain, leads to

$$P(\mathbf{w}) = \prod_{i=1}^N P(w_i | w_{i-1}). \quad (18.265)$$

The most probable word sequence  $\mathbf{w}^*$  in Eq. (18.215) is determined using a decoding algorithm such as the Viterbi algorithm.

The approach in Eq. (18.215) can also be used in statistical machine translation [96], where the acoustic model  $P(\mathbf{X}|\mathbf{w})$  is replaced by a translation model  $P(\mathbf{f}|\mathbf{w})$  which models the relation of a pair of word sequences of different languages  $\mathbf{f}$  and  $\mathbf{w}$ , where  $\mathbf{f} = (f_1, \dots, f_M)$  is a sequence with  $M$  words. The probability  $P(\mathbf{f}|\mathbf{w})$  can be interpreted as the probability that a translator produces sequence  $\mathbf{f}$  when presented sequence  $\mathbf{w}$ .

HMMs [89] for acoustic modeling of speech signals have enjoyed remarkable success over the last forty years. However, recent developments showed that there are many sophisticated extensions to HMMs represented by dynamical BNs, cf. [88] for an overview. Furthermore, in the seminal paper of [97], discriminative HMM parameter learning based on the maximum mutual information (MMI) criterion—closely related to optimizing the conditional log-likelihood objective—has been proposed, which attempts to maximize the posterior probability of the transcriptions given the speech utterances. This leads to significantly better recognition rates compared to conventional *generative* maximum likelihood learning. In speech processing, discriminative training of HMMs celebrated success over the years and in this context the extended Baum-Welch algorithm [98, 99] has been introduced.

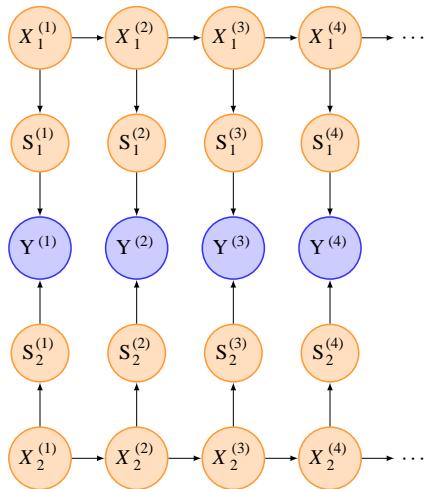

ASR for high-quality single-talker scenarios is performing reliably with good recognition performance. However, in harsh environments where the speech signal is distorted by interference with other acoustic sources, e.g., the *cocktail party problem* [100], ASR performs far from satisfactory. Recently, factorial-HMMs (FHMMs) including speaker interaction models and constraints on temporal dynamics have won the monaural speech separation and recognition challenge [101]. Remarkably, these models slightly outperformed human listeners [102] and are able to separate audio mixtures containing up to four speech signals. In the related task of multipitch tracking, Wohlmayr et al. [103] have obtained promising results using a similar FHMM model. FHMMs [63] enable to track the states of multiple Markov processes evolving in parallel over time, where the available observations are considered as a joint effect of all single Markov processes. Combining two single speakers in this way using an interaction model, we obtain the FHMM shown in Figure 18.28. The hidden state RVs denoted by  $X_k^{(t)}$  model the temporal dynamics of the pitch trajectory, where  $k$  indicates the Markov chain representing the  $k$ th speaker and  $t$  is the time frame. Realizations of observed RVs of the speech mixture spectrum at time  $t$  are collected in a  $D$ -dimensional vector  $\mathbf{Y}^{(t)} \in \mathbb{R}^D$  and  $\mathbf{S}_k^{(t)}$  models the single-speaker spectrum conditioned on state  $X_k^{(t)}$ . At each time frame, the observation  $\mathbf{Y}^{(t)}$  is considered to be produced jointly by the two single speech emissions  $\mathbf{S}_1^{(t)}$  and  $\mathbf{S}_2^{(t)}$ . This mixing process is modeled by an interaction model as for example by the MIXMAX model described in [104].

### 1.18.6.2 BNs for expert systems

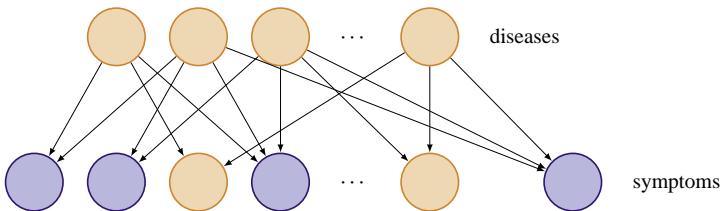

Expert and decision support systems enjoy great popularity, especially in the medical domain. They consist of two parts: a knowledge base and an inference engine. The knowledge base contains specific knowledge of some domain and the inference engine is able to process the encoded knowledge and extract information. Many of these systems are *rule-based* using logical rules. BNs have been applied in order to deal with uncertainty in these systems [54]. For instance, the Quick Medical Reference (QMR) database [105] has been developed to support medical diagnosis which consists of 600 diseases and 4000 symptoms as depicted in Figure 18.29. The aim of inference is to determine the marginal probabilities of some diseases given a set of observed symptoms. In [65], variational inference has been introduced as exact inference is infeasible for most of the practically occurring inference queries.

### 1.18.6.3 MRFs for image analysis

MRFs [84–86] have been widely used in image processing tasks over the past decades. They are employed in all stages of image analysis, i.e., for low-level vision such as image denoising,

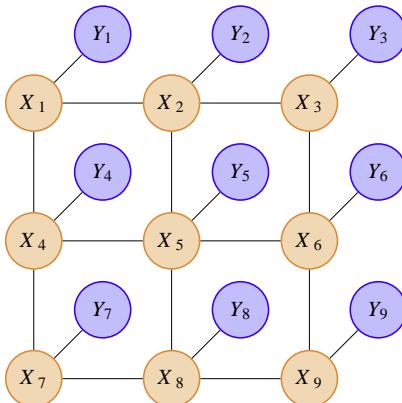

**FIGURE 18.28**

FHMM for speaker interaction. Each Markov chain models the pitch trajectory of a single speaker. At each time frame, the single speech emissions  $S_1^{(t)}$  and  $S_2^{(t)}$  jointly produce the observation  $Y^{(t)}$ .

**FIGURE 18.29**

QMR database.

segmentation, texture and optical flow modeling, and edge detection as well as for high-level tasks like face detection/recognition and pose estimation. Image processing problems can often be represented as the task of assigning labels to image pixels. For example, in the case of image segmentation, each pixel belongs to one particular label representing a segment: in the MRF in Figure 18.30, the image pixels  $\mathbf{Y}$  are observed and the underlying labels are represented as latent, i.e., unobserved, variables  $\mathbf{X}$ . The edges between the variables  $\mathbf{X}$  model contextual dependencies, e.g., using the fact that neighboring pixels have similar features. Inferring the distribution  $P_{\mathcal{M}}(\mathbf{X}|\mathbf{Y})$  is intractable for large-scale MRFs using exact methods. Approximate inference methods, such as loopy belief propagation, energy optimization, and sampling methods (MCMC) amongst others, have been deployed.

Markov random field for image analysis.

#### 1.18.6.4 FGs for decoding error-correcting codes

Transmission of information over noisy channels requires redundant information to be added to the transmitted sequence of symbols in order to facilitate the recovery of the original information from a corrupted received signal. Most error-correcting codes are either block codes or convolutional codes, including the low-density parity-check codes developed by Gallager [94].

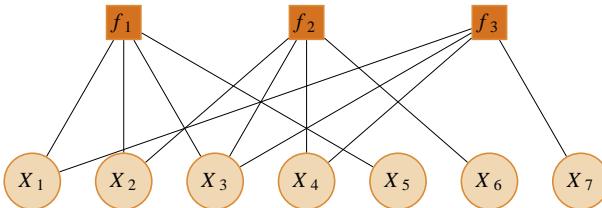

In a block code [76] the source symbol sequence of length  $K$  is converted into a symbol sequence  $\mathbf{X}$  of length  $N$  for transmission. Redundancy is added in the case of  $N$  being greater than  $K$ . Hence, a  $(N, K)$  block code is a set of  $2^K$  codewords  $\{\mathbf{x}^1, \dots, \mathbf{x}^{2^K}\}$ , where each codeword has a length of  $N$  symbols of a finite alphabet  $\mathcal{A}$ , i.e.,  $\mathbf{x}^i \in \mathcal{A}^N$  [76, 106]. Here, we assume a binary code, i.e.,  $\mathcal{A} \in \{0, 1\}$ .

In a *linear block code*, the added extra bits are a linear function of the original symbol. Those bits are known as *parity-check* bits and are redundant information. The transmitted codeword  $\mathbf{x}$  is obtained from the source sequence  $\mathbf{s}$  by calculating  $\mathbf{x} = \mathbf{G}^T \mathbf{s}$  using modulo-2 arithmetic, where  $\mathbf{G}$  is the *generator matrix* of the code. For the  $(7, 4)$  Hamming code [76] a generator matrix is

$$\mathbf{G} = \begin{bmatrix} 1 & 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 1 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 \end{bmatrix}, \quad (18.266)$$

and the corresponding *parity-check matrix*  $\mathbf{H}$  can be derived (details are given in [76]) as

$$\mathbf{H} = \begin{bmatrix} 1 & 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 1 & 1 & 0 & 1 & 0 \\ 1 & 0 & 1 & 1 & 0 & 0 & 1 \end{bmatrix}. \quad (18.267)$$

**FIGURE 18.31**

FG for the binary (7,4) Hamming code.

Each valid codeword  $\mathbf{x}$  must satisfy  $\mathbf{Hx} = \mathbf{0}$ . This parity-check can be expressed by the indicator function

$$I(x_1, \dots, x_7) = \mathbb{1}_{\{\mathbf{Hx}=\mathbf{0}\}}, \quad (18.268)$$

$$= \delta(x_1 \oplus x_2 \oplus x_3 \oplus x_5) \delta(x_2 \oplus x_3 \oplus x_4 \oplus x_6) \delta(x_1 \oplus x_3 \oplus x_4 \oplus x_7), \quad (18.269)$$

where  $\delta(a)$  denotes the Dirac delta function and  $\oplus$  is the modulo-2 addition. The term  $I(x_1, \dots, x_7) = 1$  if and only if  $\mathbf{x}$  is a valid codeword. Each row in  $\mathbf{H}$  corresponds to one  $\delta(\cdot)$  term. The function  $I(x_1, \dots, x_7)$  can be represented as the FG shown in Figure 18.31. It consists of the following factors:  $f_1(X_1, X_2, X_3, X_5) = \delta(x_1 \oplus x_2 \oplus x_3 \oplus x_5)$ ,  $f_2(X_2, X_3, X_4, X_6) = \delta(x_2 \oplus x_3 \oplus x_4 \oplus x_6)$ , and  $f_3(X_1, X_3, X_4, X_7) = \delta(x_1 \oplus x_3 \oplus x_4 \oplus x_7)$ .

After encoding, the codewords are transmitted over a noisy channel. One of the simplest noisy channel models is the *binary symmetric channel* where each transmitted bit is flipped (corrupted) with probability  $\epsilon$ . That is, if the input to the channel is denoted as  $X$  and the output of the channel is  $Y$ , then

$$P(Y = 0|X = 1) = \epsilon, \quad (18.270)$$

$$P(Y = 1|X = 1) = 1 - \epsilon, \quad (18.271)$$

$$P(Y = 0|X = 0) = 1 - \epsilon, \quad \text{and} \quad (18.272)$$

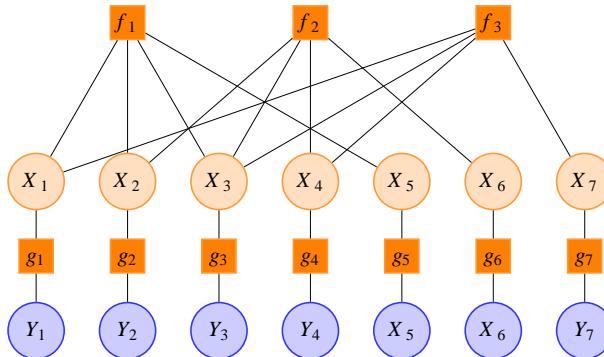

$$P(Y = 1|X = 0) = \epsilon. \quad (18.273)$$

This channel is memoryless and the channel model can be represented as  $P(\mathbf{Y}|\mathbf{X}) = \prod_{i=1}^N P(Y_i|X_i) = \prod_{i=1}^N g_i(X_i, Y_i)$ . Decoding the received symbol  $\mathbf{Y}$  requires to determine the transmitted codeword  $\mathbf{X}$  based on the observed sequence  $\mathbf{Y}$ . This is possible using the posterior probability  $P(\mathbf{X}|\mathbf{Y})$  and exploiting that

$$P(\mathbf{X}|\mathbf{Y}) = \frac{P(\mathbf{Y}|\mathbf{X})P(\mathbf{X})}{P(\mathbf{Y})}, \quad (18.274)$$

$$\propto P(\mathbf{Y}|\mathbf{X})I(\mathbf{X}) = \prod_{i=1}^N P(Y_i|X_i)I(\mathbf{X}), \quad (18.275)$$

where the probability  $P(\mathbf{X})$  is represented by the indicator function  $I(\mathbf{X})$  of the code, i.e., all codewords are assumed to be equally likely. The code together with the noisy channel model can be represented

**FIGURE 18.32**

FG for the binary (7,4) Hamming code and the binary symmetric channel.

by the FG shown in Figure 18.32. The probability  $P(\mathbf{X}|\mathbf{Y})$  is obtained by performing the sum-product algorithm in (18.206) and (18.207) or the max-product algorithm. If the FG contains cycles, as in this example, the decoding problem is iterative and amounts to loopy message passing, also known as turbo decoding in the coding community [70].

## 1.18.7 Implementation/code

In this section, we provide a list of recently developed code for PGMs. With respect to the features of the listed implementations and comparisons to other software, the interested reader is referred to the given references and websites.

- *Infer.NET*: Infer.NET provides a framework for large-scale Bayesian inference in PGMs and is developed at Microsoft Research Cambridge ([research.microsoft.com/en-us/um/cambridge/projects/infernet](http://research.microsoft.com/en-us/um/cambridge/projects/infernet)).
- *WEKA*: WEKA [107] is a data mining software applicable to various tasks in machine learning. Some of the implemented methods are directly related to PGMs such as discriminative parameter learning or structure learning heuristics of BNs.
- *LibDAI*: LibDAI [108] is an open source C++ library providing various exact and approximate inference methods for FGs with discrete variables.
- *HTK*: The HTK toolkit from Cambridge University ([htk.eng.cam.ac.uk](http://htk.eng.cam.ac.uk)) is a state-of-the-art tool used for time-series modeling such as speech recognition. It implements an HMM using discrete and continuous observation probabilities, e.g., mixtures of Gaussians. Furthermore, the tool supports parameter tying, discriminative HMM training and many other methods important for speech recognition.
- *GMTK*: GMTK ([ssli.ee.washington.edu/~bilmes/gmtk](http://ssli.ee.washington.edu/~bilmes/gmtk)) implements dynamic BNs for sequential data processing. It is mainly designed for speech recognition.
- *MMBN*: We recently developed a maximum margin parameter learning algorithm for BN classifiers. Details about the algorithm are given in [48]. The maximum margin parameter training method can

be downloaded at [www.spsc.tugraz.at/tools/MMBN](http://www.spsc.tugraz.at/tools/MMBN). Furthermore, some data sets and example code are provided.

### 1.18.8 Data sets

In the following, we list a selection of common data sets and repositories in machine learning. This list includes only a small subset of publicly available data. Detailed information are supplied in the given references:

- *UCI repository* [109]: One of the largest collection of data sets is the UCI repository. It includes more than 200 data sets for classification, clustering, regression, and time-series modeling. The types of features are categorical, real, and mixed. Benchmark results for most of the data are given in accompanying references.
- *MNIST data* [110]: The MNIST data set of handwritten digits contains 60000 samples for training and 10000 for testing. The digits are centered in a  $28 \times 28$  gray-level image. Benchmark classification results and the data are available at <http://yann.lecun.com/exdb/mnist/>.
- *USPS data*: This data set contains 11000 handwritten digit images collected from zip codes of mail envelopes ([www.cs.nyu.edu/~roweis/data.html](http://www.cs.nyu.edu/~roweis/data.html)). Each digit is represented as a  $16 \times 16$  gray-scale image. Other variants of this data set with different sample sizes are available. More details are given in the Appendix of [37].
- *TIMIT data* [111]: This data set is very popular in the speech processing community. It contains read speech of eight major dialects of American English sampled at 16 kHz. The corpus includes time-aligned orthographic, phonetic, and word transcriptions. This data has been used for various tasks, like time-series modeling, phone recognition and classification [112, 113].
- *Caltech101 and Caltech256*: For image analysis two data sets have been provided by Caltech containing images of objects belonging to either 101 or 256 categories. The data, performance results, and relevant papers are provided at [http://www.vision.caltech.edu/Image\\_Datasets/Caltech101](http://www.vision.caltech.edu/Image_Datasets/Caltech101).

### 1.18.9 Conclusion

PGMs turned out to be one of the best approaches for modeling uncertainty in many domains. They offer an unifying framework which allows to transfer methods among different domains. In this article, we summarized the main elements of PGMs. In particular, we reviewed three types of representations—Bayesian networks, Markov networks, and factor graphs, and we provided a gentle introduction to structure and parameter learning approaches of Bayesian networks. Furthermore, inference techniques were discussed with focus on exact methods. Approximate inference was covered briefly. The interested reader can immerse oneself following the references provided throughout the article.

Many relevant and interesting topics are not covered in detail within this review. One of these topics is approximate inference methods. In fact, tractable approximate inference has been one of the most challenging and active research fields over the past decade. Many of these advanced techniques are discussed in [1, 4, 62, 67, 75]. Another focal point of current research interests are learning

techniques for MNs. While we concentrated on structure and parameter learning of BNs under various perspectives, we completely omitted learning of MNs. Parameter learning of undirected models is essentially performed using iterative gradient-based methods. Each iteration requires to perform inference which makes parameter learning computationally expensive. Score-based structure learning suffers from similar considerations. One advantage of learning the structure of MNs is that there are no acyclicity constraints which renders structure learning in BNs hard.

---

## Glossary

Probabilistic graphical model	a probabilistic graphical model consists of a graph and a set of random variables. It represents a joint probability distribution where the graph captures the conditional independence relationships among the random variables
Bayesian network	a special instance of probabilistic graphical models consisting of a directed acyclic graph and a set of conditional probability tables associated with the nodes of the graph
Markov network	an undirected probabilistic graphical model. The joint probability is defined as the product of clique potentials associated with the graph
Factor graph	a probabilistic graphical model represented by a bipartite graph. One set of nodes represents the RVs in the graph, the other set of nodes the factors. The joint probability is defined as the product of the factors
Probabilistic inference	computation of the distribution or the most likely configuration of some variables while potentially observing some other variables using the joint probability distribution
Parameter learning	specification of the parameters of the probability distributions
Structure learning	specification of the factorization of the joint probability distribution represented by the structure of a probabilistic graphical model

# A Tutorial Introduction to Monte Carlo Methods, Markov Chain Monte Carlo and Particle Filtering

# 19

**A. Taylan Cemgil***Department of Computer Engineering, Boğaziçi University 34342 Bebek, Istanbul, Turkey*

## 1.19.1 Introduction

Monte Carlo (method) (MC) is an umbrella name for an arsenal of numerical techniques for computing approximate estimates via random sampling. The estimates are very often given as the result of an intractable integral and the technique could have been named “numerical integration in high dimensions via random sampling.” The term Monte Carlo was initially coined during 1940’s by von Neumann, Ulam and Metropolis [1,2] as a “cuteness” [3] to refer to the famous casino of 1940s. However, due to the central importance of the subject and wide use of the concept, it soon became an established technical term.

Monte Carlo techniques have been further popularized in applied sciences with the wider availability of computing power, starting from the 90s, most notably in statistics, computer science, operational research and signal processing. In signal processing or operational research, MC experiments are extensively used for assessing the performance of a system or a computational method by generating a random sample of typical inputs. While the term Monte Carlo experiment is also used extensively here, the goal in such applications is “system simulation,” i.e., to understand the properties of a system under uncertainty. The Monte Carlo methods in this paper are slightly different from system simulation; we have a well defined “deterministic” computational problem with a single answer and randomization is used as a tool for approximate computation. As such, we will refer to MC in this context and the applications will be parameter estimation, prediction and model selection.

In this tutorial, we will sketch the aims, the basic techniques and the principles of Monte Carlo computation. After the illustration of the law of large numbers and central limit theorem [4], we cover basic Monte Carlo methods for sampling from elementary distributions: inversion, transform and rejection techniques [5]. We cover also Markov Chain Monte Carlo (MCMC) methods [6]; but rather than giving only the basic algorithms, we sketch the implications of some of the key results in the theory of finite Markov chains [7]. We also cover importance sampling and sequential Monte Carlo methods [8–10]. Finally we give an overview of a more advanced technique, the reversible jump method [11]. Our goal is to provide a self contained introduction with a unified notation, build up a basic appreciation of modern Monte Carlo techniques and to sharpen the readers intuition using several toy examples. Parts of this material have been used in advanced undergraduate and introductory graduate courses on Monte Carlo computation, taken primarily by students interested in techniques for data analysis with signal processing, machine learning or data mining background with some working knowledge of probability

theory and statistics. Experience has shown that even tutorial texts on statistical computation were not immediately accessible due to the notation barrier and students benefited mostly from toy examples. Inevitably, in an elementary tutorial we had to omit a lot of techniques but still tried to retain the “gist” of the subject.

## 1.19.2 The Monte Carlo principle

In an abstract setting, the main principle of a Monte Carlo technique is to generate a set of samples  $x^{(1)}, \dots, x^{(N)}$  from a target distribution  $\pi(x)$  to estimate some features of this target density  $\pi$ . Features are simply expectations of “well behaving” functions that can be approximated as averages:

$$\mathbb{E}_\pi(\varphi(x)) \approx \frac{\varphi(x^{(1)}) + \dots + \varphi(x^{(N)})}{N} \equiv \bar{E}_{\varphi,N}.$$

Provided that  $N$  is large enough, we hope that our estimate  $\bar{E}_{\varphi,N}$  converges to the true value of the expectation  $\mathbb{E}_\pi(\varphi(x))$ . More concrete examples of test functions  $\varphi(x)$  will be provided in the next section. For independent and identically distributed samples, this is guaranteed by two key mathematical results: the strong Law of Large Numbers (LLN) and the Central Limit Theorem (CLT) [4, 12]. Assuming that  $\mathbb{E}_\pi(\varphi(x)) = \mu$  and  $V_\pi(\varphi(x)) = \sigma^2$  (we have finite mean and variance), the LLN states that

$$\bar{E}_{\varphi,N} \rightarrow \mu \quad \text{a.s.}$$

Here, a.s. denotes convergence *almost surely*, meaning that  $\Pr\{\lim_{N \rightarrow \infty} |\mu - E_{\varphi,N}| = 0\} = 1$ . Whilst fluctuations are inevitable (since our approximation will be based on a random and finite sample set  $x^{(1)} \dots x^{(N)}$ ) we wish these fluctuations to be small. This is guaranteed by the CLT: for sufficiently large  $N$ , the fluctuations are approximately Gaussian distributed

$$\bar{E}_{\varphi,N} \sim \mathcal{N}\left(\bar{E}_{\varphi,N} | \mu \sigma^2 / N\right)$$

and the variance of the estimate drops with increasing  $N$ , while its mean is the desired value. This result has important practical consequences. If we can generate i.i.d. samples from the distribution of  $x$ , denoted as  $\pi(x)$ , we can estimate expectations of  $\varphi(x)$ :

1. Monte Carlo provides a “noisy” but unbiased estimate of the true value  $\mu = \mathbb{E}_\pi \varphi(x)$ .
2. The error behaves as  $O(N^{-1/2})$ .
3. The convergence rate is independent of the dimensionality of  $x$ .

The third point is particularly important. It suggests that, at least in principle, with a quite small number of samples one can compute approximate solutions for arbitrary large parameter estimation problems. All one needs is obtaining independent samples. The difficulty with this approach, however, is in generating independent samples from a target distribution  $\pi(x)$  and various Monte Carlo methods aim to provide techniques for this.

### 1.19.2.1 Illustration of the MC principle

In this section, we will illustrate the MC principle, that averages obtained from several random experiments tends to stabilize. As the running example we will focus on a problem mentioned in the famous letters between Pascal and Fermat, first writings that are considered to mark the start of the modern probability theory [13]. A French nobleman and gambler Chevalier de Méré contacted Pascal. Méré was betting that in four rolls of a single die, at least one six would turn up. Later, Méré “extended” his schema where he was betting that in 24 rolls of two dice, a pair of sixes would turn up. He was not happy with this new schema and was calling Pascal for an explanation.

Indeed, the analytical solution for this problem is elementary; we merely calculate the probability that in 4 consecutive independent throws at least a 6 comes up. A quick calculation shows indeed there is a slight advantage for Méré:

$$\begin{aligned}\Pr\{\text{Méré wins in 4 throws}\} &= 1 - \Pr\{\text{no 6 is thrown}\}^4 \\ &= 1 - (5/6)^4 = 0.5177.\end{aligned}$$

In a sense, this experiment is equivalent to playing head and tail with a carefully forged coin. The bias is small and may not be easily detected by a naive opponent. Like all Casinos, Méré exploited this subtle bias to his advantage to earn money on average in repeated trials.

However, the analytical solution for the two dice game reveals that throwing the dice only 24 times is not a good bet for Méré:

$$\Pr\{\text{Méré wins in 24 throws}\} = 1 - (35/36)^{24} = 0.4914,$$

but with 25 throws, the odds turn into his favor as

$$\Pr\{\text{Méré wins in 25 throws}\} = 1 - (35/36)^{25} = 0.5055.$$

The natural question here is if one could detect with certainty that there is indeed a systematic deviation from 0.5 by just looking at the outcomes of a sequence of games. Indeed for many problems of interest, such probability calculations will be significantly harder, if at all possible, and it is natural to ask how reliable it is to estimate such quantities using data obtained from MC experiments.

Playing the game repetitively is a MC experiment. By just recording the outcome of each game (and the total number of games played), we could in principle estimate the winning probability. To be more precise, consider the single die, 4 times throw game. Let  $x_k^{(n)}$  denote the outcome of the die at  $k$ th throw in the  $n$ th game. Formally, a game is represented by the tuple  $x \equiv (x_1, x_2, x_3, x_4)$ . We assume a fair die, as such for  $k = 1, \dots, 4$

$$x_k \sim \mathcal{U}(1, 6),$$

where  $\mathcal{U}(a, b)$  denotes a uniform distribution on integers  $x$  such that  $a \leq x \leq b$ . Since each throw in the game is independent, the target distribution  $\pi(x)$  is the uniform distribution on  $\mathcal{X} = \{1, \dots, 6\}^4$  and each game is simply a random point in  $\mathcal{X}$ .

To estimate the probability of winning, we define formally the indicator function for winning the  $n$ th game

$$\varphi(x^{(n)}) = \mathbb{I} \left\{ 0 < \sum_{k=1}^4 \mathbb{I} \left\{ x_k^{(n)} = 6 \right\} \right\}.$$

Here,  $\mathbb{I}\{x\}$  is an indicator function that is 1 if  $x$  is true and 0 if false. The test function  $\varphi$  looks awkward but it just checks if in 4 throws at least a 6 is obtained. Finally, the probability  $\theta$  that Méré wins in 4 throws can be estimated as

$$\theta = \mathbb{E}_\pi(\varphi(x)) \approx \frac{1}{N} \sum_{n=1}^N \varphi(x^{(n)}) = \bar{E}_{\varphi,N}.$$

Similarly, for the two dice, 24 throws game, formally we let  $x_{i,k}^{(n)}$  denote the outcome of the die  $i$  at  $k$ th throw in the  $n$ th game.

$$\begin{aligned} \varphi(x^{(n)}) &= \mathbb{I} \left\{ 0 < \sum_{k=1}^{24} \mathbb{I} \left\{ x_{1,k}^{(n)} = 6 \right\} \mathbb{I} \left\{ x_{2,k}^{(n)} = 6 \right\} \right\}, \\ \bar{E}_{\varphi,N} &= \frac{1}{N} \sum_{n=1}^N \varphi(x^{(n)}). \end{aligned} \quad (19.1)$$

The mean and variance of  $\varphi(x^{(n)})$  are

$$\begin{aligned} \mathbb{E}(\varphi(x^{(n)})) &= \theta \\ \text{Var}\{\varphi(x^{(n)})\} &= \theta(1 - \theta) \end{aligned}$$

respectively.<sup>1</sup> As these are finite, the strong law of large numbers applies. The law guarantees the very intuitive fact that with increasing number of games  $N$ , the estimates become increasingly more and more accurate. Technically, when  $N \rightarrow \infty$  we have convergence

$$\bar{E}_{\varphi,N} \rightarrow \theta.$$

The “speed” is given by the central limit theorem, that says that for large  $N$  the estimate is distributed

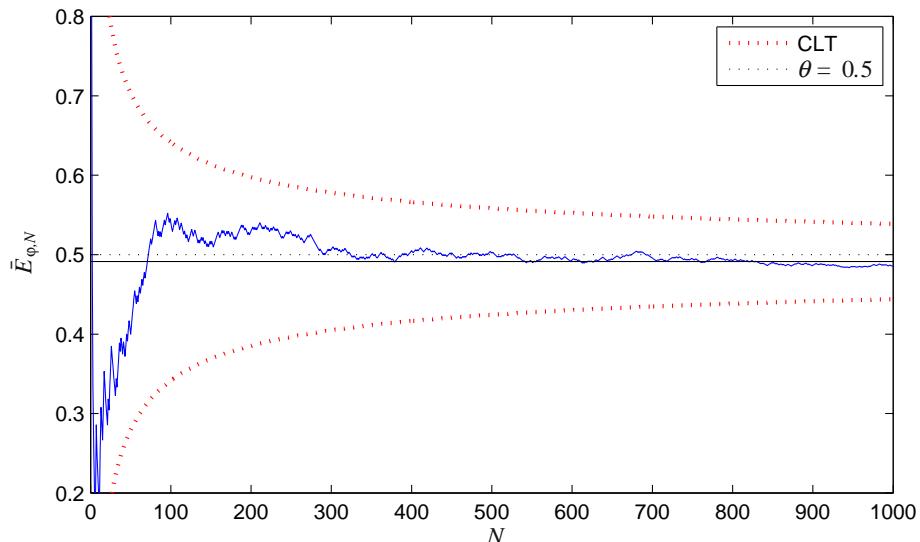

$$\bar{E}_{\varphi,N} \sim \mathcal{N}(\bar{E}_{\varphi,N} | \theta, \theta(1 - \theta)/N).$$

Provided that we can generate independent samples, the error will be  $O(N^{-1/2})$ . The most important aspect of this convergence result, that can not be overemphasized is that the error does not depend on the dimensionality of the parameter to be estimated!

To illustrate these concepts with an example consider Figure 19.1 where we simulate the estimate for a two dice, 24 throw game case for several  $N$ . The path shows the estimate  $\bar{E}_{\varphi,N}$  in Eq. (19.1) for each  $N$ . We can see that the path converges to the true value. For each  $N$ , the error bars correspond to the standard deviations given by the central limit theorem.

---

<sup>1</sup>The mean and variance of a Bernoulli random variable.

**FIGURE 19.1**

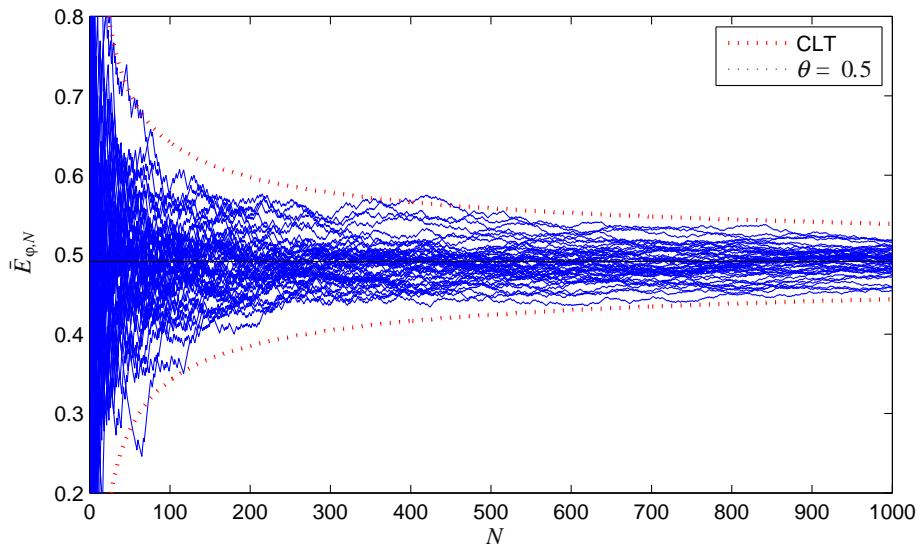

The estimate of winning probability for a pair of 6 in 24 throws game. The horizontal solid line shows the true odds  $\theta_{\text{true}}$  that is smaller than 0.5. The path shows the estimate  $\bar{E}_{\varphi, N}$  as a function of  $N$ . Law of large numbers says that all these curves eventually will converge to the true  $\theta_{\text{true}}$ , shown as a solid line.

To illustrate the implication of the central limit theorem, consider now a collection of estimates, obtained from results of  $N$  games per night with a total of  $K$  different nights. Formally, the outcome of the  $n$ th game at the  $k$ th night is denoted as  $\varphi(x^{(n,i)})$  for  $i = 1, \dots, K$  and  $n = 1, \dots, N$ . The estimate at the  $i$ th night after observing the  $N$ th game as

$$\bar{E}_{\varphi, N}^{(i)} = \frac{1}{N} \sum_{n=1}^N \varphi(x^{(n,i)}).$$

Now, we visualise all the paths together, where each path is depicted corresponds to the sequence of estimates for each independent night  $i$  (Figure 19.2). Each path corresponds to the estimate as a function of the number of games played  $N$ . We can clearly see that all the independent paths eventually stay in the “narrow tube,” as predicted by the CLT.

In the above examples, instead of experimenting with real dice, we have simulated the experiment on a computer. It turns out that it is surprisingly delicate to simulate “truly” random numbers on deterministic hardware. Instead, *pseudo-random numbers* are generated using deterministic algorithms and are briefly reviewed in the next section.

**FIGURE 19.2**

Verification of the central limit theorem. We estimate the winning probability for the 2 dice, 24 throws game. Each path corresponds to the estimate  $\bar{E}_{\varphi, N}^{(i)}$  as a function of  $N$ , where  $i = 1, \dots, K$  denotes the independent sequences of games. CLT says that at any fixed  $N$ ,  $\bar{E}_{\varphi, N}^{(i)}$  the values of these estimates is approximately normal distributed with standard deviation  $\sigma/\sqrt{N}$ . For each  $N$ , the red dotted curves designate the  $[\theta_{\text{true}} - 3\sigma/\sqrt{N}, \theta_{\text{true}} + 3\sigma/\sqrt{N}]$ . It is a common folklore in statistics to plot the  $\pm 3\sigma$  interval for a univariate Gaussian as this interval contains more than 99% of the probability mass. As given by the CLT, the paths exit the  $\pm 3\sigma/\sqrt{N}$  tube only occasionally.

### 1.19.2.2 Random number generation

“The generation of random numbers is too important to be left to chance”<sup>2</sup> and truly random numbers are impossible to generate on a deterministic computer. Published tables or other mechanical methods such as throwing dice, flipping coins, shuffling cards or turning the roulette wheels are clearly not very practical for generating the random numbers that are needed for computer simulations. Other techniques, more suited to computation exist; these rely on chaotic behavior, such as the thermal noise in Zener diodes or other analog circuits as well as the atmospheric noise (see, e.g., [www.Random.org](http://www.Random.org)) or running a hash function against a frame of a video stream. Still, the vast amount of random numbers are obtained from *pseudo-random number* generators. Apart from being very efficient, one additional advantage of these techniques is that the sequences are reproducible by setting a seed, this property is key for debugging MC code.

The most well known method for generating random numbers is based on a Linear Congruential Generator (LCG). The theory is well understood, the method is easy to implement and it runs very fast.

<sup>2</sup>Wikipedia entry on Pseudo Random Number generator.

A LCG is defined by the recurrence relation:

$$x_{n+1} \equiv (ax_n + c) \pmod{M}.$$

If the coefficients  $a$  and  $c$  are chosen carefully (e.g., relatively prime to  $M$ ),  $x$  will be roughly uniformly distributed between 0 and  $M - 1$ . Roughly uniformly means that, the sequence of numbers  $x_n$  will pass many reasonable tests for randomness. A such test suite is the so called DIEHARD tests, developed by George Marsaglia [14] that are a battery of statistical tests for measuring the quality of a random number generator.

A more recently proposed generator is the Mersenne Twister algorithm, by Matsumoto and Nishimura [15]. It has several desirable features such as a long period and being very fast. Many public domain implementations exist and it is the preferred random number generator for statistical simulations and Monte Carlo computations.

Good random number generators provide uniformly distributed numbers on an interval. Hence, provided we have a good random number generator that can generate uniformly random integers (say between 0 and  $2^{64} - 1$ ), the resulting integers can be used to generate double precision numbers almost uniformly distributed in  $[0, 1]$ . We will assume in the sequel that we have access to a good uniform random number generator that can generate real numbers on  $[0, 1]$ ; knowing that in practice such a generator generates only rational numbers (say double precision floating point numbers). We will denote this generator by  $\mathcal{U}(0, 1)$  and denote a realization, i.e., a sample drawn as  $u \sim \mathcal{U}(0, 1)$ .

### 1.19.3 Basic techniques for simulating random variables

The techniques described in this section sketch the basic techniques to generate (mostly univariate and bivariate random variables) with a given density. This is a surprisingly deep and interesting subject touching many facets of computer science. For further information, the reader is invited to look at the fantastic book by Luc Devroye, on non uniform random variate generation [16].

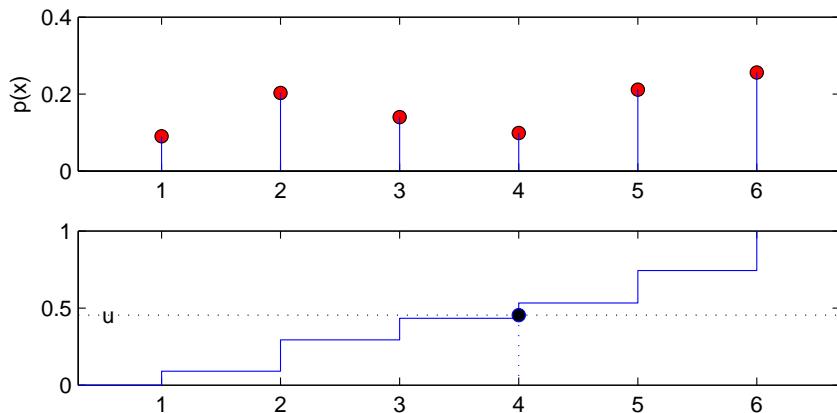

#### 1.19.3.1 Inversion

The basic technique is based on transformation; we generate a uniform random number  $u \sim \mathcal{U}(0, 1)$  and transform it to obtain  $x = g(u)$  where  $g$  is a function. This method requires calculating the cumulative density function and inverting it. Recall the definition of a Cumulative Density function (CDF)

$$F_X(x) = \int_{-\infty}^x f_X(\tau) d\tau,$$

where  $f_X$  is the probability density of the random variable  $X$ . The key observation behind the inversion method is the fact that when  $X \sim f_X$ , the quantity  $U = F_X(X)$ , when viewed as a random variable, is uniformly distributed on  $[0, 1]$ . To see this, assume that the inverse of  $F_X$  exists, and we can find  $X = F_X^{-1}(U)$ ,

$$\begin{aligned} F_X(x) &= \Pr\{X < x\}, \\ F_X(F_X^{-1}(u)) &= \Pr\{F_X^{-1}(U) < F_X^{-1}(u)\}, \\ u &= \Pr\{U < u\} \quad 0 \leq u \leq 1. \end{aligned}$$

**FIGURE 19.3**

Generation of samples from a discrete distribution. We generate  $u$  uniformly on  $[0, 1]$  and find the corresponding  $x$  via the generalised inverse  $F^{-}(u)$ . The discrete case is particularly intuitive: think of dividing a stick of length 1 into pieces of length  $\pi_i = f_X(x_i)$  and label each region with  $x_i$ . Select a point  $u$  uniformly random and return the label of the region that  $u$  falls in.

By taking the derivative, we see that the density of  $u$  is uniform. The argument works also in the opposite direction: when we first choose uniform  $U$  and pass it through the function  $X = F_X^{-1}(U)$ , the density of  $X$  will be  $f_X$ . To allow for discrete distributions or continuous densities with atoms (where single points have positive probability mass), we define the generalised inverse CDF

$$F^{-}(u) \equiv \inf\{x : F(x) \geq u\}.$$

The  $x$  generated by this method are guaranteed to be distributed by  $f_X$ . Figure 19.3 illustrates this construction. The generalized inverse allows for jumps in the cumulative density when atoms have nonzero probability (see Figure 19.4).

**Example 1.** Exponential random variables can be derived by the inversion method from uniform samples. The exponential density with *rate* parameter  $\lambda$  is

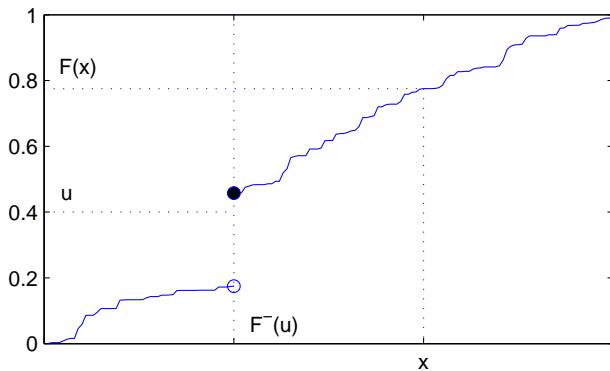

$$\mathcal{E}(x; \lambda) = \lambda \exp(-\lambda x).$$

The CDF of the exponential distribution is found as

$$F(x) = \int_0^x \lambda \exp(-\lambda \tau) d\tau = -\exp(-\lambda x) + 1.$$

The generalised inverse is obtained via

$$\begin{aligned} u &= F(x) = 1 - \exp(-\lambda x), \\ x &= -\log(1-u)/\lambda = F^{-}(u). \end{aligned}$$

**FIGURE 19.4**

Visualisation of the generalised inverse. The blue curve shows a CDF of a probability distribution with an atom, as can be seen from the discontinuity. For a given probability  $u$ ,  $F^-(u)$  is the “minimum”  $x$  such that the probability of the interval  $(\infty, x]$  is equal or exceeds  $u$ .

We can even avoid calculating  $1 - u$  by noting that both  $u$  and  $w = 1 - u$  are distributed uniformly on  $[0, 1]$ , so

$$x = F^-(w) = -\log(w)/\lambda.$$

### 1.19.3.2 Transformation

The generalised inverse method works by applying a suitable function (the generalized inverse  $F^-(u)$ ) on a random input with a known density ( $u$  with a uniform density). This method can be made more general by a technique known as the change of variables [4].

To illustrate the transformation method, we will first give an example where the mapping function will be affine (that is linear plus a constant term). Suppose we are given a random variable  $X$  with density  $f_X(x)$  and wish to find the density of  $Y$  where

$$Y = aX + b.$$

It is clear that the density of  $Y$ , denote by  $f_Y$  should be somewhat related to  $f_X$ . For example if  $X$  is uniform ( $f_X = \mathcal{U}$ ) on  $[0, 1]$  and  $a = 2$  and  $b = -1$ , one could see that  $Y$  is uniform on  $[-1, 1]$ . The general case, when  $f_X$  is any density, is perhaps slightly harder to see. To find the density of  $Y$ , we first will find the CDF  $F_Y(y)$  of  $Y$  and obtain the desired density  $f_Y(y)$  by taking the derivative w.r.t.  $y$ . In particular,

$$F_Y(y) = \Pr\{Y \leq y\} = \Pr\{aX + b \leq y\} = \begin{cases} \Pr\{X \leq (y - b)/a\}, & a > 0, \\ \Pr\{X \geq (y - b)/a\}, & a < 0. \end{cases}$$

By taking derivative we see that the density is given by

$$f_Y(y) = \frac{dF_Y}{dy} = \frac{1}{|a|} f_X((y - b)/a).$$

For the more general case, we have a more general mapping  $g$  where

$$\begin{aligned} Y &= g(X), \\ X &= g^{-1}(Y). \end{aligned}$$

The density can be found as

$$\begin{aligned} F_Y(y) &= \Pr\{Y \leq y\} = \Pr\{g(X) \leq y\} = \Pr\{X \leq g^{-1}(y)\} \\ f_Y(y) &= \frac{dF_Y}{dy} = f_X(g^{-1}(y)) \left| \frac{dg^{-1}(y)}{dy} \right| \equiv f_X(x(y)) |J(y)| \end{aligned} \quad (19.2)$$

here, the derivative of  $g^{-1}$  is denoted as the *Jacobian* and the absolute value ensures the positivity of the densities. In many textbooks it is common to drop the explicit reference to the function  $g$ ; authors often use  $y(x)$  for  $y = g(x)$  and  $x(y)$  for the inverse  $g^{-1}(y)$ . In the sequel, we will also adopt this notation. The multivariate case is analogous; here we illustrate the bivariate case, the most encountered case in derivations. The function  $g$ , that is also called a *transform*, is defined as

$$(y_1, y_2) = g(x_1, x_2).$$

If we can invert  $g$ , which is not always easy to do analytically, we find

$$\begin{aligned} x_1 &= x_1(y_1, y_2), \\ x_2 &= x_2(y_1, y_2). \end{aligned}$$

The derivative term is the *Jacobian* determinant defined as

$$J = \begin{vmatrix} \partial x_1 / \partial y_1 & \partial x_2 / \partial y_1 \\ \partial x_1 / \partial y_2 & \partial x_2 / \partial y_2 \end{vmatrix} = J(y_1, y_2).$$

Consequently, the density of the transformed variable, similar to Eq. (19.2), is given by

$$f_Y(y_1, y_2) = f_X(x_1(y_1, y_2), x_2(y_1, y_2)) |J(y_1, y_2)|.$$

**Example 2.** To illustrate the method, we describe the Box-Müller method for generating normal random variables. The Box-Müller method generates the pair  $(x_1, x_2)$

$$\begin{aligned} x_1 &\sim \mathcal{E}(x_1; 1/2) = \frac{1}{2} \exp(-x_1/2), \\ x_2 &\sim \mathcal{U}(x_2; 0, 2\pi) = \frac{1}{2\pi} \mathbb{I}\{0 \leq x_2 \leq 2\pi\}, \end{aligned}$$

where  $x_1$  is the square of the magnitude and  $x_2$  is the angle of a point in polar coordinates. The method transforms this point into cartesian coordinates

$$\begin{aligned} y_1 &= \sqrt{x_1} \cos(x_2), \\ y_2 &= \sqrt{x_1} \sin(x_2). \end{aligned}$$

It turns out, that  $y_1$  and  $y_2$  obtained via this method are independent and unit Gaussian ( $\mathcal{N}(0, 1)$ ) distributed. To show this, we find the inverse mapping

$$\begin{aligned}x_1 &= y_1^2 + y_2^2, \\x_2 &= \arctan(y_2/y_1).\end{aligned}$$

The Jacobian determinant is found as

$$J = \begin{vmatrix} \partial x_1 / \partial y_1 & \partial x_2 / \partial y_1 \\ \partial x_1 / \partial y_2 & \partial x_2 / \partial y_2 \end{vmatrix} = \begin{vmatrix} 2y_1 & \frac{1}{1+(y_2/y_1)^2} \frac{-y_2}{y_1^2} \\ 2y_2 & \frac{1}{1+(y_2/y_1)^2} \frac{1}{y_1} \end{vmatrix} = 2.$$

The resulting density is

$$\begin{aligned}f_Y(y_1, y_2) &= \mathcal{E}(x_1(y_1, y_2); 1/2)\mathcal{U}(x_2(y_1, y_2); 0, 2\pi)|J(y_1, y_2)| \\&= \frac{1}{2}\exp(-(y_1^2 + y_2^2)/2)\frac{1}{2\pi}2 = \frac{1}{\sqrt{2\pi}}\exp(-y_1^2/2)\frac{1}{\sqrt{2\pi}}\exp(-y_2^2/2) \\&= \mathcal{N}(y_1; 0, 1)\mathcal{N}(y_2; 0, 1).\end{aligned}$$

### 1.19.3.3 Rejection sampling

Rejection sampling is a technique for indirectly sampling from a target distribution  $\pi$  by sampling from a *proposal* distribution  $q$ . We reject some of the generated samples to compensate for the fact that  $q \neq \pi$ . The algorithm is as follows: We sample  $x^{(i)}$  for  $i = 1, \dots, N$  independently from  $q$ . We accept the sample  $x^{(i)}$  with acceptance probability  $a(x^{(i)})$  where the acceptance probability is

$$a(x) \equiv \frac{\pi(x)}{Mq(x)}.$$

Here,  $M$  is a positive number that guarantees  $\pi(x) \leq Mq(x)$  for all  $x$ , i.e., that  $Mq(x)$  completely covers the density  $\pi(x)$ . The approach also works when the normalization constant  $Z$  of  $\pi$  is unknown, that is we can only evaluate  $\phi$  pointwise where

$$\pi(x) = \frac{1}{Z}\phi(x).$$

In this case, we let the acceptance probability be

$$\tilde{a}(x) \equiv \frac{\phi(x)}{\tilde{M}q(x)},$$

where  $\phi(x) \leq \tilde{M}q(x)$  for all  $x$ . If a suitable  $M$  (or  $\tilde{M}$ ) can be found, the algorithm is simple to implement and requires only sampling from  $q$  and pointwise evaluation of  $\phi$ . To understand the idea behind rejection sampling, we observe that for any density function  $f(x)$ , (including obviously our target  $\pi$  and the proposal  $q$ ) we have the following identity:

$$f(x) = \int_0^{f(x)} 1 d\tau = \int \mathbb{I}\{0 \leq \tau \leq f(x)\} d\tau. \quad (19.3)$$

In other words,  $f(x)$  can be written as a *marginal density* of a distribution with density  $\mathbb{I}\{0 \leq \tau \leq f(x)\}$  on the extended space  $(x, \tau)$ . This density is simply the uniform density over the volume under the curve  $f(x)$ . The equation Eq. (19.3) says that generating samples from  $f(x)$  is equivalent to uniformly generating samples on the set  $A = \{(x, \tau) : 0 \leq \tau \leq f(x)\}$  and then simply ignoring the  $\tau$  coordinate. When  $f(x) = \phi(x)/Z$  and we don't know  $Z$

$$f(x) = \frac{1}{Z} \phi(x) = \frac{1}{Z} \int_0^{\phi(x)} 1 d\tau = \frac{1}{Z} \int \mathbb{I}\{0 \leq \tau \leq \phi(x)\} d\tau. \quad (19.4)$$

By integrating over  $x$  on both sides we get the normalization constant  $Z$  as the area of the region  $A = \{(x, \tau) : 0 \leq \tau \leq \phi(x)\}$ :

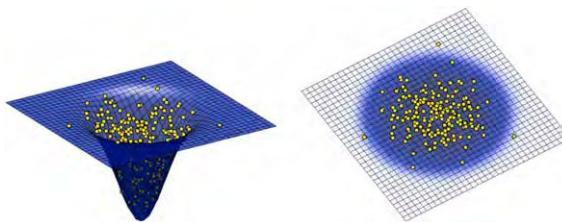

$$Z = \int \int \mathbb{I}\{0 \leq \tau \leq \phi(x)\} d\tau dx.$$

Hence

$$f(x) = \frac{\int \mathbb{I}\{0 \leq \tau \leq \phi(x)\} d\tau}{\int \int \mathbb{I}\{0 \leq \tau \leq \phi(x)\} d\tau dx}.$$

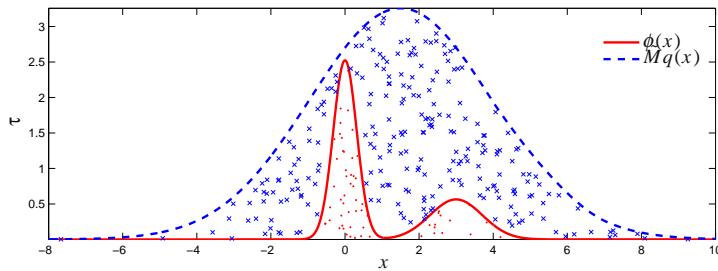

This equation suggests that  $f(x)$  is the marginal density of uniform density over the set  $A$ . A useful metaphor for understanding the concept is of thinking fishes in a lake [5], where  $x$  is a coordinate on the water surface and  $\tau$  is the depth, which is illustrated in Figure 19.5. If all fishes in the lake are distributed uniformly in the water, when viewed from above they will be marginally distributed with density  $f(x)$  (see Figure 19.6).

Note that the reasoning of Eq. (19.3) works also in the reverse direction: when we have samples  $x^{(i)}$  for  $i = 1, \dots, N$  generated from a proposal  $q(x)$ , we can select the  $\tau$  coordinate for each  $x^{(i)}$  simply by choosing  $\tau^{(i)}$  uniformly on  $[0, Mq(x^{(i)})]$ . The resulting pairs  $(x^{(i)}, \tau^{(i)})$  will be uniformly distributed on the set  $A_{Mq} = \{(x, \tau) : 0 \leq \tau \leq Mq(x)\}$ . Provided that  $\phi(x) \leq Mq(x)$ , if we now select only the pairs such that  $\tau^{(i)} < \phi(x^{(i)})$ , these accepted tuples will be distributed uniformly on the set  $A_\phi = \{(x, \tau) : 0 \leq \tau \leq \phi(x)\}$ . But, by Eq. (19.4), the marginal of this uniform density will be  $p$ .

**FIGURE 19.5**

Fishes in a lake. We view the bivariate density function  $f(x)$  as the bottom surface of a lake. Take uniformly distributed points in this volume. When viewed from above, i.e., when we ignore their depth, the points will be distributed more densely where the lake is deeper.

**FIGURE 19.6**

Rejection sampling. Sampling  $x$  from the proposal  $q(x)$  and then sampling the associated  $\tau$  uniformly on  $[0, \tilde{M}q]$  results in uniformly distributed tuples  $(x, \tau)$  (all the points under  $\tilde{M}q(x)$ ). Restricting those to only points such that  $\tau \leq \phi(x)$  provides the accepted points (red dots), the other points are rejected (blue crosses). Note that the probability  $\Pr\{\tau \leq \phi(x)\} = \phi(x)/\tilde{M}q(x)$  is the acceptance probability  $\tilde{\alpha}(x)$ .

## 1.19.4 Markov Chain Monte Carlo

In Markov Chain Monte Carlo methods [6, 17–20], instead of directly attempting to sample from  $\pi(x)$ , we sample from a Markov chain with transition density (“kernel”)  $K(x^{(n)}|x^{(n-1)})$  where  $n$  indexes the sample number.<sup>3</sup> To see how this connects to our ultimate desire to sample from a target  $\pi(x)$  consider first drawing samples from the Markov chain. Given an initial state  $x^{(1)}$ , we draw  $x^{(2)}$ , then conditioned on  $x^{(2)}$  we draw  $x^{(3)}$  and so on by iteratively drawing from  $K(x^{(n)}|x^{(n-1)})$ . The distribution of state occupancy at time  $n$ ,  $\pi_n(x)$ , is found from

$$\pi_n(x) = \int K(x|x')\pi_{n-1}(x')dx'$$

---

<sup>3</sup>Note that, the sample number is conceptually different than the “time” index in a time series model; for example, in a time series model  $x_t$  corresponds to the state at time  $t$ , whereas here  $x^n$  can correspond to a vector of all state variables—a full state trajectory. In this context, it is convenient to think of  $n$  simply as the iteration number of the sampling algorithm and  $x^{(n)}$  as a particular realisation of all random variables being sampled.

which we write more compactly as  $\pi_n = K\pi_{n-1}$ . This generates a sequence of marginal distributions  $\pi_1, \pi_2, \dots$ . Does this sequence of distributions converge and, if so, what does it converge to? A stationary distribution,  $\pi$  satisfies  $\pi = K\pi$ . A key result here is that for an ergodic chain (i.e., irreducible (chain) and aperiodic (chain)) there exists a unique distribution  $\pi$  for which  $\pi = K\pi$  and therefore a unique stationary distribution to which all the occupancy distributions converge, irrespective of their initial states [7]. For finite state Markov chains, irreducibility means that each state can be visited starting from each one (related to connectedness of the state transition diagram) and aperiodicity means that each state can be visited at any time  $n$  larger than some fixed number.

The first question is, given a Markov chain with transition kernel  $K$ , how to find the marginal distribution  $\pi_n(x)$  for large  $n$ . The second question is how to construct a transition kernel that is easy to sample from and converges to the desired target distribution. In the finite state case, a solution to the first question is provided by the eigenvalue-eigenvector decomposition of the transition matrix that will be introduced in the next section. The answer to the second question turns out to be very elegant and simple and underlies the celebrated Metropolis-Hastings Markov Chain Monte Carlo method [2,21] that will be covered afterwards.

### 1.19.4.1 Stationary distribution of a Markov Chain with finite number of states

We first focus our attention on the convergence of a Markov chain and illustrate results in the finite state case. The finite state case may seem to be too restrictive, and in a sense it indeed is. From a mathematical perspective, the theory of Markov chains for more general spaces is more delicate and it does not rely on linear algebra. Nevertheless, it turns out that the results for more general state spaces have similar flavor and understanding what is happening in the finite case provides the basic intuition about the issues involved. For technicalities on countable state spaces, see [7] or uncountable state spaces, see [22], Chapter 13.

For the finite state case, we proceed as follows. First, we note that the marginals of a Markov chain satisfy the following recursive relation

$$\pi_n(x_n) = \sum_{x_{n-1}} K(x_n|x_{n-1})\pi(x_{n-1}).$$

Now, a probability mass function on a finite state space is simply a vector of positive entries which sum up to one so in index notation we write

$$\pi_n(i) = \sum_j K_{i,j}\pi_{n-1}(j),$$

where the marginal distribution of the chain is denoted by  $\pi_n(i) \equiv \pi_n(x_n)$  and the transition model is denoted by the transition matrix  $K$  with the entries  $K_{i,j} = K(x_n = i|x_{n-1} = j)$ . Adopting the matrix notation, we write  $\pi_n = K\pi_{n-1}$ . This gives the expression for the marginal  $\pi_n$  as a function of the initial occupancy density  $\pi_0$

$$\pi_n = K^n\pi_0.$$

This is simply a (linear) fixed point iteration and the question reduces to finding a stationary point  $\pi$  that satisfies

$$\pi = \lim_{n \rightarrow \infty} K^n\pi_0 \equiv K^\infty\pi_0,$$

where  $K^\infty = \lim_{n \rightarrow \infty} K^n$ . An eigen-decomposition of the transition matrix  $K$

$$K = D\Lambda D^{-1}$$

provides insight about the limit behavior of  $K^n$  where  $D$  is the matrix of eigenvectors and  $\Lambda$  is a diagonal matrix of eigenvalues. It turns out that for transition matrices  $K$ , the maximum eigenvalue is always 1. If the magnitude of the second largest eigenvalue  $\lambda_2$  is strictly less,  $|\lambda_2| < 1$ , we have a unique stationary distribution. To see this consider

$$K^n = D\Lambda D^{-1}D\Lambda D^{-1} \cdots D\Lambda D^{-1} = D\Lambda^n D^{-1}.$$

But as  $\Lambda$  is diagonal,  $\Lambda^n$  for large  $n$  is a matrix very close to all zeros matrix with only a single 1 on the diagonal. Say without loss of generality that the first eigenvalue  $\lambda_1 = 1$  is at position  $\Lambda(1, 1)$  (otherwise construct a permutation matrix  $P$  and consider  $T = (DP^\top)(P\Lambda P^\top)(PD^{-1}) = \tilde{D}\tilde{\Lambda}\tilde{D}^{-1}$ ). Then  $K^\infty$  is the rank-one matrix given by the outer product

$$K^\infty = D(:, 1)D^{-1}(1, :).$$

Here,  $D(:, i)$  denotes the  $i$ th column of the matrix  $D$  and  $D^{-1}(i, :)$  is the  $i$ th row of  $D^{-1}$ . These are respectively the right and left eigenvectors. But what is  $D^{-1}(1, :)$ ? By definition we have

$$\begin{aligned} D^{-1}K &= \Lambda D^{-1}, \\ D^{-1}(1, :)K &= \Lambda(1, 1)D^{-1}(1, :) = D^{-1}(1, :). \end{aligned}$$

But as  $K$  is a transition matrix, all its columns sum up to one. In other words, if we would left multiply  $K$  by an all-ones vector  $v$ , we get  $vK = v$  so it is easy to see that the left eigenvector corresponding to the largest eigenvalue is proportional to the all ones vector

$$D^{-1}(1, :) = (1 \ 1 \ \dots \ 1).$$

But this implies that the columns of  $K^\infty$  are all the same as

$$K^\infty = [D(:, 1), D(:, 1), \dots, D(:, 1)].$$

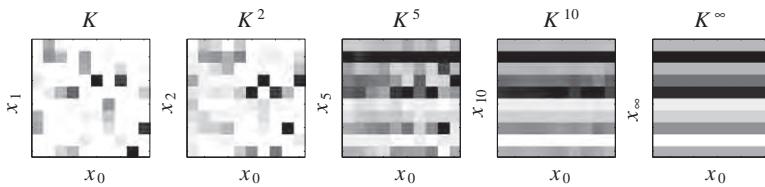

We can conclude that, regardless of the initial state, the probabilities are all the same and the stationary density is proportional to the (right) eigenvector corresponding to the eigenvalue  $\lambda_1 = 1$ . This is pictorially illustrated using a random transition matrix  $K$  in Figure 19.7. In the MC literature, we use the term transition kernel instead of transition matrix as the latter is restricted only to countable state spaces.

A natural question to ask is how fast a chain converges to stationarity. For Markov Chains, the rate of convergence is governed by the second eigenvalue. The convergence to the stationary distribution is geometric and is given by

$$\|K^n\pi_0 - \pi\|_{\text{var}} \leq C|\lambda_2|^n,$$

where  $C$  is a positive constant and the function  $\|\cdot\|_{\text{var}}$  measures the distance between two densities. It is known as the total variation norm and is given by

$$\|P - Q\|_{\text{var}} \equiv \frac{1}{2} \sum_{s \in \mathcal{X}} |P(s) - Q(s)|.$$

**FIGURE 19.7**

The powers  $K^\tau$  of a transition matrix  $K(x_n = i|x_{n-1} = j)$  with  $\tau = 1, 2, 5, 10, \infty$ . Darker colors correspond to higher transition probabilities. The identical columns of  $K^\infty$  depicts the stationary distribution, which is reached independent of any starting density. We see that for this transition matrix  $K$ , even after a few iterations  $\tau$  the columns of  $K^\tau$  are close to the stationary density, suggesting a rapid convergence. The magnitude of the second eigenvalue is  $|\lambda_2| \approx 0.64$  which verifies that our observation is indeed correct.

However, for a large transition matrix, it may be hard to show algebraically that  $|\lambda_2| < 1$ . Fortunately, there is a convergence result that states that if  $K$  is irreducible and aperiodic, then there exist  $0 < r < 1$  and  $C > 0$  s.t.

$$\|K^n\pi_0 - \pi\|_{\text{var}} \leq Cr^n,$$

where  $\pi$  is the invariant distribution [20]. This result also generalizes to more general Markov chains, such as on countable infinite or uncountable state spaces where explicit calculation of the second largest eigenvalue of the transition kernel is intractable.

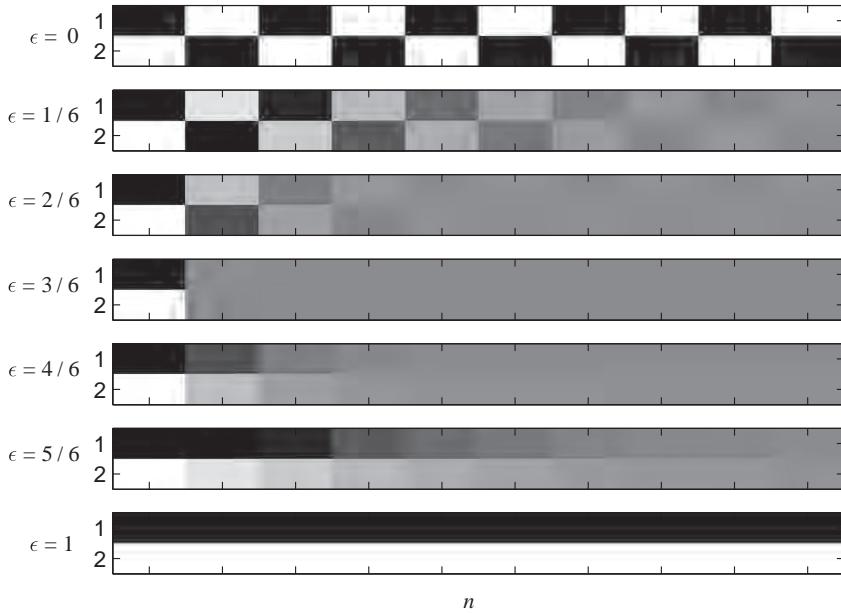

To see an example how convergence speed is affected consider a very simple chain  $x_n$  with two states, labeled as 1 and 2 with the transition matrix

$$K = \begin{pmatrix} \epsilon & 1-\epsilon \\ 1-\epsilon & \epsilon \end{pmatrix}, \quad (19.5)$$

where  $0 \leq \epsilon \leq 1$ . In other words, if at time  $t$  the chain is in state  $i$ , with probability  $\epsilon$ , the chain stays put, or jumps to the other state with probability  $1 - \epsilon$ . One natural question to ask is: where would we find the chain if we stop it at a large  $n$ ? Say we start initially from state  $i$  but in the previous section we saw that this initial choice won't matter (most of the time). It turns out that for  $0 < \epsilon < 1$  the answer is 0.5: it is equally likely to find the chain in any of the two states, regardless of the initial state but for each  $\epsilon$  the rate of convergence is different. We illustrate these concepts on Figure 19.8.

#### 1.19.4.2 Designing a Markov Chain for a given target distribution: The Metropolis-Hastings method

The discussion of the previous section suggests that, if we can design a transition kernel  $K$  such that the target density  $\pi(x)$  is its stationary distribution, at least in principle one can generate samples from the Markov chain that eventually will tend to be drawn from the target distribution. After ignoring samples obtained from an initial “burn in” period, as the chain moves towards the stationary distribution, the generated samples can be subsequently used to estimate expectations under the target distribution, as if they are independent. There are a couple of caveats: formally we require the chain to be

**FIGURE 19.8**

Convergence to the stationary distribution for the transition matrix  $K$  defined in Eq. (19.5) with  $\epsilon = 0, 1/6, 2/6, \dots, 1$  from top to bottom. Horizontal axis denotes the time  $n$  and the vertical axis is the state  $x$ . The probability  $\pi_n(x)$  is high for darker regions. For  $\epsilon = 1$  (bottom), the state transition matrix is  $K = I$  and the states are no longer connected. The chain fails to be irreducible and the chain fails to have a unique stationary distribution. For  $\epsilon = 0$  (top), the states alternate periodically. The chain is periodic and similarly fails to have a unique stationary distribution. For all other cases with  $0 < \epsilon < 1$  we have convergence to the uniform distribution, whilst with different speed. The second eigenvalues are  $\lambda_2 = 2\epsilon - 1$ ; as expected the chains converge slower when  $|\lambda_2|$  is closer to one.

ergodic—otherwise the chain might never reach the desired stationary distribution. Even if the chain is ergodic, typically we would not know in practice how close the chain is to the stationary distribution.

Here we set aside the issue of ergodicity and concentrate on designing a transition kernel  $K$  for a given target  $\pi$ . This is surprisingly simple via the approach proposed by Metropolis [1], later generalised by Hastings [21], for a rigorous treatment see [17, 23]. Note that this approach does not provide explicit formula for the transition Kernel  $K$  (which is often intractable to compute even in finite state spaces); it merely states a procedure to draw a new sample given the previous one. Suppose we are given a target density  $\pi = \phi/Z$ , where  $Z$  is a (possibly unknown) normalisation constant. The Metropolis-Hastings (MH) algorithm uses a proposal density  $q(x'|x)$ , which generates a candidate sample  $x'$  possibly dependent<sup>4</sup> on the current sample  $x$ . The algorithm is very simple, we define a chain by the

<sup>4</sup>Note that whilst one can consider proposals  $q(x')$  which are independent of  $x$ , the actual MH transition  $K(x'|x)$  nevertheless depends on  $x$ .

following rule: Accept the proposed sample with probability

$$\alpha(x \rightarrow x') = \min \left\{ 1, \frac{q(x|x')\pi(x')}{q(x'|x)\pi(x)} \right\},$$

where  $\alpha$  is the *acceptance probability* satisfying clearly the condition  $0 \leq \alpha(x|x') \leq 1$ . If the sample is not accepted, the chain stays put at the old location  $x$ . This procedure implicitly defines the following MH transition kernel  $K$ :

$$K(x|x') = q(x|x')\alpha(x|x') + \delta(x - x')\rho(x'), \quad (19.6)$$

here,  $\delta(x)$  is the Dirac delta  $\rho$  is the *rejection probability* satisfying  $0 \leq \rho(x') \leq 1$  is given by

$$\rho(x') \equiv \int (1 - \alpha(x|x'))q(x|x')dx.$$

This simply sums up all the probability of rejection. Note that we don't directly sample from  $K$ , we merely sample from the proposal  $q$  but reject some of the samples. In practice we typically don't need to evaluate  $K$  – indeed very often this is intractable. Recall that the stationary distribution should satisfy the following condition

$$\pi(x) = \int K(x|x')\pi(x')dx'.$$

---

**Algorithm 2.** Metropolis-Hastings

---

```

1: Initialise  $x^{(1)}$  arbitrarily
2: for  $n = 2, 3, \dots$  do
3:   Propose a candidate:  $x^{new} \sim q(x^{new}|x^{(n-1)})$ 
4:   Compute acceptance probability:

$$\alpha(x^{new}|x^{(n-1)}) = \min \left\{ 1, \frac{q(x^{(n-1)}|x^{new})\pi(x^{new})}{q(x^{new}|x^{(n-1)})\pi(x^{(n-1)})} \right\}$$

5:   Sample from uniform distribution:  $a \sim \mathcal{U}(0, 1)$ 
6:   if  $a < \alpha$  then
7:     Accept candidate:  $x^{(n)} \leftarrow x^{new}$ 
8:   else
9:     Reject candidate:  $x^{(n)} \leftarrow x^{(n-1)}$ 
10:  end if
11: end for
```

---

For an arbitrary kernel  $K$ , it is hard to verify stationarity. However, if  $K$  happens to satisfy a stronger condition,<sup>5</sup> known as the *detailed balance condition*

$$K(x'|x)\pi(x) = K(x|x')\pi(x'),$$

---

<sup>5</sup>A sufficient condition; a kernel  $K$  may have  $\pi$  as the stationary distribution while not satisfying detailed balance.

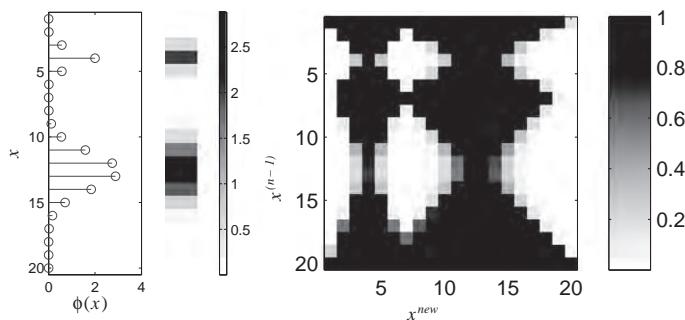

one sees directly that  $\pi$  must be the stationary distribution by integrating both sides over  $x'$ . Verification of detailed balance for the Metropolis-Hastings kernel is straightforward:

$$\begin{aligned}
 K(x|x')\pi(x') &= (q(x|x')\alpha(x|x') + \delta(x - x')\rho(x'))\pi(x') \\
 &= q(x|x')\min\left\{1, \frac{q(x'|x)\pi(x)}{q(x|x')\pi(x')}\right\}\pi(x') + \delta(x - x')\rho(x')\pi(x') \\
 &= \min\{q(x|x')\pi(x'), q(x'|x)\pi(x)\} + \delta(x - x')\rho(x')\pi(x') \\
 &= q(x'|x)\min\left\{\frac{q(x|x')\pi(x')}{q(x'|x)\pi(x)}, 1\right\}\pi(x) + \delta(x' - x)\rho(x)\pi(x) \\
 &= K(x'|x)\pi(x).
 \end{aligned}$$

Note that to compute the acceptance probability  $\alpha$ , we only need to evaluate  $\pi$  up to a normalisation, since the normalisation constant cancels out. For a given target  $\pi$  and assumed proposal  $q(x'|x)$  we now have a procedure for sampling from the Markov chain  $K(x'|x)$  with stationary distribution  $\pi$ . Sampling from the transition (19.6) can be achieved using the procedure detailed in Algorithm 2.

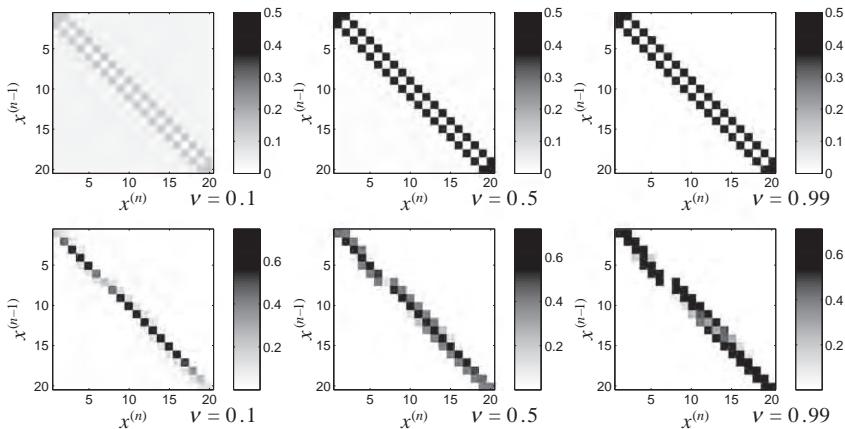

#### 1.19.4.3 Illustration

In this section, we will derive a MH algorithm for sampling from a discrete distribution  $\pi(x) = \phi(x)/Z$  where  $x \in \{1, 2, \dots, 20\}$ . The target, which has two bumps is shown on Figure 19.9. Our proposal  $q(x'|x)$  is a mixture of a random walk with a uniform density: with probability  $\nu$ , we choose a random walk. If we choose the random walk, with equal probability we let  $x' \leftarrow \max\{0, x - 1\}$  or  $x' \leftarrow \min\{20, x + 1\}$ . Alternatively, with probability  $1 - \nu$ , we choose  $x'$  uniformly on  $\{1, 2, \dots, 20\}$ . The random walk component corresponds to a “local exploration” whereas the uniform jump corresponds to a “restart.” Here, the parameter  $\nu$  is a algorithm parameter that will effect the behavior of our overall proposal and we will show how this may effect the convergence rate of the resulting MH algorithm. In Figure 19.10, we show the proposals and corresponding MH transition matrices.

**FIGURE 19.9**

Target density and the acceptance probability  $\alpha(x^{new}|x^{(n-1)})$  under a symmetric proposal  $q(x^{new}|x^{(n-1)}) = q(x^{(n-1)}|x^{new})$ .

**FIGURE 19.10**

(Top, left to right) The proposal density with  $v = 0.1, 0.5, 0.99$ . (Bottom, left to right) The corresponding transition matrices  $K$ , computed by Eq. (19.6).

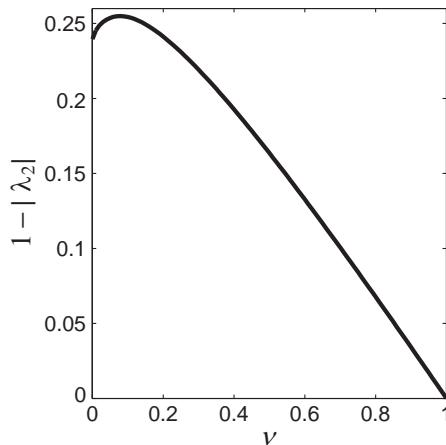

A moments thought would reveal that the local moves are not sufficient to cross the low probability region between the two bumps of the target, so setting  $v$  close to 1 might be a poor choice in terms of the convergence, also known as the *mixing time*. In this case, having the uniform proposal is certainly useful as it may help the chain to investigate the state space, hence reducing the mixing time. However, longer jumps have the risk of hitting low probability regions, increasing the rejections. The optimal choice for  $v$  seems to be somewhere in between those two extremes and we will numerically illustrate this.

In this simple example, we can numerically compute the effective MH transition matrix and compute the *spectral gap*, given as  $1 - |\lambda_2|$ ; the distance between magnitudes of two largest eigenvalues. For all  $v$ , the spectral gap is plotted in Figure 19.11. The bigger this gap, the faster is the convergence: an illustration of this fact is shown in Figure 19.12.

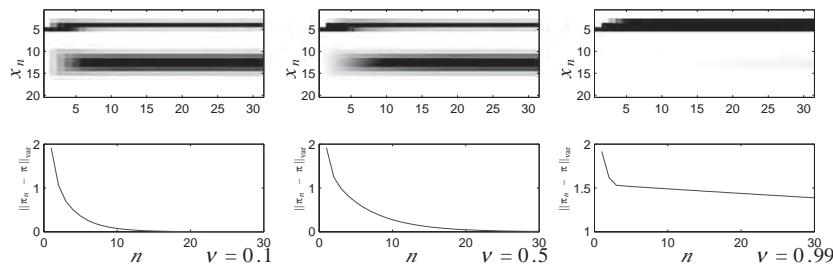

For real problems, the above computations are typically intractable but fortunately they are also not needed at all for the application of the MH algorithm. All we need is to sample from the proposal and evaluate the acceptance probability. In Figure 19.13, we show the results that would reflect a typical MH run. For different parameter settings with  $v = 0.1, 0.5, 0.99$ , we generate sample paths using the algorithm in 2. Then, following a burn in period of 100 iterations, for each state  $x$  we simply count the number of times the chain visits  $x$  to estimate  $\pi(x)$ . Formally, we construct the estimator

$$\bar{\pi}_n(x) = \frac{1}{n - 100} \sum_{\tau=101}^n [x^{(\tau)} = x]. \quad (19.7)$$

Note that, while the samples  $x^{(\tau)}$  are correlated, we calculate our estimate as if they are independent. This is still valid as after convergence all the  $x^{(\tau)}$  are effectively drawn from the same stationary distribution  $\pi(x)$ . The results are shown in Figure 19.13.

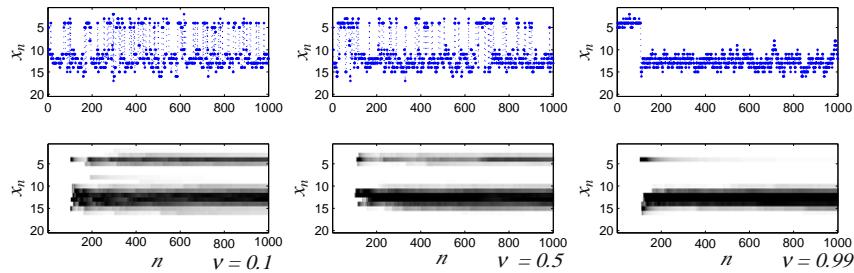

**FIGURE 19.11**

The spectral gap  $(1 - |\lambda_2|)$  computed numerically for the transition matrix  $K$  obtained using the proposals shown in Figure 19.10. The picture suggests that for fastest convergence, we need to set  $\nu \approx 0.1$ . Only using the local moves ( $\nu = 1$  case) results in poor mixing and uniform proposal seems to be a better choice for this problem. Yet, using local moves occasionally improves mixing as the gap at  $\nu = 0.1$  is slightly bigger than  $\nu = 0$ .

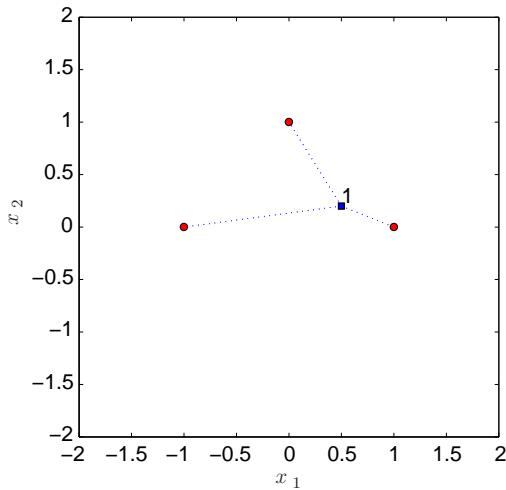

**FIGURE 19.12**

Convergence to the stationarity when using the proposal with parameters  $\nu = 0.1, 0.5, 0.99$ . (Top) The marginals  $\pi_n$ , as computed via  $K^n\pi_0$  where darker color indicates higher probability. (Bottom) The total variation distance between stationary distribution  $\pi = \pi_\infty$  and the marginal  $\pi_n$ . As predicted, the distance drops very slowly for  $\nu = 0.99$  and faster for the other cases. This example suggests that the algorithm is not very sensitive to  $\nu$  and a broad range of values are useful in practice.

**Example 3 (Object position estimation from range measurements).** In this section, we will illustrate the MH algorithm on a synthetic example of object localization. In this example, we have 3 noisy sensors at known positions  $s_j$ ,  $j = 1, \dots, 3$ , each measuring with noise the distance to an object at an unknown

**FIGURE 19.13**

Sample paths and estimates of the marginal when using the proposal with parameters  $v = 0.1, 0.5, 0.99$ . (Top) An example of a sample paths generated by the algorithm. (Bottom) Estimate of the marginal  $\bar{\pi}_\tau(x)$  (see Eq. (19.7)) using averages over a single realization after an initial burn-in period of 100 iterations.

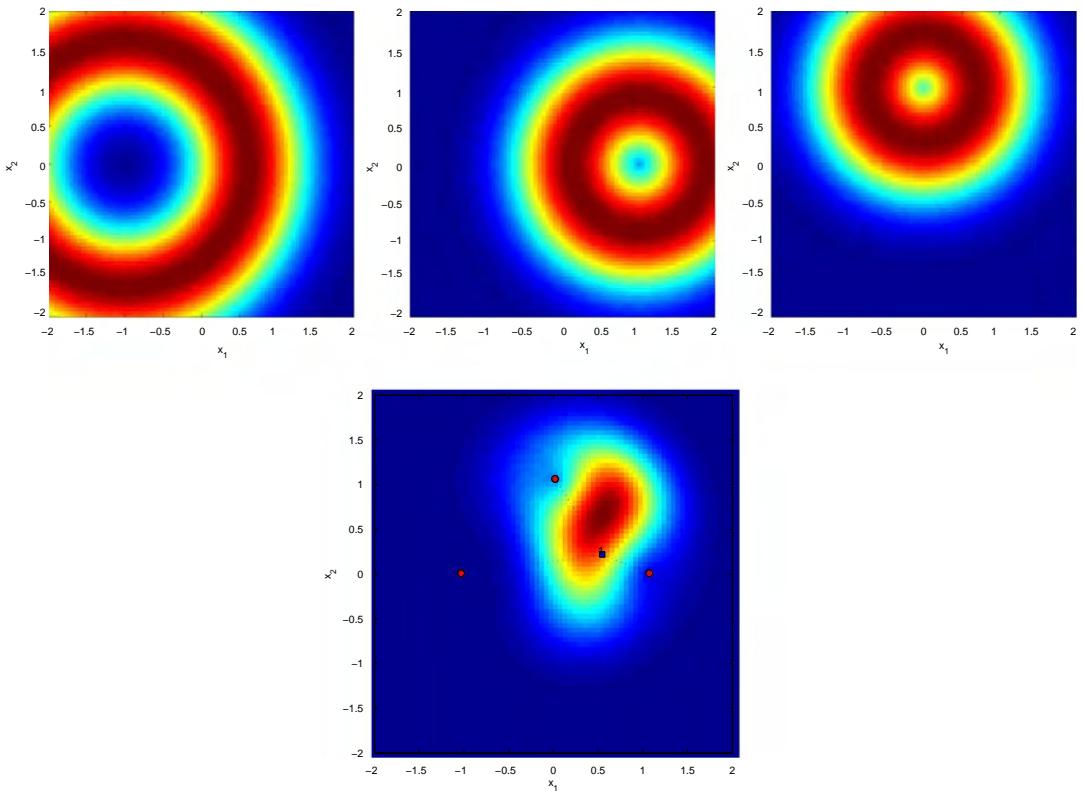

**FIGURE 19.14**

location  $x$ . The setup is shown in Figure 19.14. Each sensor observes a noisy distances with the following model

$$y_j|x, s_j \sim \mathcal{N}(y_j; \|x - s_j\|, R),$$

where  $\|x\| \equiv (\sum_k x_k^2)^{1/2}$  denotes the Euclidian distance and  $R$  is the noise variance of each sensors. We assume that we don't have any information about the position of the object so we choose a flat prior

**FIGURE 19.15**

(Top) The likelihood terms  $p(y_i|x)$ , (Bottom) The target posterior, proportional to  $\phi(x) = \prod_i p(y_i|x)$ .

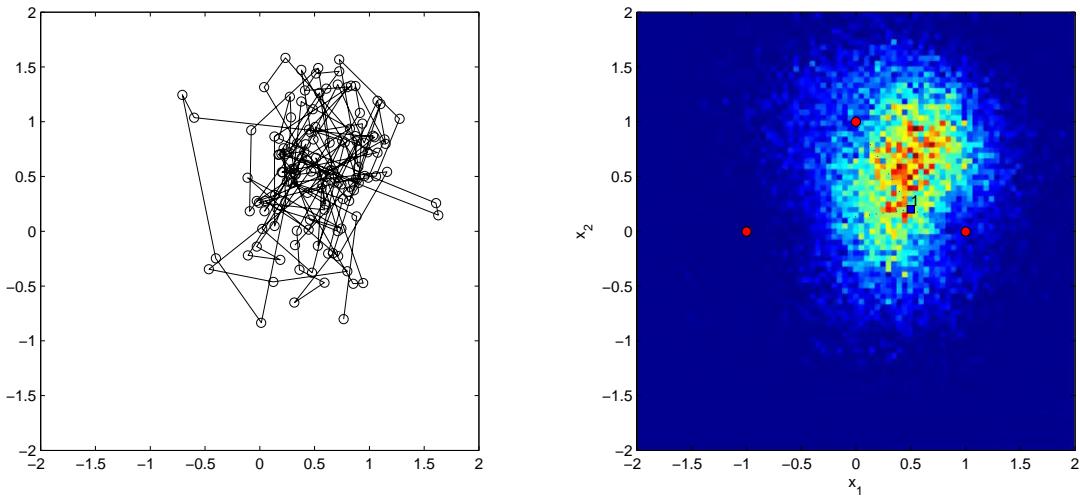

$p(x) \propto 1$ . The solution for this problem is given by the posterior

$$\pi(x) = p(x|y_1, y_2, y_3) = \frac{1}{Z} p(y_1|x)p(y_2|x)p(y_3|x)p(x) \equiv \frac{1}{Z}\phi(x).$$

The true target posterior density is depicted in Figure 19.15. As the target posterior  $\pi(x)$  is nonstandard, we will sample from it using a MH algorithm. We design a MH algorithm with a symmetric random walk proposal where  $q(x'|x) = \mathcal{N}(x, \sigma^2 I)$ . The acceptance probability is

$$\alpha(x \rightarrow x') = \min \left\{ 1, \frac{\phi(x')}{\phi(x)} \right\}.$$

Note that the symmetric proposal has been canceled out. By construction, the resulting kernel will admit  $\pi$  as the unique stationary density. In Figure 19.16, we show a sequence of samples obtained from this MH algorithm. We see that the chain visits states around the high probability region. The consecutive

**FIGURE 19.16**

(Left) A state trajectory obtained from the MH algorithm. (Right) A 2-D histogram estimate of the target density (from a longer state trajectory).

samples are dependent (as can be seen from the connecting lines) but as expected, a 2-D histogram obtained from a single chain shows a fairly accurate approximation.

#### 1.19.4.4 The Gibbs sampler

The MH schema is a very general technique for deriving MCMC algorithms. This generality stems partially from the arbitrariness of the proposal  $q$ ; in complex models the design of a reasonable proposal such that the chain mixes well can require a lot of work. It would be desirable if somehow the proposal design phase could be automated. The Gibbs sampler [20,24] is an attempt in this direction.

The Gibbs sampler is suitable for sampling a multivariate random variable  $x = (x_1, \dots, x_D)$  with intractable joint target density  $\pi(x)$ . Gibbs sampling proceeds by partitioning the set of variables  $x$  into a chosen variables  $x_d$  and the rest,  $x = (x_d, x_{-d})$ . The assumption is that the *full conditional densities*  $\pi(x_d|x_{-d})$  are tractable. One then proceeds coordinatewise by sampling from full conditionals as in Algorithm 3. The Gibbs sampler is actually a MH schema with a sequence of proposals for  $d = 1, \dots, D$

$$q_d(x|x') = p(x_d|x'_{-d})\delta(x_{-d} - x'_{-d})$$

each corresponding to a Gibbs transition kernels  $K_d$ . Moreover, it is easy to check that using this proposal results in a MH acceptance probability of 1, so that every move is accepted. This guarantees that each kernel  $K_d$  admits the same stationary distribution  $\pi$  as a stationary distribution, so we have  $\pi = K_d\pi$  for all  $d$ . Now, we see that  $\pi = K_1\pi$  and  $\pi = K_2\pi$  implies

$$\pi = K_1K_2\pi$$

---

**Algorithm 3.** Gibbs sampler

---

```

1: Initialize  $x^{(1)} = (x_1, \dots, x_D)^{(1)}$  arbitrarily
2: for  $n = 2, 3, \dots$  do
3:    $x_1^{(n)} \sim p(x_1|x_2^{(n-1)}, x_3^{(n-1)}, \dots, x_D^{(n-1)})$ 
4:    $x_2^{(n)} \sim p(x_2|x_1^{(n)}, x_3^{(n-1)}, \dots, x_D^{(n-1)})$ 
   :
5:    $x_D^{(n)} \sim p(x_D|x_1^{(n)}, x_2^{(n)}, \dots, x_{D-1}^{(n)})$ 
6: end for

```

---

and by induction

$$\pi = (K_1 K_2 \dots K_D) \pi \equiv K \pi.$$

Here, the transition kernel  $K$  is the effective Gibbs kernel after we sweep over all the variables  $x_d$  once. Unless the full conditionals are degenerate, the effective kernel  $K$  will be aperiodic and irreducible while none of the individual kernels  $K_d$  are. Note that we could visit the variables in any deterministic or order, provided each  $x_d$  is visited infinitely often in the limit. If we choose a deterministic order, the resulting sampler is known as a *deterministic scan Gibbs sampler*; if we choose a random order, not surprisingly, the sampler is called a *random scan Gibbs sampler*.

The ease of use of the Gibbs sampler has resulted the method being employed in many applications. There are very effective programs that generate a Gibbs sampler automatically from a model specification, such as BUGS. In the sequel, we will illustrate the Gibbs sampler on a change-point model for count data [25].

**Example 4 (Gibbs sampling for a change-point model).** In this model, at each time  $t$  we observe the count of an event  $y_t$ . All the counts up to an unknown time  $\tau$  come from the same distribution after which the distribution changes. We assume that the change-point  $\tau$  is uniformly distributed over  $1, \dots, T$ . The two different distributional regimes up to and after  $\tau$  are indicated by the random variables  $\lambda_i$ ,  $i = 1, 2$ , which are assumed to follow a Gamma distribution.

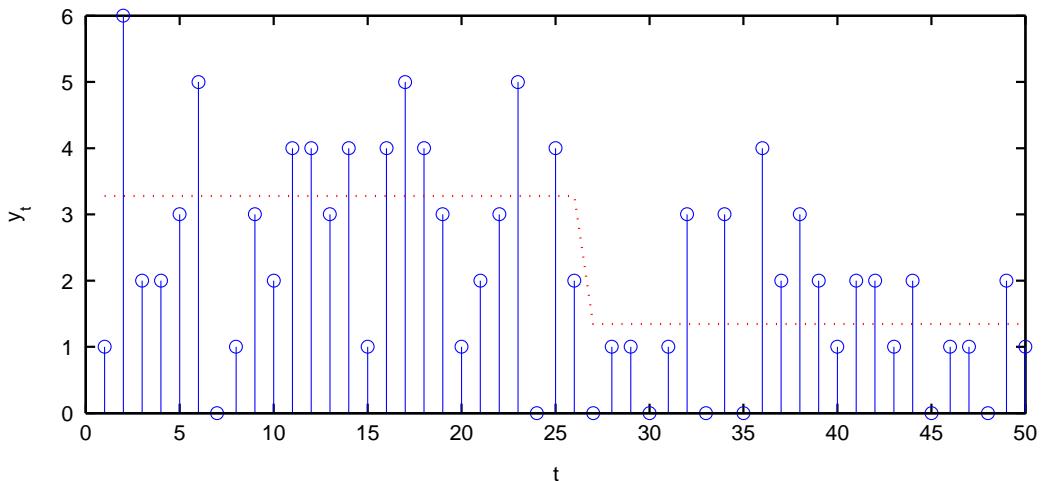

$$\mathcal{G}(\lambda_i; a, b) = \frac{1}{\Gamma(a)} b^a \lambda_i^{a-1} e^{-b\lambda_i} = e^{(a-1)\log \lambda_i - b\lambda_i - \log \Gamma(a) + a \log b}.$$

Under regime  $\lambda_i$ , the counts are assumed to be identically Poisson distributed

$$\mathcal{PO}(y_t; \lambda_i) = \frac{\lambda_i^{y_t}}{y_t!} e^{-\lambda_i} = e^{y_t \log \lambda_i - \lambda_i - \log(y_t!)}$$

This leads to the following generative model:

$$\begin{aligned} p(\tau) &= 1/T \text{ uniform,} \\ \lambda_i &\sim \mathcal{G}(\lambda_i; a, b), \quad i = 1, 2, \\ y_t &\sim \begin{cases} \mathcal{PO}(y_t; \lambda_1) & 1 \leq t \leq \tau, \\ \mathcal{PO}(y_t; \lambda_2) & \tau < t \leq T. \end{cases} \end{aligned}$$

**FIGURE 19.17**

A typical realisation from the change-point model. True intensities are shown with a dotted line. The intensity has dropped from  $\lambda_1 = 3.2$  to  $\lambda_2 = 1.2$  at  $\tau = 26$ . The time index is indicated by  $t$  and the number of counts by  $y_t$ . Generating such synthetic datasets provide intuition about the underlying models qualitative behaviour.

A typical draw from this model is shown in Figure 19.17. The inferential goal is to compute the posterior distribution of the change-point location and the intensities given the count data,  $p(\lambda_1, \lambda_2, \tau | y_{1:T})$ . In this problem the posterior is actually tractable [26] and could serve to assess the quality of the Gibbs sampling approximation.

To implement Gibbs sampling we need to compute the distribution of each variable, conditioned on the rest. These conditionals can be derived by writing the log of the full joint distribution and collecting terms that depend only on the free variable.<sup>6</sup> To derive the full conditional densities  $p(\lambda_1 | \cdot)$ ,  $p(\lambda_2 | \cdot)$  and  $p(\tau | \cdot)$ , we proceed by writing the full joint density. The log of the full joint density is given by:<sup>7</sup>

$$p(y_{1:T}, \lambda_1, \lambda_2, \tau) = \left( \prod_{t=1}^{\tau} p(y_t | \lambda_1) \right) \left( \prod_{t=\tau+1}^T p(y_t | \lambda_2) \right) p(\lambda_1) p(\lambda_2) p(\tau),$$

$$\log p(y_{1:T}, \lambda_1, \lambda_2, \tau) = \sum_{t=1}^{\tau} (+ y_t \log \lambda_1 - \lambda_1 - \log(y_t!))$$

$$+ \sum_{t=\tau+1}^T (+ y_t \log \lambda_2 - \lambda_2 - \log(y_t!))$$

<sup>6</sup>since  $p(X_d | x_{-d} = x_{-d}) = p(X_d, x_{-d} = x_{-d}) / p(x_{-d} = x_{-d}) \propto p(X_d, x_{-d} = x_{-d})$ .

<sup>7</sup>Here,  $f(x) =^+ g(x)$  means  $f(x) = g(x) + C$  where  $C$  is an irrelevant constant. This implies  $\exp(f(x)) \propto \exp(g(x))$ .

$$\begin{aligned}
& + (a - 1) \log \lambda_1 - b \lambda_1 - \log \Gamma(a) + a \log b \\
& + (a - 1) \log \lambda_2 - b \lambda_2 - \log \Gamma(a) + a \log b - \log T,
\end{aligned}$$

and collect terms that depend only on the free variable.

$$\log p(\lambda_1 | \tau, \lambda_2, y_{1:T}) = {}^+ \left( a + \sum_{t=1}^{\tau} y_t - 1 \right) \log \lambda_1 - (\tau + b) \lambda_1 = {}^+ \log \mathcal{G}(a + \sum_{t=1}^{\tau} y_t, \tau + b).$$

Calculation of  $p(\lambda_2 | \cdot)$  is similar.

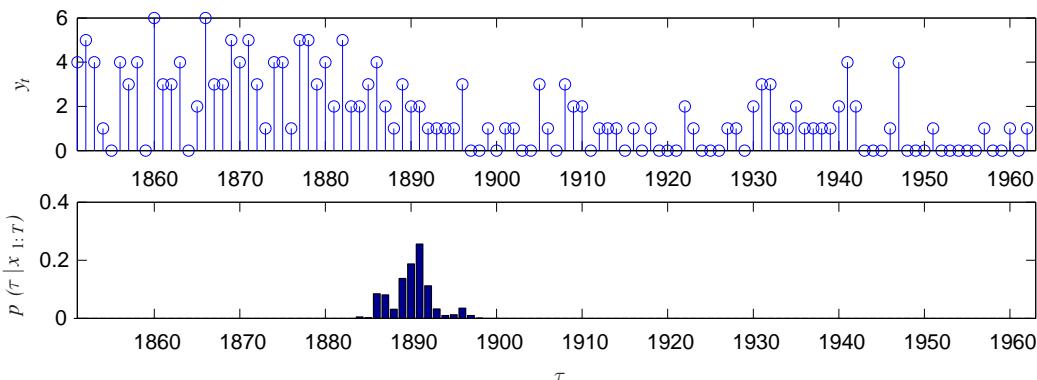

$$\begin{aligned}
\log p(\tau | \lambda_1, \lambda_2, y_{1:T}) &= \sum_{t=1}^{\tau} (+y_t \log \lambda_1 - \lambda_1 - \log(y_t!)) \\
&\quad + \sum_{t=\tau+1}^M (+y_t \log \lambda_2 - \lambda_2 - \log(y_t!)) \\
&= + \left( \sum_{t=1}^{\tau} y_t \right) \log \lambda_1 - \tau \lambda_1 + \left( \sum_{t=\tau+1}^M y_t \right) \log \lambda_2 - (M - \tau) \lambda_2.
\end{aligned}$$

We have to evaluate the above expression for  $\tau = 1, \dots, M$ . This Gibbs procedure is summarized in Algorithm 4.

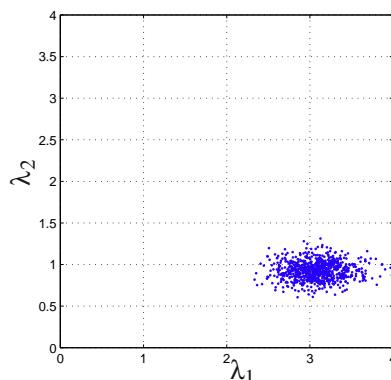

**Algorithm 4.** A Gibbs sampler for the change-point model

- 
- 1: Initialize  $\lambda_2^1, \tau^1$
  - 2: **for**  $n = 2, 3, \dots$  **do**
  - 3:    $\lambda_1^{(n)} \sim p(\lambda_1 | \lambda_2^{(n-1)}, \tau^{(n-1)}, y_{1:T}) = \mathcal{G}(a + \sum_{t=1}^{\tau} y_t, \tau + b)$
  - 4:    $\lambda_2^{(n)} \sim p(\lambda_2 | \lambda_1^{(n)}, \tau^{(n-1)}, y_{1:T}) = \mathcal{G}(a + \sum_{t=\tau+1}^M y_t, M - \tau + b)$
  - 5:    $\tau^{(n)} \sim p(\tau | \lambda_1^{(n)}, \lambda_2^{(n)}, y_{1:T})$
  - 6: **end for**

We illustrate the algorithm on a coal mining disaster dataset [27], see Figure 19.18. The data consists of the number of deadly coal-mining disasters in England per year over a time span of 112 years from 1851 to 1962. It is widely agreed in the statistical literature that a change in the intensity (the expected value of the number of disasters) occurs around the year 1890, after new health and safety regulations were introduced. In Figure 19.18 we show the samples obtained from the posterior of the changepoint location. The posterior of the intensities  $\lambda_1, \lambda_2$  are shown in Figure 19.19.

**FIGURE 19.18**

Estimation of change points on the coal mining disaster dataset. (Top) The number of deadly disasters  $y_t$  each year  $t$ . (Bottom) The posterior distribution of the changepoint location  $p(\tau | y_{1:T})$ .

**FIGURE 19.19**

Samples drawn from the posterior intensities  $p(\lambda_1, \lambda_2 | y_{1:T})$  on the coal mining disaster dataset. This results clearly indicate that after the health and safety regulations, the intensity has dropped from about  $\lambda_1 = 3$  to  $\lambda_2 = 1$ .

## 1.19.5 Sequential Monte Carlo

The MCMC techniques described in the previous section are widely used in many areas of applied sciences and engineering. However, they may have some potential drawbacks in signal processing: MCMC methods are by construction batch algorithms that require availability of all data records. This can be prohibitive in some signal processing application such as tracking when the data arrives

sequentially and decisions have to be taken in real time. One could in principle design online MCMC algorithms that operate on the full data record observed so far. However, such batch algorithms take increasingly more time. In such cases, it is desirable to have alternative methods which process data sequentially and take a constant time per observation.

Sequential Monte Carlo (SMC) is an umbrella term for Monte Carlo techniques that process data in an online fashion [9]. Popular techniques such as particle filtering or sequential importance sampling (SIS) are special SMC algorithms. SMC techniques are particularly natural for probabilistic signal models where data has a natural order.<sup>8</sup> A very large class of signal models can be described as *state space models*, that have the following general form:

$$x_0 \sim p(x_0), \quad (19.8)$$

$$x_t | x_{t-1} \sim p(x_t | x_{t-1}), \quad (19.8)$$

$$y_t | x_t \sim p(y_t | x_t). \quad (19.9)$$

Here,  $x_t$  is the state and  $y_t$  are the observations and  $t = 0, \dots, T$  is a discrete time index. Note that  $t$  does not have to correspond to the wall clock, it only specifies some natural ordering of the underlying data. The Eq. (19.8) and Eq. (19.9) are known as *transition* and *observation* models. State space models, also named as hidden Markov models, are ubiquitous in signal processing and many popular models, such as linear dynamical systems or autoregressive (AR) models, can be formulated as special cases.

There are several inference problems of interest for state space models, where inference in this context is the task of using a distribution to answer questions of interest. A common inference problem is the *prediction* of an unseen future variable  $y_{T+1}$ , which requires computing  $p(y_{T+1} | y_{1:T})$  from a joint distribution. Another one is the so called *filtering* problem, estimation of the state  $x_t$  given observations so far  $y_{1:t}$ . This is achieved via calculation of the posterior quantity  $p(x_t | y_{1:t})$ . One of the challenges in statistical signal processing is to develop efficient inference routines for answering such questions.

In this context, SMC techniques [10, 28] have proved very useful. SMC methods are based on importance sampling/resampling which we review in the following sections. We first review importance sampling and resampling techniques and subsequently introduce the SMC algorithm as a sequential importance sampler.

### 1.19.5.1 Importance sampling (IS)

Consider a target distribution  $\pi(x) = \phi(x)/Z$  where the non-negative function  $\phi(x)$  is known, but the overall normalisation constant  $Z$  is assumed to be computationally intractable. The main idea of (IS) is to estimate expectations  $E_\pi(\varphi(x))$  by using weighted samples from a tractable IS distribution  $q(x)$ . Note that unlike other MC methods, our goal is not directly generating samples but estimating expectations via weighted samples. However, we can also generate unweighted independent samples, if we desire to do so by a mechanism called *resampling*.

More specifically, we can write the normalization constant as

$$Z = \int \phi(x) dx = \int \frac{\phi(x)}{q(x)} q(x) dx = \int W(x) q(x) dx = E_q(W(x)),$$

---

<sup>8</sup>SMC techniques are not necessarily limited to such systems, though, see, e.g., [20].

where  $W(x) \equiv \phi(x)/q(x)$  is called *weight function*. Therefore we have

$$\mathbb{E}_\pi(\varphi(x)) = \frac{1}{Z} \int \varphi(x) \frac{\phi(x)}{q(x)} q(x) dx = \frac{\mathbb{E}_q(\varphi(x) W(x))}{\mathbb{E}_q(W(x))}.$$

A Monte Carlo estimate of  $\mathbb{E}_\pi \varphi(x)$  is then given by

$$\hat{\mu}_N = \frac{\sum_{i=1}^N W^{(i)} \varphi(x^{(i)}) / N}{\sum_{i=1}^N W^{(i)} / N},$$

where  $W^{(i)} \equiv W(x^{(i)})$  and the ‘‘particles’’  $x^{(1)}, \dots, x^{(N)}$  are sampled from  $q(x)$ . Using normalised weights  $w^{(i)} \equiv W^{(i)} / \sum_{i'=1}^N W^{(i')}$  we can write the approximation as

$$\hat{\mu}_N = \sum_{i=1}^N w^{(i)} \varphi(x^{(i)}).$$

In other words, instead of sampling from the target density  $p(x)$ , we sample from a different tractable distribution  $q(x)$  and correct by reweighing the samples accordingly. An example is given in Figure 19.20.

#### 1.19.5.1.1 Resampling

A practical issue is that, unless the IS sampling density  $q(x)$  is close to the target density  $\pi(x)$ , the normalised weights will typically have mass in only a single component. This can be partially addressed using re-sampling as we now describe. Given a weighted particle system  $\sum_{i=1}^N w^{(i)} \delta(x - x^{(i)})$ , resampling is the term for a set of methods for generating *randomly* an unweighted particle system of the form  $\frac{1}{M} \sum_{j=1}^M \delta(x - \tilde{x}^{(j)})$  such that

$$\mathbb{E} \left( \frac{1}{M} \sum_{j=1}^M \delta(x - \tilde{x}^{(j)}) \right) = \sum_{i=1}^N w^{(i)} \delta(x - x^{(i)}),$$

where the expectation is over the draws from the resampling algorithm. In resampling, typically the total number of particles are unchanged, so we have  $N = M$ . Alternatively, one can view resampling as a randomised pruning algorithm where we discard particles with low weight and increase the number of particles with high weight. Unlike a deterministic pruning algorithm, the random nature of resampling does not introduce a systematic bias and ensures an asymptotically consistent algorithm when the number of samples  $N$  goes to infinity. In Figure 19.21, we illustrate the result of resampling from a weighted particle set. It is instructive to compare histograms obtained from weighted particle set (Figure 19.20); the resampling stage introduces additional Monte Carlo variation but the histogram is still a reasonable approximation to the underlying density. Two popular methods for resampling are multinomial resampling and systematic resampling, which we will review in the sequel. For a discussion and comparison of various resampling schemata, see [10, 29].

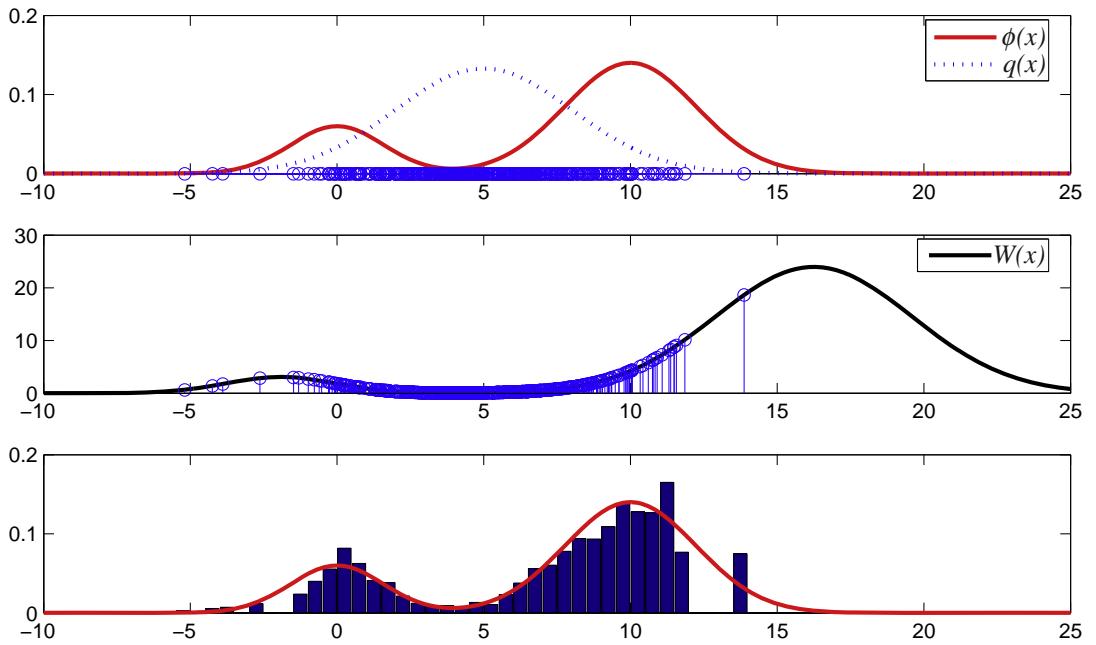

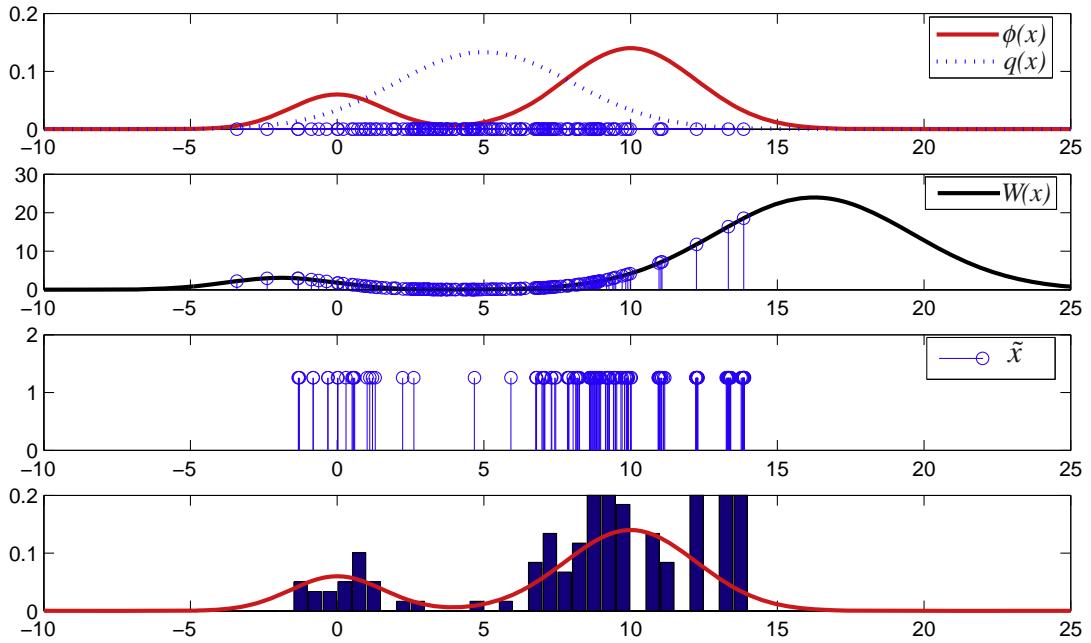

**FIGURE 19.20**

Illustration of Importance Sampling. (Top): The solid curve denotes the unnormalised target density  $\phi(x)$  and the dashed curve the tractable IS density  $q(x)$ . We assume that it is straightforward to generate samples  $x^{(i)}$  from  $q(x)$ ; these are plotted on the  $x$  axis. Middle: To account for the fact that the samples are from  $q$  and not from the target  $\pi = \phi/Z$ , we need to reweight the samples. In this example, the IS density  $q$  generated far too many samples where  $\pi$  has low mass, and too few where  $\pi$  has high mass. The samples in these regions are reweighted according to the weight function  $W(x)$ . Bottom: Binning the weighted samples from  $q$ , we obtain an approximation to  $\pi$  such that averages with respect to this approximation will be close to averages with respect to  $\pi$ .

Multinomial resampling equivalent to the inversion method when the target is a discrete distribution, as explained in Figure 19.3. Here, we view the weighted sample set  $x^{(i)}$  as a discrete distribution with categories  $i = 1, \dots, N$  where the probability of the  $i$ th category is given by the normalized weight  $w^{(i)}$ . To sample  $M$  times independently from this target, we generate  $u^{(j)} \sim \mathcal{U}(0, 1)$  for  $j = 1, \dots, M$  and we obtain an unweighted set of particles by evaluating the generalized inverse at each  $u^{(j)}$ , as explained in Figure 19.3.

Systematic resampling is quite similar to multinomial resampling, only the generation of  $u^{(j)}$  is not entirely random but “systematic.” To generate  $M$  samples we only select  $u^{(1)}$  uniformly random from the interval  $[0, 1/M]$  and set  $u^{(j)} = u^{(1)} + (j - 1)/M$ . The  $u$  are located on a uniform grid with a random initial shift. In Figure 19.22, we illustrate both methods.

**FIGURE 19.21**

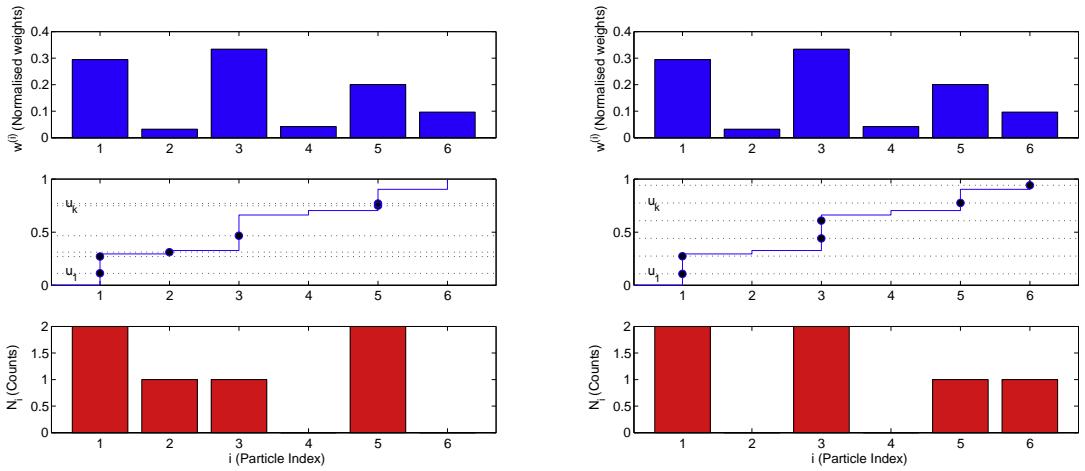

Importance Sampling with Resampling. We can generate from the weighted samples  $x$  generated by importance sampling unweighted samples  $\tilde{x}$  by resampling. Some of the particles in the original set will be replicated while others will be simply discarded.

From only a theoretical perspective, the actual details of a resampling schema are not important and the estimates converge to their true values in the infinite particle limit. One has to only ensure that the expectation under the resampled particle set is *on average* equal to the expectation under the original weighted particle set. However, with a finite number of particles, there may be notable differences.

It can be shown that systematic resampling achieves a lower variance while both methods have the same expectation and no bias. Coupled with its ease of implementation, this makes systematic resampling a popular choice in practice.

### 1.19.5.2 Sequential importance sampling

We now apply importance sampling to the state space model introduced earlier in Eq. (19.8) and Eq. (19.9). “Plain” importance sampling is actually not very effective in high dimensional problems but when executed sequentially using resampling techniques, it has become a very efficient and effective tool for inference. The resulting sequential IS methods are also known as particle filters [10]. The goal

**FIGURE 19.22**

Multinomial Resampling (left column) versus Systematic Resampling (right column). (Top) True weights, (Middle) Cummulative weight function, (Bottom) Bin counts after resampling. Note that the resulting histograms can be thought of as approximations of the original discrete distribution.

is to draw samples from the posterior

$$p(x_{1:t}|y_{1:t}) = \underbrace{p(y_{1:t}|x_{1:t})p(x_{1:t})}_{\phi(x_{1:t})} / \underbrace{p(y_{1:t})}_{Z_t},$$

where we assume that the normalisation term  $Z_t$  is intractable. An importance sampling approach uses at each time  $t$  an importance distribution  $q_t(x_{1:t})$ , from which we draw samples  $x_{1:t}^{(i)}$  with corresponding importance weights

$$W_t^{(i)} = \phi(x_{1:t}^{(i)}) / q_t(x_{1:t}^{(i)}).$$

The key idea in SMC is the sequential construction of the IS distribution  $q$  and the recursive calculation of the importance weights. Without loss of generality, we may write

$$q_t(x_{1:t}) = q_t(x_t|x_{1:t-1})q_t(x_{1:t-1}).$$

In particle filtering, one chooses a IS proposal  $q$  that only updates the current  $x_t$  and leaves previous samples unaffected. This is achieved using

$$q_t(x_{1:t}) = q_t(x_t|x_{1:t-1})q_{t-1}(x_{1:t-1}).$$

As we are free to chose the IS proposal  $q$  fairly arbitrarily, we can also “construct” the proposal on the fly conditioned on the observations seen so far:

$$q_t(x_{1:t}|y_{1:t}) = q_t(x_t|x_{1:t-1}, y_{1:t})q_{t-1}(x_{1:t-1}|y_{1:t-1}).$$

In the sequel, we won't include  $y_{1:t}$  in our notation but it should be understood that the proposal  $q$  can be constructed at the observations so far.

Due to the sequential nature of the state space model and  $q$ , the weight function  $W_t(x_{1:t})$  admits a recursive computation

$$\begin{aligned} W_t(x_{1:t}) &= \frac{\phi(x_{1:t})}{q_t(x_{1:t})} = \frac{p(y_t|x_t)p(x_t|x_{t-1})\prod_{\tau=1}^{t-1} p(y_\tau|x_\tau)p(x_\tau|x_{\tau-1})}{q_t(x_t|x_{1:t-1})\prod_{\tau=1}^{t-1} q_\tau(x_\tau|x_{1:\tau-1})} \\ &= \underbrace{\frac{p(y_t|x_t)p(x_t|x_{t-1})}{q_t(x_t|x_{1:t-1})}}_{v_t} W_{t-1}(x_{1:t-1}), \end{aligned}$$

where  $v_t$  is called the incremental weight. Particle filtering algorithms differ in their choices for  $q_t(x_t|x_{1:t-1})$ . The optimal choice (in terms of reducing the variance of weights) is the one step filtering distribution [30]

$$q_t(x_t|x_{1:t-1}) = p(x_t|x_{t-1}, y_t).$$

However, sampling from this filtering density is often difficult in practice, and simpler methods are required. The popular *bootstrap* filter uses the model transition density as the proposal

$$q_t(x_t|x_{1:t-1}) = p(x_t|x_{t-1}),$$

for which the incremental weight is  $v_t = p(y_t|x_t)$ . For the bootstrap filter, the IS distribution does not make any use of the recent observation and therefore has the tendency to lose track of the high-mass regions of the posterior. Indeed, it can be shown that the variance of the importance weights for the bootstrap filter increases in an unbounded fashion [20, 30] so that the state estimates are not reliable. In practice, therefore, after a few time steps the particle set typically loses track of the exact posterior mode. A crucial extra step to make the algorithm work is resampling which prunes branches with low weights and keeps the particle set located in high probability regions. It can be shown that although the particles become dependent due to resampling, the estimations are still consistent and converge to the true values as the number of particles increases to infinity. A generic particle filter algorithm is shown in Algorithm 5.

**Example 5 (Particle Filtering).** We will consider the following model of a sequence of Poisson random variables  $y_t$  with intensities  $\exp(l_t)$ :

$$y_t|l_t \sim p(y_t|l_t) = \mathcal{PO}(y_t; \exp(l_t)) = \exp(y_t l_t - \exp(l_t) - \log(y_t!)). \quad (19.10)$$

The latent log intensities  $l_t$  are assumed to be changing slowly with  $t$ ; this can be modeled by a random drift

$$l_t|l_{t-1} \sim p(l_t|l_{t-1}) = \mathcal{N}(l_t; l_{t-1}, R) = \exp\left(-\frac{1}{2}\frac{(l_t - l_{t-1})^2}{R} - \frac{1}{2}\log 2\pi R\right). \quad (19.11)$$

This model can be considered as an alternative to the single change point model introduced in Section 4. Rather than allowing for a single abrupt change, this model proposes slowly varying intensities where the drift is controlled by the transition variance parameter  $R$ . If  $R$  is small, consecutive log intensities  $l_t$

**Algorithm 5.** Particle Filter

---

**for**  $i = 1, \dots, N$  **do**

 Compute the IS distribution:  $q_t(x_t|x_{1:t-1}^{(i)})$  possibly using the latest observation  $y_t$ 

 Generate offsprings:  $\hat{x}_t^{(i)} \sim q_t(x_t|x_{1:t-1}^{(i)})$ 

Evaluate importance weights:

$$v_t^{(i)} = \frac{p(y_t|\hat{x}_t^{(i)})p(\hat{x}_t^{(i)}|x_{t-1}^{(i)})}{q_t(\hat{x}_t^{(i)}|x_{1:t-1}^{(i)})}, \quad W_t^{(i)} = v_t^{(i)} W_{t-1}^{(i)}$$

**end for**

$$\text{ESS} = 1 / \sum_i (\tilde{w}_{1:t}^{(i)})^2$$

**if** ESS > Threshold **then**

 Extend particles:  $x_{1:t}^{(i)} = (x_{1:t-1}^{(i)}, \hat{x}_t^{(i)}), i = 1, \dots, N$ 
**else**
*Resample*

Normalise importance weights:

$$\tilde{Z}_t \leftarrow \sum_j W_t^{(j)}, \quad \tilde{\mathbf{w}}_t \leftarrow (W_t^{(1)}, \dots, W_t^{(N)}) / \tilde{Z}_t$$

Generate Associations via a Resampling method

$$(a(1), \dots, a(N)) \leftarrow \text{Resample}(\tilde{\mathbf{w}}_t)$$

Discard or Keep particles and Reset weights:

$$x_{0:t}^{(i)} \leftarrow (x_{0:t-1}^{a(i)}, \hat{x}_t^{a(i)}), \quad W_t^{(i)} \leftarrow \tilde{Z}_t / N, \quad i = 1, \dots, N$$

**end if**

---

and  $l_{t+1}$  will be close to each other. In the limit of  $R$  going to zero, the model degenerates into a constant intensity model. In this example, we will assume that we know  $R$ .

To design a SMC algorithm, we need to decide upon a proposal mechanism and derive the expression for the incremental importance weight

$$v_t(l_t|l_{1:t-1}) = \frac{p(y_t|l_t)p(l_t|l_{t-1})}{q_t(l_t|l_{1:t-1})}.$$

For illustration purposes, we will consider here two different proposal mechanisms:

1. *Transition density as the proposal* (the Bootstrap filter):

Here, we choose as our proposal the models transition density

$$q_t(l_t|l_{1:t-1}) = p(l_t|l_{t-1}).$$

This choice is the most widely used one for constructing proposals because of its simplicity, ease of implementation and the intuitive interpretation as a “the survival of the fittest” algorithm. The resulting algorithm is known in the SMC literature as the *bootstrap filter* and in computer

vision as the *condensation algorithm*. For the bootstrap filter, the incremental weight expression becomes

$$\begin{aligned} v_t(l_t | l_{1:t-1}) &= \frac{p(y_t | l_t) p(l_t | l_{t-1})}{p(l_t | l_{t-1})} = p(y_t | l_t) \\ &= \exp(y_t l_t - \exp(l_t) - \log(y_t!)), \end{aligned}$$

## 2. The observation likelihood as the proposal

Here, we choose a density that is proportional to the likelihood term

$$q_t(l_t | l_{1:t-1}) = q_t(l_t) = p(y_t | l_t) / c_t,$$

where  $c_t = \int p(y_t | l_t) dl_t$ . Note that this proposal can only be used when the normalizer  $c_t$  is not infinite hence a density exists.<sup>9</sup> This option is perhaps less intuitive to understand but could be a lot more efficient than the bootstrap in problems where the transition model is very diffuse but the observations are very informative. Using a bootstrap filter may be inefficient in this case, as most of the proposed particles will fall into low probability regions.

$$v_t(l_t | l_{1:t-1}) = \frac{p(y_t | l_t) p(l_t | l_{t-1})}{p(y_t | l_t) / c_t} = c_t p(l_t | l_{t-1}).$$

In practice, unless we need to explicitly evaluate the marginal likelihood  $p(y_{1:t})$ , we do not need to evaluate normalizer  $c_t$  as it will cancel out when calculating the normalized weights.

To find this proposal density, we make the following observation: the Poisson density, when viewed as a function of the intensity is proportional to a Gamma density<sup>10</sup>

$$\begin{aligned} \mathcal{PO}(y; \lambda) &\propto \exp(y \log \lambda - \lambda) \\ &\propto \exp((y + 1 - 1) \log \lambda - \lambda - \log \Gamma(y + 1)) = \mathcal{G}(\lambda; y + 1, 1). \end{aligned}$$

So for a given Poisson observation, we can easily generate  $\lambda$  by a unit gamma random number generator with shape parameter  $y + 1$ . To generate the log intensities  $l$ , we sample  $\lambda$  and set  $l = \log(\lambda)$ . The density of  $l = \log \lambda$  when  $\lambda$  is gamma distributed is found via the transformation method

$$\begin{aligned} l(\lambda) &= \log(\lambda), \\ \lambda(l) &= \exp(l), \\ |J| &= \partial \lambda(l) / \partial l = \exp(l), \\ p(l) &= \mathcal{G}(\lambda(l); a, b) \exp(l). \end{aligned}$$

So the density of our proposal is

$$q_t(l_t) \propto \exp((y_t + 1)l_t - \exp(l_t) - \log \Gamma(y_t + 1)).$$

---

<sup>9</sup>Here,  $c_t$  is not to be confused with the actual normalizing constant of the model which is the marginal likelihood  $Z_t = p(y_t | y_{1:t-1})$ .

<sup>10</sup>This is due to the so called conjugacy property.

The weight expression is

$$\begin{aligned} v_t(l_t | l_{1:t-1}) &= \frac{\exp(y_t l_t - \exp(l_t) - \log \Gamma(y_t)) \exp\left(-\frac{1}{2} \frac{(l_t - l_{t-1})^2}{R}\right)}{\exp((y_t + 1) l_t - \exp(l_t) - \log \Gamma(y_t + 1))} \\ &\propto \exp\left(-\frac{1}{2} \frac{(l_t - l_{t-1})^2}{R} - l_t\right). \end{aligned}$$

Here, we have simply ignored the terms that do not depend on  $l_t$  as these do not contribute to the normalized importance weight.

As mentioned earlier, in practice the transition model is taken often as the proposal density. It should be stressed that, the choice of an efficient proposal has a profound effect on the performance and the transition model need not to be always the best choice. As the above example illustrates, there are typically always alternative proposals and in the context of an application, at least a few alternatives should be considered before opting to the transition density. As a guideline, one should look for a proposal that is close to the filtering density but that does not require extensive computation to sample. If a proposal is too costly to sample from, one may consider using a simpler but poorer proposal with more samples for a given computational cost.

## 1.19.6 Advanced Monte Carlo methods

We have reviewed some of the basic Monte Carlo techniques in previous sections. However, there are many problems that need techniques beyond standard strategies. In this section, we will review such a technique: reversible jump MCMC (RJMCMC) [11, 31]. This technique is an extension of the Metropolis-Hastings method to more general state spaces [23]. It is mostly used in settings where we wish to perform model selection, such as inferring a model where the order is unknown.

### 1.19.6.1 Reversible jump MCMC

The reversible jump MCMC is a Metropolis-Hastings method for sampling from Markov chains in state spaces of varying dimensionality. Such state spaces arise naturally in model selection problems where we have several candidate models  $\{\mathcal{M}_k\}$  with model index  $k$ , formally denoted as  $k \in \mathcal{K}$  for some finite set  $\mathcal{K}$ . With each model  $\mathcal{M}_k$  there is an associated parameter vector  $\theta_k$  of dimensionality  $N_k$ , i.e.,  $\theta_k \in \mathbb{R}^{N_k}$ . The inferential goal is to sample from the joint density  $\pi(k, \theta_k)$  of model index  $k$  and the parameters  $\theta_k$  where

$$\pi(\theta_k, k) = \frac{1}{Z_k} \phi_k(\theta_k) \tilde{p}_k, \quad (19.12)$$

$$\tilde{p}_k \equiv \frac{p_k}{\sum_{k' \in \mathcal{K}} p_{k'}}. \quad (19.13)$$

Here, for all models  $k \in \mathcal{K}$ ,  $Z_k = \int d\theta_k \phi_k(\theta_k)$  are unknown normalizing constants and  $p_k$  are prior weights, usually taken as flat with  $p_k = 1$ . These quantities have direct counterparts in a Bayesian

model selection setting: we have a probability model that couples observations  $x$  with parameters as  $p(x, \theta_k, k) = p(x, \theta_k|k)p(k)$ . In this context, the target density is the posterior

$$\pi(\theta_k, k) = p(\theta_k, k|x) = p(\theta_k|k, x)p(k|x)$$

and the joint distribution of parameters and data for each model  $\mathcal{M}_k$  is  $\phi_k(\theta_k) = p(x, \theta_k|k)$  and  $Z_k = \int d\theta_k \phi_k(\theta_k) = p(x|k)$ . To find the model order after observing the data  $x$  we would need the posterior marginal

$$p(k|x) = \frac{p(k, x)}{\sum_{k' \in \mathcal{K}} p(k', x)} = \frac{\tilde{p}_k Z_k}{\sum_{k \in \mathcal{K}} \tilde{p}_k Z_k} = \frac{p_k Z_k}{\sum_{k \in \mathcal{K}} p_k Z_k},$$

where the equalities follow by noting that  $p(k, x) = \int p(\theta_k, k, x)d\theta_k = \tilde{p}_k Z_k$  and  $p(x) = \sum_k \tilde{p}_k Z_k$ . With these results, the posterior can be written as

$$\pi(\theta_k, k) = \frac{1}{Z_k} \phi_k(\theta_k) \frac{p_k Z_k}{\sum_{k \in \mathcal{K}} p_k Z_k} = \phi_k(\theta_k) \frac{p_k}{\sum_{k \in \mathcal{K}} p_k Z_k}.$$

One possible approach for calculating the posterior of models order  $p(k|x)$  would require estimation of individual normalizing constants  $Z_k$ . The RJ-MCMC approach circumvents this need by setting up a chain to sample from  $(k, \theta_k)$  pairs. The difficulty is that now the target density  $\pi$  is defined on a nonstandard state space  $\mathcal{E}$  where

$$\begin{aligned} \mathcal{E} &= \bigcup_{k \in \mathcal{K}} \mathcal{E}_k, \\ \mathcal{E}_k &\equiv \{\{k\} \times \mathbb{R}^{N_k}\}, \end{aligned}$$

and we need to set up a so called *transdimensional* Markov chain that can jump across spaces of different dimensions  $\mathcal{E}_k$  and  $\mathcal{E}_{k'}$  as  $(k, \theta_k) \rightarrow (k', \theta_{k'})$ . This chain is “nonstandard” in the sense that its dimension varies over time but is otherwise completely natural for the class of model selection problems.

There is a technical caveat: The “ordinary” Metropolis-Hastings algorithm requires that we design a proposal

$$q(k', \theta_{k'}|k, \theta_k) = q(\theta_{k'}|k', k, \theta_k)q(k'|k, \theta_k)$$

and evaluate the acceptance probability as

$$\alpha((k, \theta_k) \rightarrow (k', \theta_{k'})) = \min \left\{ 1, \frac{q(k, \theta_k|k', \theta_{k'})\pi(k', \theta_{k'})}{q(k', \theta_{k'}|k, \theta_k)\pi(k, \theta_k)} \right\}.$$

We need to construct the proposals carefully, as as a proper lower dimensional space embedded into a higher dimensional space may have measure zero with respect to the probability measure defined on the larger space.<sup>11</sup> The remedy comes from the transformation method introduced earlier. By introducing auxiliary variables, we design the proposal as a “reversible” transformation between both spaces.

---

<sup>11</sup>The probability of jumping to an isolated point (a proper low dimensional space) under a proposal with an absolutely continuous density is zero. As an example, think of the probability of hitting an interval  $(-\epsilon, \epsilon)$  when  $\epsilon \rightarrow 0$ .

Suppose we wish to jump from a lower dimensional space  $\mathcal{E}_k$  to a higher dimensional space  $\mathcal{E}_{k'}$ . We define  $\bar{N}_k$  such that  $N_{k'} = N_k + \bar{N}_k$  and draw the  $\bar{N}_k$  dimensional vector  $u_k$  from a proposal  $q_k(u_k)$  and match the dimensions of both spaces via a transformation defined as

$$\theta_{k'} = g_{k \rightarrow k'}(\theta_k, u_k).$$

The mapping  $g_{k \rightarrow k'}$  is fairly general but must be invertible such that  $g_{k \rightarrow k'}^{-1} = g_{k' \rightarrow k}$  exists. As an alternative notation for  $g$  or its inverse  $g^{-1}$ , we omit the letter  $g$  and write  $\theta_{k'}(\theta_k, u_k)$  and  $(\theta_k(\theta_{k'}), u_k(\theta_{k'}))$  respectively. More naturally, it is also possible to match dimensions on a higher dimensional space where  $N_{k'} + \bar{N}_k = N_k + \bar{N}_k$  where  $(\theta_{k'}, u_{k'}) = g(\theta_k, u_k)$  but we won't discuss this option further here.

In order to design a MH algorithm, we will construct our proposal in two stages as in

$$q(k', \theta_{k'}|k, \theta_k) = q(k'|k, \theta_k)q(\theta_{k'}|k', k, \theta_k).$$

The first factor in this proposal is the probability of choosing a jump from  $k$  to  $k'$  when the chain is in  $\theta_k$ . Often, this term is taken to be independent of  $\theta_k$ , so  $q(k'|k) = q(k'|k, \theta_k)$ . We will denote the jump probabilities  $q(k'|k)$  as  $q_{k \rightarrow k'}$ . The second factor, which we will denote as  $f_{k'}(\theta_{k'}) \equiv q(\theta_{k'}|k', k, \theta_k)$ , will be defined via the variable transformation  $g_{k \rightarrow k'}$ . Noting that  $\theta_{k'} = g_{k \rightarrow k'}(\theta_k, u_k)$ , for some density  $f_k(\theta_k)$ , the density of  $\theta_{k'}$  can be written as is

$$\begin{aligned} f_{k'}(\theta_{k'}) &= f_k(\theta_k(\theta_{k'}))q_k(u_k(\theta_{k'})) \left| \frac{\partial g_{k \rightarrow k'}^{-1}(\theta_{k'})}{\partial \theta_{k'}} \right| \\ &= f_k(\theta_k(\theta_{k'}))q_k(u_k(\theta_{k'})) \left| \frac{\partial g_{k \rightarrow k'}(\theta_k, u_k)}{\partial (\theta_k, u_k)} \right|^{-1}. \end{aligned}$$

To simplify the notation, in the sequel we will denote the Jacobian terms as

$$J_{k \rightarrow k'} \equiv \frac{\partial g_{k \rightarrow k'}(\theta_k, u_k)}{\partial (\theta_k, u_k)} \quad J_{k' \rightarrow k} \equiv \frac{\partial g_{k \rightarrow k'}^{-1}(\theta_{k'})}{\partial \theta_{k'}} = J_{k \rightarrow k'}^{-1}.$$

Now, interpret  $f_k(\theta_k)$  as a reverse jump proposal  $q(\theta_k|k, k', \theta_{k'})$ . The ratio of the proposals to compute the MH-acceptance probability can be written for this case as

$$\begin{aligned} \frac{q(k, \theta_k|k', \theta_{k'})}{q(k', \theta_{k'}|k, \theta_k)} &= \frac{f_k(\theta_k)q_{k' \rightarrow k}}{f_{k'}(\theta_{k'})q_{k \rightarrow k'}} = \frac{f_k(\theta_k)q_{k' \rightarrow k}}{f_k(\theta_k(\theta_{k'}))q_k(u_k(\theta_{k'}))q_{k \rightarrow k'}} \left| \frac{\partial g_{k \rightarrow k'}(\theta_k, u_k)}{\partial (\theta_k, u_k)} \right| \\ &= \frac{q_{k' \rightarrow k}}{q_k(u_k(\theta_{k'}))q_{k \rightarrow k'}} |J_{k \rightarrow k'}|. \end{aligned}$$

The ratio of the targets is

$$\frac{\pi(k', \theta_{k'})}{\pi(k, \theta_k)} = \frac{\phi_{k'}(\theta_{k'}) \frac{p_{k'}}{\sum_{\kappa \in \mathcal{K}} p_{\kappa} Z_{\kappa}}}{\phi_k(\theta_k) \frac{p_k}{\sum_{\kappa \in \mathcal{K}} p_{\kappa} Z_{\kappa}}} = \frac{\phi_{k'}(\theta_{k'}) p_{k'}}{\phi_k(\theta_k) p_k}.$$

Consequently, we arrive at the rather complicated looking formula for the RJ-MCMC acceptance probability

$$\alpha((k, \theta_k) \rightarrow (k', \theta_{k'})) = \min \left\{ 1, \frac{\phi_{k'}(\theta_{k'}) p_{k'}}{\phi_k(\theta_k) p_k} \frac{q_{k' \rightarrow k}}{q_k(u_k) q_{k \rightarrow k'}} |J_{k \rightarrow k'}| \right\} \quad (19.14)$$

$$\equiv \min\{1, r_{k \rightarrow k'}\} \quad (19.15)$$

$$\equiv \alpha_{k \rightarrow k'}. \quad (19.16)$$

The  $r_{k \rightarrow k'}$  argument min function is known as the MH-ratio. The acceptance probability of the jump in the reverse direction is

$$\begin{aligned} \alpha_{k' \rightarrow k} &= \min \left\{ 1, \frac{\phi_k(\theta_k) p_k}{\phi_{k'}(\theta_{k'}) p_{k'}} \frac{q_k(u_k) q_{k \rightarrow k'}}{q_{k' \rightarrow k}} |J_{k' \rightarrow k}| \right\} \\ &= \min\{1, r_{k' \rightarrow k}\} = \min \left\{ 1, r_{k \rightarrow k'}^{-1} \right\} \end{aligned}$$

Note that for a pair of reversible jumps  $(k \rightarrow k')$  and  $(k' \rightarrow k)$ , the corresponding MH-ratios are simply the inverses of each other  $r_{k' \rightarrow k} = r_{k \rightarrow k'}^{-1}$ .

### 1.19.6.2 RJ-MCMC algorithm

The RJ-MCMC algorithm is actually a special Metropolis Hastings method with a special proposal mechanism for transdimensional moves. To construct the algorithm, for each pair  $k, k' \in \mathcal{K}$  we need to decide on the jump probabilities  $q_{k \rightarrow k'}$  and  $q_{k' \rightarrow k}$ . Note that these are just parameters of the sampling algorithm and not the model, but a careful choice is important for good mixing. In practice, often only jumps between “adjacent”  $k$  and  $k'$  are used as it is relatively simpler to design proposals with reasonable acceptance probability. Here, a popular choice is only allowing moves with  $k' = k+1, k' = k-1, k' = k$ , where these are called *birth, death and update* moves.

If a pair of moves have nonzero probability,  $q_{k \rightarrow k'} q_{k' \rightarrow k} > 0$ , we have to have to design the following:

- For jumps to a larger space  $N_{k'} > N_k$  we design a suitable invertible transformation  $g_{k \rightarrow k'}$  and a proposals for  $q_k(u_k)$  to sample a  $\bar{N}_k$  dimensional random vector to match the dimensions such that  $N_{k'} = N_k + \bar{N}_k$ . Note that our choice completely fixes the moves in the reverse direction as well.
- Calculate the Jacobian determinants  $|J_{k \rightarrow k'}| = |J_{k' \rightarrow k}|^{-1}$ .
- Calculate the acceptance probabilities. Remember that if

$$\alpha_{k' \rightarrow k} = \min \{1, r_{k' \rightarrow k}\} \Leftrightarrow \alpha_{k \rightarrow k'} = \min \{1, r_{k \rightarrow k'}\} = \min \left\{ 1, \frac{1}{r_{k' \rightarrow k}} \right\}$$

A summary of the RJ-MCMC is shown as Algorithm 6

**Example 6 (Reversible Jump - MCMC).** As a illustrative toy example, we define a target density on the union of two spaces  $\mathcal{E} = \mathcal{E}_1 \cup \mathcal{E}_2$  where

$$\mathcal{E}_1 = \{\{1\} \times r\} \quad \mathcal{E}_2 = \{\{2\} \times (x, y)\}$$

with parameters corresponding to each space as

$$\theta_1 \equiv r \quad \theta_2 \equiv (x, y)$$

We choose, for  $k = 1$ , a target proportional to a truncated exponential distribution. For  $k = 2$ , our target is a two dimensional Gaussian density truncated on an elliptical region

$$\begin{aligned} \phi_1(r) &= e^{-\lambda r} [0 \leq r \leq 1] \\ \phi_2(x, y) &= \exp \left( -\frac{(x - \mu_x)^2 + (y - \mu_y)^2}{2\sigma^2} \right) \left[ \left( \frac{x}{a} \right)^2 + \left( \frac{y}{b} \right)^2 \leq 1 \right] \end{aligned}$$

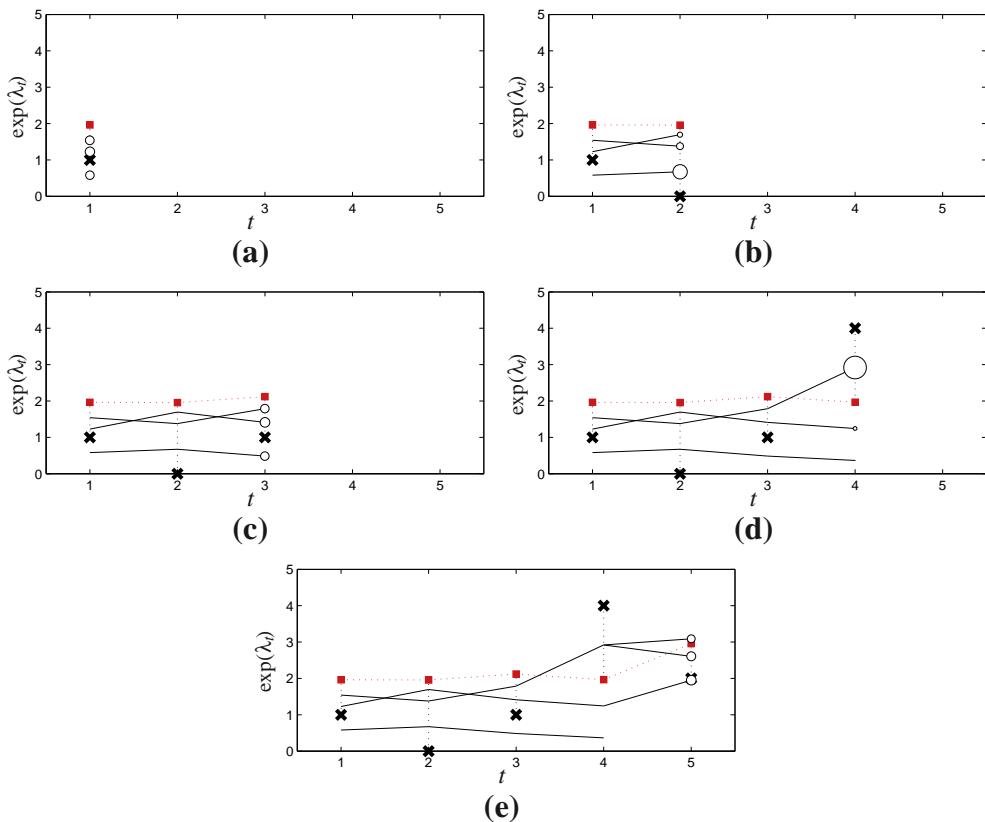

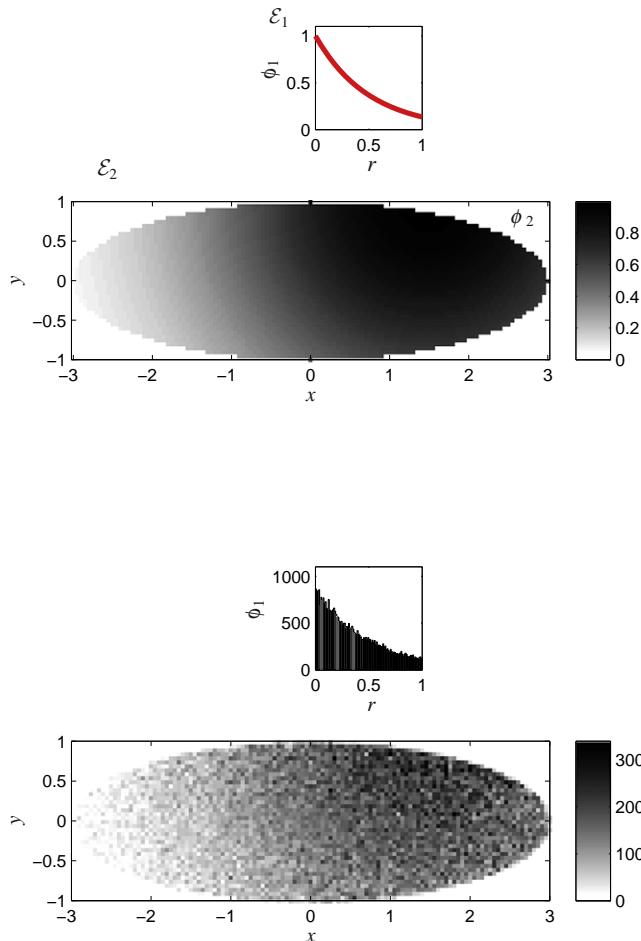

**FIGURE 19.23**

Illustration of the Bootstrap particle filter for the model in Eq. (19.10) and Eq. (19.11) using  $N = 3$  particles. The observations  $y_t$  are shown as black crosses. The squares show the true state of the process  $\exp(\lambda_t)$  used for generating the observations  $y_t$ . Remember that  $\langle y_t \rangle = \exp(\lambda_t)$  due to the Poisson assumption so it is natural to plot the  $y_t$  and  $\exp(\lambda_t)$  on the same plot. At each time  $t$ , the particles are shown as individual trajectories of  $\lambda_{1:t}$  with the circle size proportional to the normalized weight at time  $t$ . The edges denote the ancestral links. While the term “particle” suggests that each particle is only a point in  $\lambda_t$ , it is actually more natural to view a particle as an entire trajectory of  $\lambda_{1:t}$ . At each time  $t$ , each particle selects a new position  $l_{t+1}$  and the new weight  $W_{t+1}(l_{1:t+1})$  is computed recursively. If the effective sample size drops below a chosen threshold, we compute the normalized weights  $\tilde{w}^{(1:N)}$  and select each particle via resampling (See at time  $t = 4$ ) and reset the weights to  $1/N$ .

the normalization constants  $Z_1 = \int_0^1 e^{-\lambda r} dr$  and  $Z_2 = \int \int \phi_2(x, y) dx dy$  are assumed to be unknown. As shown earlier, these cancel out in the acceptance probability. The target density is

$$\pi(k, \theta_k) = \frac{1}{p_1 Z_1 + p_2 Z_2} ([k = 1] \phi_1(r) p_1 + [k = 2] \phi_2(x, y) p_2) \quad (19.17)$$

**FIGURE 19.24**

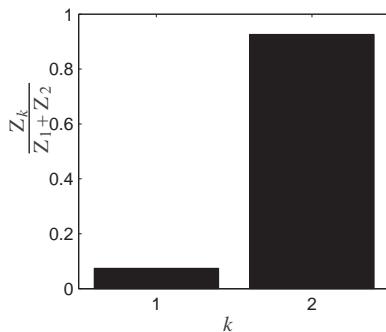

(Top) The target density  $\pi \propto [k = 1]\phi_1(r)p_1 + [k = 2]\phi_2(x, y)p_2$ , with parameters  $\lambda = 1, a = 3, b = 1, \mu_x = 1.5, \mu_y = 1, \sigma^2 = 4, p_1 = p_2 = 1$ . (Bottom) Histograms obtained from samples of the RJ-MCMC algorithm.

This target density is illustrated on Figures 19.23, 19.24, 19.25.

We will derive now a RJ-MCMC method to sample from the target density defined in Eq. (19.17).

### 1.19.6.2.1 Acceptance probabilities

To design a RJ-MCMC algorithm, we should define an “ordinary” MCMC algorithm to sample within each space  $\mathcal{E}_k$  for all  $k \in \mathcal{K}$  and transdimensional moves for each pair  $k, k'$  such that  $k \neq k'$  using the general formula for the RJ-MCMC acceptance probability  $\alpha$  as given in 19.14.

**FIGURE 19.25**

Histogram estimate of the marginal  $\pi(k)$ . By simply counting and normalizing the number of steps the chain spends in each space, we can estimate the marginal  $\pi(k)$ , with probabilities  $p_1 Z_1 / (p_1 Z_1 + p_2 Z_2)$  and  $p_2 Z_2 / (p_1 Z_1 + p_2 Z_2)$ . Such quantities are useful for model comparison.

$\mathcal{E}_1 \rightarrow \mathcal{E}_1$ .

We use a Metropolis algorithm with an independent uniform proposal such that

$$r' \sim \mathcal{U}(0, 1),$$

giving the acceptance probability as

$$\alpha_{1 \rightarrow 1} = \min \left\{ 1, \frac{\phi_1(r')}{\phi_1(r)} \right\}, \quad (19.18)$$

$\mathcal{E}_2 \rightarrow \mathcal{E}_2$

We choose a symmetric random walk proposal

$$\begin{pmatrix} x' \\ y' \end{pmatrix} = \begin{pmatrix} x \\ y \end{pmatrix} + \epsilon, \quad (19.19)$$

where  $\epsilon \sim \mathcal{N}(0, vI)$ . Since the proposal is symmetric, the Metropolis acceptance probability is

$$\alpha_{2 \rightarrow 2} = \min \left\{ 1, \frac{\phi_2(x', y')}{\phi_2(x, y)} \right\} \quad (19.20)$$

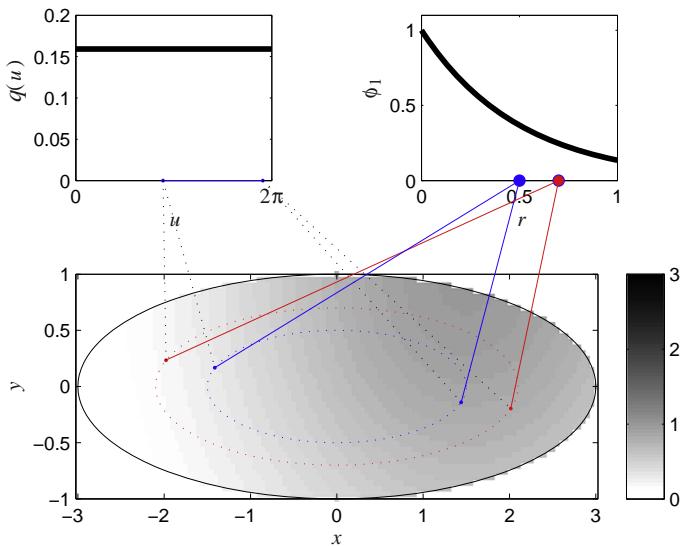

$\mathcal{E}_1 \rightarrow \mathcal{E}_2$

In order to make a transition from the one dimensional space  $\mathcal{E}_1$  to the two dimensional space  $\mathcal{E}_2$ , we define the auxiliary variable  $u_1$  such that

$$u_1 \sim q_1(u_1) = U(0, 2\pi) = \frac{1}{2\pi} \quad (19.21)$$

and define the following one-to-one transformation  $(x, y) = g(r, u)$  as

$$x = ar \cos(u) \quad y = br \sin(u).$$

**FIGURE 19.26**

The mapping  $(x, y) = g(r, u)$ . For trans-dimensional jumps between the spaces  $\mathcal{E}_1$  (top, right) and  $\mathcal{E}_2$  (bottom), to match the dimensions, we draw an angle uniformly  $u \sim q(u) = \mathcal{U}(0, 2\pi)$  and construct a one-to-one mapping  $g$ . A proposal  $f_1$  on  $\mathcal{E}_1$  translates to a proposal  $f_2$  on  $\mathcal{E}_2$  as  $f_2(x, y) = f_1(r(x, y))q(u(x, y))|J_{2 \rightarrow 1}|$ . The acceptance probability does not depend on  $f_1$  or  $f_2$  as these cancel out; only the term  $q(u(x, y))|J_{2 \rightarrow 1}|$  remains.

Each  $r$  is mapped uniformly into a point on the ellipse  $x^2/a + y^2/b = r^2$ . This mapping is depicted in Figures 19.26, 19.27. To compute the acceptance probability, we need the Jacobian. The partial derivatives of the transformation are obtained as follows

$$\begin{aligned} \frac{\partial x}{\partial r} &= a \cos(u) & \frac{\partial x}{\partial u} &= -ar \sin(u) \\ \frac{\partial y}{\partial r} &= b \sin(u) & \frac{\partial y}{\partial u} &= br \cos(u) \end{aligned} \quad (19.22)$$

and the Jacobian term can then be determined as

$$\begin{aligned} |J_{1 \rightarrow 2}| &= \left| \frac{\partial x}{\partial r} \frac{\partial y}{\partial u} - \frac{\partial x}{\partial u} \frac{\partial y}{\partial r} \right| \\ &= |a \cos(u)br \cos(u) + ar \sin(u)b \sin(u)| = \left| abr(\cos^2(u) + \sin^2(u)) \right| = abr \end{aligned}$$

Finally, substituting the results the acceptance probability  $\alpha_{1 \rightarrow 2}$  is obtained as

$$\alpha_{1 \rightarrow 2} = \min \left\{ 1, \frac{\phi_2(x, y)p_2}{\phi_1(r)p_1} \frac{q_{2 \rightarrow 1}}{q_{1 \rightarrow 2}} \frac{1}{(1/2\pi)} |J_{1 \rightarrow 2}| \right\} \quad (19.23)$$

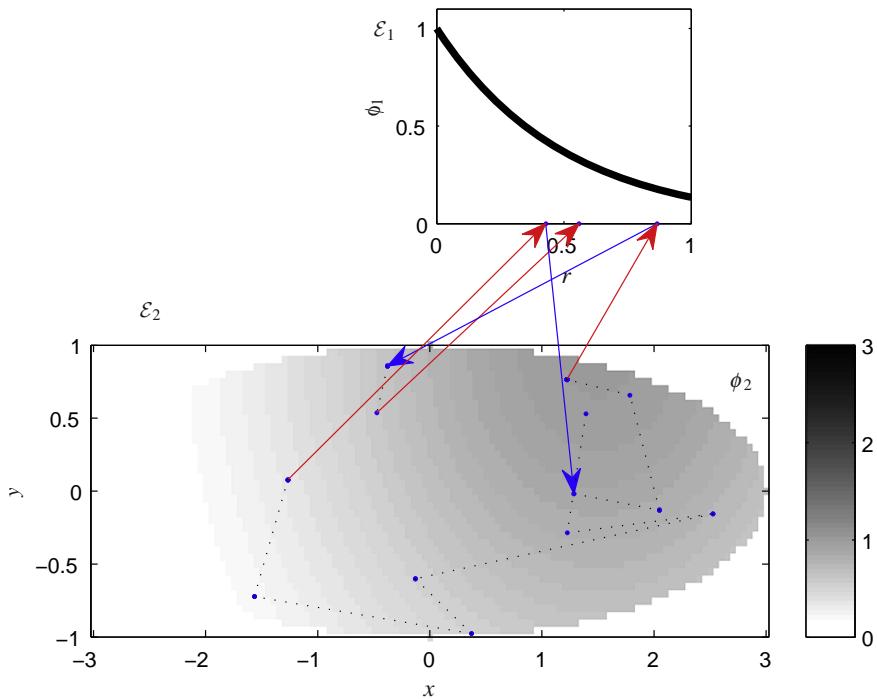

**FIGURE 19.27**

Illustration of the RJ-MCMC algorithm on the toy problem. The dotted lines corresponds to accepted moves within the same space, and arrows correspond to transdimensional moves. The algorithm proceeds as follows: Suppose at step  $\tau$ , the chain is in space  $\mathcal{E}_{k(\tau)}$ . We first propose the next index  $k'$  with probability  $q_{k(\tau) \rightarrow k'}$ . If  $k' = k(\tau)$ , we use an ordinary MH move. Otherwise, we draw a new  $u \sim p(u)$  and propose a new point  $\theta_{k'}(\theta_{k(\tau)}^{(\tau)}, u) \in \mathcal{E}_{k'}$  and accept it with probability  $\alpha_{k(\tau) \rightarrow k}'$ . If the move is accepted we set  $(k^{(\tau+1)}, \theta_{k^{(\tau+1)}}^{(\tau+1)}) \leftarrow (k', \theta_{k'})$ . Otherwise, the chain stays at the same point point is equal to the old point  $(k^{(\tau+1)}, \theta_{k^{(\tau+1)}}^{(\tau+1)}) \leftarrow (k^{(\tau)}, \theta_{k(\tau)}^{(\tau)})$ .

$$\mathcal{E}_2 \rightarrow \mathcal{E}_1$$

We find the inverse transformation  $g^{-1}$ ,

$$r = \sqrt{\frac{x^2}{a^2} + \frac{y^2}{b^2}} \quad u = \arccos\left(\frac{xb}{\sqrt{x^2b^2 + y^2a^2}}\right)$$

The Jacobian  $J_{2 \rightarrow 1}$  is obtained by calculating the partial derivatives

$$\begin{aligned} \frac{\partial r}{\partial x} &= \frac{xb}{a\sqrt{x^2b^2 + y^2a^2}} & \frac{\partial r}{\partial y} &= \frac{ya}{b\sqrt{x^2b^2 + y^2a^2}} \\ \frac{\partial u}{\partial x} &= -\frac{yab}{x^2b^2 + y^2a^2} \frac{y}{|y|} & \frac{\partial u}{\partial y} &= \frac{xab}{x^2b^2 + y^2a^2} \frac{y}{|y|} \end{aligned}$$

and the determinant is

$$|J_{2 \rightarrow 1}| = \frac{1}{\sqrt{x^2 b^2 + y^2 a^2}}$$

Note that we could have avoided this calculation by directly using the Jacobian of the inverse as  $|J_{2 \rightarrow 1}| = |J_{1 \rightarrow 2}|^{-1} = 1/(abr)$ , giving the same result. The acceptance probability  $\alpha_{2 \rightarrow 1}$  is found as follows:

$$\alpha_{2 \rightarrow 1} = \min \left\{ 1, \frac{\phi_1(r)p_1}{\phi_2(x, y)p_2} \frac{q_{1 \rightarrow 2}(1/2\pi)}{q_{2 \rightarrow 1}} |J_{2 \rightarrow 1}| \right\} \quad (19.24)$$

## 1.19.7 Open issues and problems

In this tutorial, we have sketched in a self contained manner the basic techniques and the principles of Monte Carlo computation, along with several examples. Monte Carlo computation is a very broad topic and with the available computing power, researchers are tackling increasingly more complex models and problems. The need for extracting structure from large datasets forces the researchers to devise increasingly more complicated models that ask for more efficient inference methodologies. In some research communities, most notably machine learning, the MC methods are considered not very scalable to very large data sets due to their heavy computational requirements. It is an open issue in research for developing MC methods for such datasets. The research frontier, at the time of this writing, is swiftly moving. Researchers deal with techniques such as adaptive methods that learn suitable proposals[32], combining sequential Monte Carlo with MCMC [33], likelihood free inference [6] or exploiting parallel computation [34] for scalability.

## 1.19.8 Further reading

To investigate topics more deeper, we suggest a few key references. For basic probability theory, Grimmett and Stirzaker [4] is a very good reference. More rigorous material, needed for a deeper understanding of advanced subjects is covered in Rosenthal [12] and for the theory of Markov chains Norris is a key reference [7]. A very gentle introduction to basic Monte Carlo methods from a machine learning perspective is in MacKay's book [5]. A good tutorial introduction to Markov chain Monte Carlo methods can be found in [6,18]. There are also excellent tutorials on sequential Monte Carlo methods, most notably by Doucet et. al. [10,30] or Liu et. al. [8,20].

## 1.20.1 Introduction

Every day, society generates large amounts of data, which can be subjected to analysis and management. One vital way to handle these data is to classify or group them into a set of categories or clusters. In order to learn a new object or understand a new phenomenon, people seek features to describe it; additionally, they compare it with other known objects or phenomena based on similarity or dissimilarity, generalized as proximity, according to some certain standards or rules. In unsupervised classification, also called clustering or exploratory data analysis, no labeled data are available. The goal of clustering is to separate a finite, unlabeled data set into a finite, discrete set of “natural,” hidden data structures, rather than to accurately characterize unobserved samples generated from the same probability distribution [1,2]. As noted by Backer and Jain, “in cluster analysis a group of objects is split up into a number of more or less homogeneous subgroups on the basis of an often subjectively chosen measure of similarity (i.e., chosen subjectively based on its ability to create “intersecting” clusters), such that the similarity between objects within a subgroup is larger than the similarity between objects belonging to different subgroups” [3].

Clustering algorithms partition data into clusters (groups, subsets, or categories), but these clusters have no universally agreed-upon definition [4]. A cluster can be “a set of entities which are alike, and entities from different clusters are not alike” or “an aggregate of points in the test space such that the distance between any two points in the cluster is less than the distance between any point in the cluster and any point not in it” [4]. A cluster also can be defined as a continuous region of a space containing a relatively high density of points, separated from other such regions by regions containing a relatively low density of points.

Furthermore, a cluster can be defined based on the method used to solve the clustering problem. In hierarchical clustering, a cluster is an entity of connectivity. In partition-based clustering, each cluster is represented by a single prototype vector. In model-based clustering, each cluster is modeled by a statistical distribution. In density estimation clustering, each cluster is defined as a connected dense region. Subspace clustering views clusters as a subspace. If graph theory techniques are used for clustering, each cluster typically is called a clique, a subset of nodes fully connected among themselves. From a membership point of view, clustering can be classified as hard or fuzzy. In hard clustering, each object belongs to one and only one cluster, while in fuzzy clustering, each object has some degree of membership in each cluster.

**FIGURE 20.1**

Clustering procedure (From [5]). Many if not most papers consider mainly the algorithm design or selection, but all the steps shown are important.

In describing a cluster, most researchers consider internal homogeneity and external separation [6–8], i.e., patterns in the same cluster should be similar to each other, while patterns in different clusters should not. Similarities and dissimilarities both should have the potential to be examined in a clear and meaningful way.

Figure 20.1 depicts the four basic steps of the cluster analysis procedure.

Clustering has been applied in a wide variety of fields, ranging from engineering (machine learning, artificial intelligence, pattern recognition, mechanical engineering, electrical engineering), computer sciences (web mining, spatial database analysis, textual document collection, image segmentation) and life and medical sciences (genetics, biology, microbiology, paleontology, psychiatry, clinic, pathology), to earth sciences (geography, geology, remote sensing), social sciences (sociology, psychology, archeology, education), and economics (marketing, business) [4,9]. Accordingly, clustering also is known as numerical taxonomy, learning without a teacher (or unsupervised learning), typological analysis and partitioning. While the diversity of these names reflects the important position of clustering in scientific research, the differing terminologies and goals also results in confusion. Clustering algorithms developed to solve a particular problem in a specialized field usually make assumptions in favor of the application of interest. These biases inevitably affect the algorithm's performance in other problems that do not satisfy the same premises.

Clustering has a long history, dating back to Aristotle [8]. General references on clustering techniques include textbooks by Duda et al. [10], Hartigan [9], Everitt et al. [4], Jain and Dubes [6], Späth [11], Duran and Odell [12], Gordon [7], and Anderberg [13]. Important survey papers on clustering techniques also exist in the literature. Starting from a statistical pattern recognition perspective, Jain, Murty and Flynn reviewed clustering algorithms and other important issues related to cluster analysis [14], while Hansen and Jaumard described clustering problems under a mathematical programming scheme [8]. Kolatch and He investigated applications of clustering algorithms for spatial database systems [15] and information retrieval [16], respectively. Berkhin [17] further expanded the topic to the field of data mining. Murtagh [18] reported advances in hierarchical clustering

**Table 20.1** Notations Used in this Chapter

K,c	Number of clusters
$X = \{x_1, \dots, x_j, \dots, x_N\}$	A set of $N$ input patterns
$x = (x_1, x_2, \dots, x_d)^T \in \mathbb{R}^d$	A pattern belonging to a $d$ -dimensional pattern space
$\{C_1, \dots, C_K\}$	A $K$ -partition of input patterns
$D(\cdot, \cdot)$	Distance function
$S(\cdot, \cdot)$	Similarity function
$J(\cdot)$	Criterion function
$M = (m_1, \dots, m_K)$	Prototype matrix of clusters
$\Gamma = \{\gamma_{ij}\}$	Partition matrix
$\Theta = (\theta_1, \dots, \theta_K)$	Model parameter matrix

algorithms, and Baraldi surveyed several fuzzy and neural network clustering methods [19]. Additional survey papers include those by Baraldi and Schenato [20], Bock [21], Dubes [22], Fasulo [23], and Jain et al. [24]. In addition to these review papers, comparative research on clustering algorithms is also significant [25] presented empirical results for five typical clustering algorithms. Wei et al., [26] compared fast algorithms for large databases. Scheunders [27] compared several clustering techniques for color image quantization, emphasizing computation time and the possibility of obtaining global optima. Applications and evaluations of different clustering algorithms for the analysis of gene expression data from DNA microarray experiments were described by Shamir and Sharan, [28] and Tibshirani et al. [29]. An experimental evaluation of document clustering techniques based on hierarchical and  $K$ -means clustering algorithms was summarized by Steinbach et al. [30].

High-dimensional clustering has become very significant as data continue to become more complex. Surveys regarding biclustering [31,32] and tutorials on subspace clustering [33] review a variety of clustering techniques for such high-dimensional data. On the other hand, researchers such as Andrew Ng [34] have suggested achieving improved performance in classification using unsupervised methods. This idea combines both supervised and unsupervised learning to accomplish recognition tasks. The purpose of this chapter is to extend the review offered by Xu and Wunsch [35] in order to provide a description of some influential and important clustering algorithms rooted in statistics, computer science, and machine learning, with an emphasis on signal and image processing. Much of this chapter's material has been taken or adapted from [5,35–37].

## 1.20.2 Clustering algorithms

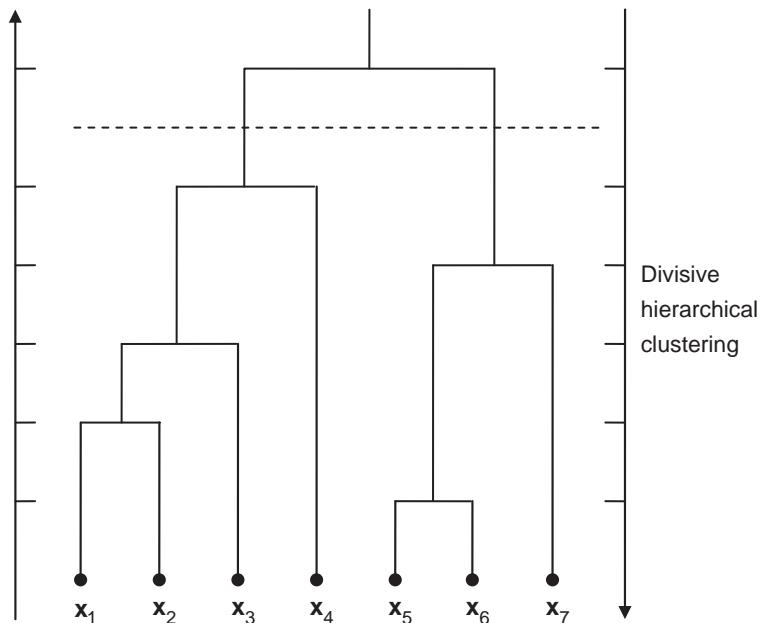

Several taxonomies of clustering algorithms [4,6,8,14,15,17] have been utilized, but the most widely accepted clustering techniques are hierarchical clustering and partitional clustering based on the properties of the clusters they generate [14]. Hierarchical clustering gathers data objects with a sequence of partitions, either from singleton clusters to a cluster including all individuals or vice versa. Partitional

clustering directly divides data objects into some pre-specified (either known or estimated) number of clusters without the hierarchical structure.

We begin with a discussion of hierarchical clustering followed by classical partitional clustering algorithms. Then, recent advanced techniques for subspace clustering and biclustering will be discussed. Finally, we will review unsupervised feature learning in the last part of the section. Table 20.1 lists notations used in this chapter.

### 1.20.2.1 Hierarchical clustering

As described by Xu and Wunsch [35], hierarchical clustering (HC) algorithms organize data into a hierarchical structure according to the proximity matrix. The results of HC usually are depicted by a binary tree or dendrogram, as depicted in Figure 20.2. The root node of the dendrogram represents the whole data set, and each leaf node represents a data object. The intermediate nodes thus describe the extent to which the objects are proximal to each other, and the height of the dendrogram usually expresses the distance between each pair of objects or clusters, or one object and one cluster. The best clustering results can be obtained by cutting the dendrogram at different levels. This representation provides very informative descriptions and a visualization of the potential data clustering structures, especially when real hierarchical relationships exist in the data, such as in the data from evolutionary

**FIGURE 20.2**

An example of a dendrogram in hierarchical clustering. The dotted line corresponds to choosing a number of clusters based on where the tree is cut. Note that the line does not necessarily have to be a straight, horizontal cut.

research on different species of organisms. HC algorithms are classified primarily as agglomerative methods or divisive methods. Agglomerative clustering starts with  $N$  clusters, each of which includes exactly one object. A series of merge operations then combines all objects into the same group. Divisive clustering proceeds in an opposite way. The entire data set initially belongs to a single cluster, and then a procedure successively divides it until all clusters are singletons. For a cluster with  $N$  objects, there are  $2^{N-1} - 1$  possible two-subset divisions, which is very computationally expensive [38]. Therefore, divisive clustering is not commonly used in practice. We focus on agglomerative clustering in the following discussion.

The variety of agglomerative clustering algorithms originally came about because of the different definitions for the distance between two clusters. The general formula for distance was proposed by Lance and Williams [39] as:

$$\begin{aligned} D(C_l, (C_i, C_j)) = & \alpha_i D(C_l, C_i) + \alpha_j D(C_l, C_j) + \\ & \beta D(C_i, C_j) + \gamma |D(C_l, C_i) - D(C_l, C_j)|, \end{aligned} \quad (20.1)$$

where  $D()$  is the distance function, and  $\alpha_i$ ,  $\alpha_j$ ,  $\beta$ , and  $\gamma$  are coefficients whose values depend on the scheme used.

The formula describes the distance between a cluster  $l$  and a new cluster formed by the merging of the two clusters  $i$  and  $j$ . Note that when  $\alpha_i = \alpha_j = 1/2$ ,  $\beta = 0$ , and  $\gamma = -1/2$ , the formula becomes

$$D(C_l, (C_i, C_j)) = \min(D(C_l, C_i), D(C_l, C_j)), \quad (20.2)$$

which corresponds to the single linkage method. When  $\alpha_i = \alpha_j = \gamma = 1/2$  and  $\beta = 0$ , the formula is

$$D(C_l, (C_i, C_j)) = \max(D(C_l, C_i), D(C_l, C_j)), \quad (20.3)$$

which corresponds to the complete linkage method.

Several more complicated agglomerative clustering algorithms, including group average linkage, median linkage, centroid linkage, and Ward's method, can also be constructed by selecting appropriate coefficients in the formula. A detailed table describing the coefficient values for different algorithms is offered in [6, 18]. Single-linkage, complete-linkage and average-linkage methods, all of which also are called graph methods, consider all points of a pair of clusters when calculating their inter-cluster distance. The other methods are called geometric methods because they use geometric centers to represent clusters, and they determine the distances between clusters based on these centers. The important features and properties of these methods were summarized by Everitt [4]. More inter-cluster distance measures, especially the mean-based ones, were introduced by Yager [40], who further discussed their potential for controlling the hierarchical clustering process.

Recently, to handle the limits of HC clustering and large-scale data sets, many new HC techniques have been proposed. Guha, Rastogi and Shim [41] developed an HC algorithm called CURE to explore more sophisticated cluster shapes. The crucial feature of CURE lies in its use of a set of well-scattered points to represent each cluster, which makes it possible to find rich cluster shapes other than hyperspheres while avoiding both the chaining effect [4] of the minimum linkage method and the tendency to favor clusters with similar centroid sizes. These representative points are further gathered towards the cluster centroid according to an adjustable parameter in order to weaken the effects of outliers.

CURE utilizes a random sample (and partition) strategy to reduce computational complexity [42] also proposed another agglomerative HC algorithm, ROCK, to group data with qualitative attributes. They used a novel measure, a “link,” to describe the relationship between a pair of objects and their common neighbors. Like CURE, ROCK uses a random sample strategy to handle large data sets.

Noticing the inability of centroid-based HC to identify arbitrary cluster shapes, relative hierarchical clustering (RHC) was developed, which considers both the internal distance (distance between a pair of clusters that may be merged to yield a new cluster) and the external distance (distance from the two clusters to the rest). It uses the ratio of these distances to decide proximities [43]. Leung et al. [44] demonstrated an interesting hierarchical clustering technique based on scale-space theory. They interpreted clustering using a blurring process, in which each data point is regarded as a light point in an image, and a cluster is represented as a blob. [45] extended agglomerative HC to handle both numeric and nominal data. The proposed algorithm, called SBAC (Similarity-Based Agglomerative Clustering), employs a mixed data measurement scheme that pays extra attention to less common matches of feature values. Parallel techniques for HC are discussed by Olson [46] and Dahlhaus [47].

### 1.20.2.2 Partitional clustering

As opposed to hierarchical clustering, partitional clustering assigns data into  $K$  clusters without any hierarchical structure by optimizing a criterion function, one of which is the sum of squared error criterion. Suppose we want to organize a set of objects  $\mathbf{x}_j \in \Re^d$ ,  $j = 1, \dots, N$ , into  $K$  subsets  $C = \{C_1, \dots, C_K\}$ . The squared error criterion then is defined as:

$$\mathbf{J}(\mathbf{U}, \mathbf{M}) = \sum_{i=1}^K \sum_{j=1}^N u_{ij} \|\mathbf{x}_j - \mathbf{m}_i\|^2, \quad (20.4)$$

where

$\mathbf{M} = [\mathbf{m}_1, \dots, \mathbf{m}_k]$  is the cluster prototype (means) matrix.

$\mathbf{U} = \{u_{ij}\}$  is a partition matrix,  $u_{ij} \in [0, 1]$  and  $\sum_{i=1}^K u_{ij} = 1$ .  $u_{ij}$  is the membership of data  $x_j$  in cluster  $C_i$ . In hard clustering,  $u_{ij} = 0$  or  $1$ , as is the case with well-known k-means. In fuzzy clustering,  $u_{ij}$  can have any value from  $0$  to  $1$ , as is the case with Fuzzy C-means (FCM).

### 1.20.2.3 K-means and Fuzzy C-means algorithm

The K-means algorithm is one of the best-known clustering algorithms [48]. The basic steps of K-means are as follows:

- S1.** Initialize a  $K$ -partition randomly or based on some prior knowledge, and calculate the cluster prototype matrix  $\mathbf{M} = [\mathbf{m}_1, \dots, \mathbf{m}_K]$ ;
- S2.** Assign each object in the data set to the nearest cluster  $C_w$ ;
- S3.** Recalculate the cluster prototype matrix based on the current partition:

$$\mathbf{m}_i = \frac{1}{N_i} \sum_{x_j \in C_i} \mathbf{x}_j. \quad (20.5)$$

**S4.** Repeat steps 2–3 until there is no change for each cluster.

Note that the update in step S3 requires all the data points. One way to enhance the K-means to online learning is to adjust the cluster means each time a data point is presented:

$$\mathbf{m}^{\text{new}} = \mathbf{m}^{\text{old}} + \eta(\mathbf{x} - \mathbf{m}^{\text{old}}), \quad (20.6)$$

where  $\eta$  is the learning rate.

In the signal processing community, an algorithm similar to k-means, known as the Linde-Buzo-Gray (LBG) algorithm, was suggested for vector quantization (VQ) [49] in order to signal compression. In this context, prototype vectors are called code words, which constitute a code book. VQ aims to represent the data with a reduced number of elements while minimizing information loss.

As stated above regarding fuzzy clustering, the object can hold a certain degree of membership in all clusters. This is particularly useful when the boundary between the clusters is ambiguous. The procedure of fuzzy C-means [50] is similar to that of k-means, with the exception of the following updating rules:

- S1.** Select appropriate values for  $m$ ,  $c$ , and a small positive number  $\varepsilon$ . Initialize the prototype matrix  $\mathbf{M}$  randomly. Set step variable  $t = 0$ ;
- S2.** Calculate (at  $t = 0$ ) or update (at  $t > 0$ ) the membership matrix  $\mathbf{U}$  using:

$$u_{ij}^{(t+1)} = 1 / \left( \sum_{l=1}^c (D(x_j, m_l)/D(x_j, m_l))^{2/(1-m)} \right), \quad \text{for } i = 1, \dots, c \text{ and } j = 1, \dots, N; \quad (20.7)$$

- S3.** Update the prototype matrix  $\mathbf{M}$  using:

$$\mathbf{m}_i^{(t+1)} = \left( \sum_{j=1}^N (u_{ij}^{(t+1)})^m \mathbf{x}_j \right) / \left( \sum_{j=1}^N (u_{ij}^{(t+1)})^m \right), \quad \text{for } i = 1, \dots, c \quad (20.8)$$

- S4.** Repeat steps 2–3 until  $\|\mathbf{M}^{(t+1)} - \mathbf{M}^{(t)}\| < \varepsilon$ .

FCM, like k-means, suffers from initial partition dependence, as well as noise and outliers. Yager and Filev [51] proposed the mountain method to estimate the cluster centers as an initial partition. Gath and Geva [52] addressed the initialization problem by dynamically adding cluster prototypes, which are located in the space that is not represented well by the previously generated centers. Changing the proximity distance can improve the performance of FCM in relation to outliers [53]. In another approach for mitigating the effect of noise and outliers, Keller interpreted memberships as “the compatibility of the points with the class prototype” [54] rather than as the degree of membership. This relaxes to and  $u_{ij}$  to  $u_{ij} > 0$  results in a possibilistic C-means clustering algorithm.

#### 1.20.2.4 Mixture density-based clustering

From a probabilistic perspective, as described by Xu and Wunsch [35], data objects are assumed to be generated according to several probability distributions. Data points in different clusters are generated

by different probability distributions and can be derived from different types of density functions (e.g., multivariate Gaussian or  $t$ -distribution), or from the same families but with different parameters. If the distributions are known, finding the clusters of a given data set is equivalent to estimating the parameters of several underlying models. Suppose the prior probability (also known as the mixing probability)  $P(C_i)$  for cluster  $C_i$ ,  $i = 1, \dots, K$  (here,  $K$  is assumed to be known; methods for estimating  $K$  are discussed in section II-M) and the conditional probability density  $p(\mathbf{x}|C_i, \boldsymbol{\theta}_i)$  (also known as the component density), where  $\boldsymbol{\theta}_i$  is the unknown parameter vector, are known. Then, the mixture probability density for the entire data set is expressed as:

$$P(\mathbf{x}|\boldsymbol{\theta}) = \sum_{i=1}^K p(\mathbf{x}|C_i, \boldsymbol{\theta}_i)P(C_i), \quad (20.9)$$

where  $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \dots, \boldsymbol{\theta}_K)$ , and  $\sum_{i=1}^K P(C_i) = 1$ . As long as the parameter vector  $\boldsymbol{\theta}$  is decided, the posterior probability for assigning a data point to a cluster can be calculated easily with Bayes's theorem. Here, the mixtures can be constructed with any type of component, but more commonly, a multivariate Gaussian density is used due to its complete theory and analytical tractability [4, 36]. Parameter  $\boldsymbol{\theta}$  can be estimated using maximum likelihood estimation (ML).

Unfortunately, because the solutions of the likelihood equations cannot be obtained analytically in most circumstances [55], iteratively optimal approaches are required to approximate the ML estimates. Among these methods, the expectation-maximization (EM) algorithm is the most popular [56]. EM regards the data set as incomplete and divides each data point  $\mathbf{x}_j$  into two parts,  $\mathbf{x}_j = \{\mathbf{x}_j^g, \mathbf{x}_j^m\}$ , in which  $\mathbf{x}_j^g$  represents the observable features and  $\mathbf{x}_j^m = (x_{j1}^m, \dots, x_{jK}^m)$  is the missing data, where  $x_{ji}^m$  chooses a value of 1 or 0 according to whether or not  $\mathbf{x}_j$  belongs to the component  $i$ . Thus, the complete data log-likelihood is:

$$l(\boldsymbol{\theta}) = \sum_{j=1}^N \sum_{i=1}^K \mathbf{x}_{ji}^m \log[P(C_i)p(\mathbf{x}_j^g|\boldsymbol{\theta}_i)]. \quad (20.10)$$

The standard EM algorithm generates a series of parameter estimates  $\{\boldsymbol{\theta}^0, \boldsymbol{\theta}^1, \dots, \boldsymbol{\theta}^T\}$ , where  $T$  represents reaching the convergence criterion, as accomplished through the following steps:

1. Initialize  $\boldsymbol{\theta}^0$  and set  $t = 0$ ;
2. E-step: Compute the expectation of the complete data log-likelihood:

$$Q(\boldsymbol{\theta}, \boldsymbol{\theta}^t) = E[\log p(\mathbf{x}^g, \mathbf{x}^m|\boldsymbol{\theta})|\mathbf{x}^g, \boldsymbol{\theta}^t]. \quad (20.11)$$

3. M-step: Select a new parameter estimate that maximizes the  $Q$ -function:

$$\boldsymbol{\theta}^{t+1} = \arg \max_{\boldsymbol{\theta}} Q(\boldsymbol{\theta}, \boldsymbol{\theta}^t). \quad (20.12)$$

4. Increase  $t = t + 1$ ; Repeat steps 2 and 3 until the convergence condition is satisfied.

The major disadvantages of the EM algorithm are its sensitivity to the selection of initial parameters, the effect of a singular covariance matrix, the possibility of convergence to a local optimum, and the slow convergence rate [56]. Variants of EM that address these problems were discussed by McLachlan and Krishnan [56].

A valuable theoretical note pertains to the relationship between the EM algorithm and the K-means algorithm. Celeux and Govaert [57] proved that a classification EM (CEM) algorithm under a spherical Gaussian mixture is equivalent to the K-means algorithm.

MCLUST is a software implementation of a multivariate Gaussian distribution developed by Fraley and Raftery [58]. The initial guess is computed from agglomerative hierarchical clustering, along with the maximum number of clusters. Each component is parameterized by virtue of eigenvalue decomposition, represented as  $\Sigma = \lambda \boldsymbol{\Pi} \mathbf{A} \boldsymbol{\Pi}^T$ , where  $\lambda$  is a scalar,  $\boldsymbol{\Pi}$  is the orthogonal matrix of eigenvectors, and  $\mathbf{A}$  is the diagonal matrix based on the eigenvalues of  $\Sigma$ . The optimal clustering result is achieved by checking the Bayesian Information Criterion (BIC) value.

Gaussian Mixture Density Decomposition (GMDD) also is based on multivariate Gaussian densities and is designed as a recursive algorithm that sequentially estimates each component [59]. GMDD views data points that are not generated from a distribution as noise and the original data as a contaminated model. It utilizes an enhanced model-fitting estimator to iteratively construct each component from the contaminated model. AutoClass considers more families of probability distributions (e.g., Poisson and Bernoulli) for different data types [60]. AutoClass uses a Bayesian approach to find the optimal partition of the given data based on the prior probabilities.

### 1.20.2.5 Neural network-based clustering

Popular neural network-based clustering algorithms include Self-Organizing Feature Maps (SOFM) and Adaptive Resonance Theory (ART), both of which were reviewed by Xu and Wunsch [5, 35].

The objective of SOFM is to represent high-dimensional input patterns with prototype vectors that can be visualized in a usually two-dimensional lattice structure [61, 62]. Each unit in the lattice is called a neuron, and adjacent neurons are connected to each other, offering a clear map depicting how this neuron network fits itself to the input space. Input patterns are fully connected to all neurons via adaptable weights, and during the training process, neighboring input patterns are projected into the lattice, corresponding to adjacent neurons. In this sense, some authors prefer to think of SOFM as a method by which to display latent data structures in a visual way rather than via a clustering approach.

While SOFM enjoy the merits of input space density approximation and independence regarding the order of input patterns, a number of user-dependent parameters become problematic when applied in real practice. Like the *K*-means algorithm, SOFM must predefine the size of the lattice, i.e., the number of clusters, which is unknown in most circumstances. Additionally, trained SOFM may suffer from input space density misrepresentation [63], where areas of low and high pattern density may be over-represented and under-represented, respectively. Kohonen [62] reviewed a variety of SOFM variants that help to eliminate the drawbacks of basic SOFM and broaden its applications. SOFM also can be integrated with other clustering approaches (e.g., *K*-means algorithm or HC) to provide more effective, faster clustering. Su and Chang [64] and Vesanto and Alhoniemi [65] illustrated two such hybrid systems. The basic procedures of SOFM are then summarized using an algorithm, as follows:

1. Determine the topology of the SOFM. Initialize the weight vectors  $\mathbf{w}_j(0)$  for  $j = 1, \dots, K$ , randomly;
2. Present an input pattern  $\mathbf{x}$  to the network. Choose the winning node  $J$  that has the minimum Euclidean distance to  $\mathbf{x}$ ,

$$J = \arg_j \min (\|\mathbf{x} - \mathbf{w}_j\|). \quad (20.13)$$

3. Calculate the current learning rate and size of the neighborhood;
4. Update the weight vectors of all the neurons in the neighborhood of  $J$ ,

$$\mathbf{w}_j(t + 1) = \mathbf{w}_j(t) + h_{Jj}(t)(\mathbf{x} - \mathbf{w}_j(t)), \quad (20.14)$$

where  $h_{Jj}(t)$  is the neighborhood function, defined, for example, as

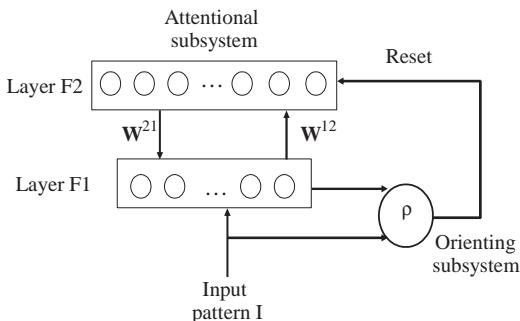

$$h_{Jj}(t) = \eta(t) \exp \left( \frac{-\|\mathbf{r}_J - \mathbf{r}_j\|^2}{2\sigma^2(t)} \right), \quad (20.15)$$

where  $\mathbf{r}_J$  and  $\mathbf{r}_j$  represent the positions of the corresponding neurons on the lattice, and  $\sigma(t)$  is the monotonically decreasing Gaussian kernel width function.

5. Repeat steps 2–4 until the change of the neuron’s position is below a pre-specified small positive number.

Adaptive resonance theory (ART) was developed by Carpenter and Grossberg [66] as a solution to the plasticity and stability dilemma. ART can learn arbitrary input patterns in a stable, fast and self-organizing way, thus overcoming the effect of learning instability that plagues many other competitive networks. ART is not, as is popularly imagined, a neural network architecture. It is a learning theory suggesting that resonance in neural circuits can trigger fast learning. As such, it subsumes a large family of current and future neural network architectures with many variants. ART1, the first member, only deals with binary input patterns [67], although it can be extended to arbitrary input patterns by a variety of coding mechanisms. ART2 extends the applications to analog input patterns [66], and ART3 introduces a new mechanism originating from elaborate biological processes to achieve a more efficient parallel search in hierarchical structures [66]. By incorporating two ART modules, which receive input patterns ( $\text{ART}_a$ ) and corresponding labels ( $\text{ART}_b$ ), respectively, with an inter-ART module, the resulting ARTMAP system can be used for supervised classifications [68]. The match-tracking strategy ensures consistency in category prediction between two ART modules by dynamically adjusting the vigilance parameter of  $\text{ART}_a$ .

As seen in Figure 20.3, ART1 consists of 2-layer nodes, the feature representation field F1 and category (cluster) representation F2. The neurons in layer F1 are activated by input patterns, while the neurons in layer F2 store cluster information. The neurons in layer F2 already being used as representations of input patterns are said to be committed; otherwise, they are uncommitted. Two layers are connected by adaptive weights  $W^{12}$  and  $W^{21}$ . The parameter  $\rho$  determines when the pattern and the expectation match, at which point weight adaption occurs.

**FIGURE 20.3**

ART1 architecture. Two layers are included in the attentional subsystem, connected via bottom-up and top-down adaptive weights. Their interactions are controlled by the orienting subsystem through a vigilance parameter. An attractive feature of this approach is that the number of clusters does not need to be specified in advance.

The ART1 algorithm can be described as follows:

1. Initialize weight matrices  $\mathbf{W}^{12}$  and  $\mathbf{W}^{21}$  as,  $\mathbf{W}^{12} = \xi / (\xi + d - 1)$ , where  $d$  is the dimensionality of the binary input  $\mathbf{x}$ ,  $\xi$  is a parameter that is larger than 1 and  $\mathbf{W}_{ji}^{21} = 1$ ;
2. For a new pattern  $\mathbf{x}$ , calculate the input from layer  $F_1$  to layer  $F_2$  as:  $T_j = \sum_{i=1}^d \mathbf{W}_{ij}^{12} x_i$ ;
3. Activate layer  $F_2$  by choosing node  $J$  with the winner-takes-all rule  $T_J = \max_j \{T_j\}$ ;  
Compare the expectation from layer  $F_2$  with the input pattern. If  $\rho \leq \frac{|\mathbf{x} \cap \mathbf{W}_J^{21}|}{|\mathbf{x}|}$ , where  $\cap$  represents the logic AND operation, go to step 5a; otherwise, go to step 5b.
4.
  - a. Update the corresponding weights for the active node as  $\mathbf{W}_J^{21} = \mathbf{x} \cap \mathbf{W}_J^{21}$  and  $\mathbf{W}_J^{12} = \frac{\xi \mathbf{W}_J^{12}}{\xi - 1 + |\mathbf{W}_J^{12}|}$ ;
  - b. Send a reset signal to disable the current active node using the orienting subsystem, and return to step 3;
5. Present another input pattern, and return to step 2 until all patterns are processed.

Note the relationship between the ART network and other clustering algorithms described in traditional and statistical language. Moore [69] used several clustering algorithms to explain the clustering behaviors of ART1 and therefore induced and proved a number of important ART1 properties, notably, its equivalence to varying  $K$ -means clustering. She also showed how to adapt these algorithms under the ART1 framework.

Fuzzy ART (FA) benefits from incorporating fuzzy set theory with ART. FA operates in a way similar to ART1 and uses the fuzzy set operators to replace the binary operators, allowing it to work

for all real data sets. FA exhibits many desirable characteristics, such as fast and stable learning and atypical pattern detection. Huang and Heileman [70] investigated and revealed more FA properties, classified as template, access, reset and the number of learning epochs. To overcome these shortcomings, Williamson [71] described Gaussian ART (GA), in which each cluster is modeled with a Gaussian distribution and represented geometrically as a hyperellipsoid. GA does not inherit the offline fast learning property of FA. Hypersphere ART (HA) [72] for hyperspherical clusters and ellipsoid ART (EA) ([73] for hyperellipsoidal clusters are proposed to offer a more efficient representation of clusters while maintaining the important properties of FA.

### 1.20.2.6 Spectral clustering

Spectral clustering has become popular because it is easy to implement yet outperforms traditional algorithms, such as k-means.

The name *spectral clustering* comes from the technique of using the spectrum (eigenvalues) of the similarity matrix to perform dimension reduction before clustering with traditional clustering methods. The similarity matrix is built from the dataset.

Given a dataset  $\mathbf{x}_1, \dots, \mathbf{x}_n$  the similarity matrix can be built as follows. Each vertex  $v_i$  represents a data point  $x_i$ . Two vertices are connected by an edge weighted by  $w_{ij}$ , which is the similarity between the two data points, usually given in the clustering problem. If no prior information about the similarity exists, a Gaussian similarity function can be used instead:  $w_{ij, i \neq j} = \exp\left(-\frac{\|x_i - x_j\|^2}{2\sigma^2}\right)$ , where  $\sigma$  controls the width of the neighborhood. The degree of vertex  $v_i$  is defined as  $d_i = \sum_{j=1}^n w_{ij}$ .

The adjacent matrix is given by  $\mathbf{W} = (w_{ij})_{i,j=1 \dots n'}$  and the degree matrix is defined as the diagonal matrix  $\mathbf{D}$  with the degrees  $d_1, \dots, d_n$  on the diagonal. From those, a Laplacian matrix can be built:

Unnormalized Laplacian matrix:  $\mathbf{L} = \mathbf{D} - \mathbf{W}$ .

Normalized Laplacian matrix [74]:  $\mathbf{L}_{\text{sym}} = \mathbf{D}^{-1} \mathbf{L}$ .

Normalized Laplacian matrix [75]:  $\mathbf{L}_{\text{rw}} = \mathbf{D}^{-1/2} \mathbf{L} \mathbf{D}^{-1/2}$ .

Each Laplacian matrix has a respective corresponding spectral clustering algorithm. As these algorithms are similar, we only list here the normalized spectral clustering algorithm by Ng et al. [74]; for other algorithms, see [76]:

- S1.** Compute the normalized Laplacian  $\mathbf{L}_{\text{sym}}$ .
- S2.** Compute the first  $k$  eigenvectors  $\mathbf{u}_1, \dots, \mathbf{u}_k$  of  $\mathbf{L}_{\text{sym}}$ .
- S3.** Let  $\mathbf{U} \in R^{n \times k}$  be the matrix containing the vectors  $\mathbf{u}_1, \dots, \mathbf{u}_k$  as columns.
- S4.** From the matrix  $\mathbf{T}$ , form  $\mathbf{U}$  by normalizing the rows to norm 1.
- S5.** For  $i=1, \dots, n$ , let  $\mathbf{y}_i \in R^k$  be the vector corresponding to the  $i$ th row of  $\mathbf{T}$ .
- S6.** Cluster the points  $\mathbf{y}_i$  with  $k$ -means into clusters  $C_1, \dots, C_k$ .

A special spectral clustering technique is to change the representation of the abstract data points  $\mathbf{x}_i$  into points  $\mathbf{y} \in R^k$ . Laplacian properties make this change of representation useful so that clusters can be made trivially using k-means.

Concerning computational complexity, spectral clustering is  $O(n^3)$  because of the computation of eigenvectors. One can reduce this complexity substantially by making the similarity matrix sparse and applying a special routine for the sparse matrix to compute only the first  $k$  smallest eigenvectors.

### 1.20.2.7 Subspace clustering and biclustering

As technology continues to develop, more and more increasingly complex (especially in dimension) data are being generated, and the assumption that the number of elements is larger than the number of features no longer holds true. This voids many approaches and demands new algorithms to process high-dimensional data.

In this section, we will first clarify the difference between biclustering (BC) and subspace clustering (SC) by explaining their applications and intra-cluster relationships. Then, we will review a variety of popular algorithms for both clustering techniques.

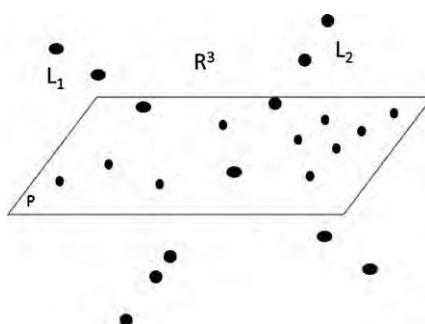

The inputs for clustering are a set of features  $F$  (called the set of genes  $V$  in BC, or the set of dimensions  $D$  in SC, row-wise) and a set of samples  $S$  (called the set of conditions  $U$  in BC, or the set of vectors  $V$  in SC, column-wise).  $F$  coupled with  $S$  forms an input matrix for the clustering problem, matrix  $E$ , whose size is  $|F| \times |S|$ , where  $|\cdot|$  denotes the cardinal of the set.

A bicluster  $(U', V')$  is defined by a subset of genes  $V'$  in  $V$  and a subset of conditions  $U'$  in  $U$ . Different clustering algorithms use different criteria to qualify a bicluster solution. In order to define a subspace cluster, let  $\{x_j \in R^d\}$  be a set of points drawn from the union of  $n$  subspaces. A subspace cluster then is defined as:

$$S_i = \{x : x = \mu_i + U_i y\}_{i=1}^n, \quad (20.16)$$

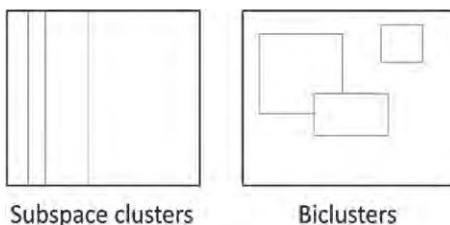

where  $\mu_i$  is a point in subspace  $S_i$ ,  $U \in R^{D \times d_i}$  is a basis for subspace  $S_i$ , and  $y \in R^{d_i}$  is a low-dimensional representation of the subspace. The goal of subspace clustering is to determine the number of subspaces  $n$ , their dimensions, and their bases and then to segment the points according to the subspaces (see Figure 20.4a).

The following section addresses the difference between biclustering and subspace clustering in partition structures, intra-cluster relationships, and application datasets.

**FIGURE 20.4a**

Three subspaces—two lines and a plane.

**FIGURE 20.4b**

Subspace clusters and biclusters.

### **1.20.2.7.1 Comparing subspace clustering and biclustering**

#### **1.20.2.7.1.1 Partition structure**

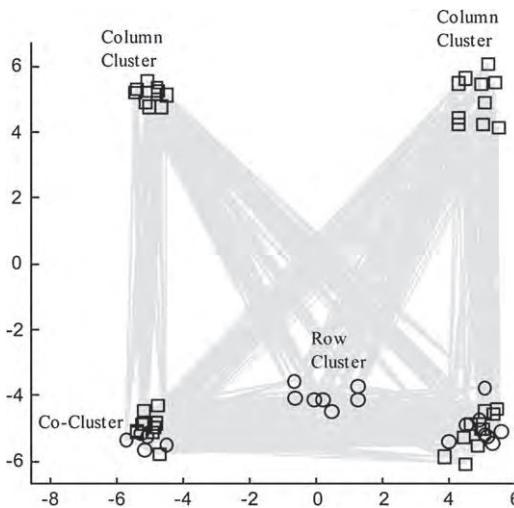

SC is a 1-dimensional matrix clustering that groups the elements in  $V$  into groups that form a subspace in the  $D$ -dimension. A permutation is performed on matrix  $E$  after clustering produces consecutive samples that belong to the same group (see Figure 20.4b). On the other hand, BC provides a new way to look at the data structure. It is a 2-dimensional clustering, also called co-clustering, in which a bicluster of  $E$  is a submatrix of  $E$  formed by a subset of  $F$  and a subset of  $S$ . Performing a permutation on matrix  $E$  after biclustering reveals that the biclusters form small rectangles inside the big rectangle  $E$ . Therefore, biclustering and subspace clustering produce very different results.

Biclustering, first used by Cheng and Church [77] in the bioinformatics community, addresses this problem by performing clustering simultaneously on both the row (gene) and column (sample) dimensions instead of clustering these two dimensions separately [31, 78]. In essence, biclustering can be regarded as a combination of clustering and automatic feature selection if one dimension (e.g., column) is treated as data objects and the other dimension (e.g., row) as description features. This task becomes particularly challenging without ground truth.

Note that the feature selection in biclustering is different from the feature selection usually considered in subspace clustering in that biclustering selects different subsets of features for different clusters of data objects, while standard feature selection chooses a subset of features from the candidate pool for all data objects. As such, biclustering can identify local relationships between subsets of genes and subsets of samples or conditions. Biclustering indicates gene groups that display similar patterns across a set of conditions, which is important for gene functional annotation and co-regulated gene identification [79] or in terms of gene groups that are related to certain cancer types (for cancer classification discovery and diagnosis) [78]. In contrast, subspace clustering focuses on uncovering global relationships between genes and samples or conditions. In fields other than bioinformatics, biclustering is also known as co-clustering or block clustering, among other names.

#### **1.20.2.7.1.2 Intra-cluster relationship**

One way in which BC and SC differ is in the data relationships between elements in the same cluster. In BC, data in the same clusters are homogeneous, i.e., the bicluster in BC must have some kind of homogeneity across the rows or columns of the sub-matrix, meaning that the rows or columns must be the same or have coherent additive or multiplicative values [31]. On the contrary, data in the same SC cluster can be very different, but as long as the samples lie in the same subspace, they are grouped into the same cluster.

**FIGURE 20.5**

Normal cluster (row cluster, column cluster) vs. bicluster (co-cluster) (From [48]).

Figure 20.5 illustrates the relationships between elements in the same bicluster. Matrix  $\mathbf{E}$  is formed from the relationship between points in  $R^2$ , which includes 20 points for the row objects (circles) and 40 points for the column objects (squares). Matrix  $\mathbf{E}$  has the entry  $E_{i,j} = \text{Euclidian distance between the } i\text{th point among the row objects and the } j\text{th point among the column objects}$ . Points are chosen so that they form three clusters for row objects and four clusters for column objects. The most remarkable observation in this arrangement is that the points in row and column objects form two co-clusters (the portion of the figure that circles and squares cohabit). The length of a line connecting a circle to a square is the value of the entry in matrix  $\mathbf{E}$ . Therefore, the subset of rows and columns where points cohabit in matrix  $\mathbf{E}$  displays homogeneity in that the entries in this sub-matrix are much smaller than those in the other sub-matrix.

### 1.20.2.7.1.3 Dataset

Biclustering can be applied comfortably to relational datasets, those in which some relationship exists between the rows and columns. In other words, datasets with relational characteristics are very good for biclustering. Below are some examples of biclustering data.

- *Gene expression:* Each sample comprises a gene, and each gene is profiled differently in each sample. See [31] for more information about gene expression.
- *Document classification:* Each row is a document, and each column is a word in a document. An entry in matrix  $\mathbf{E}$  is the occurrence of a word in a document.
- *Netflix database:* Rows are the number of movies, and columns are the number of people who rent movies from Netflix. A matrix  $\mathbf{E}$  entry measures a user's satisfaction with a specific movie.

Unlike BC, SC is suitable for space datasets, meaning that if the positions of all the samples in the dataset can be plotted, they all will form subspaces. The problem is that those subspaces are not easy to

visualize and typically are not independent. The most applicable form of subspace clustering is motion segmentation, which can be found in [80].

### 1.20.2.7.2 Subspace clustering algorithms

#### 1.20.2.7.2.1 Matrix factorization algorithms

Algebraic clustering algorithms are based on linear algebra matrix factorization. As a pure math theory development, the algorithms require independent subspaces and noise-free data.

Let  $\mathbf{X}$  be the matrix representing the dataset and  $[\mathbf{S}_1, \mathbf{S}_2, \dots, \mathbf{S}_n] = \mathbf{X}\Gamma$  be the sorted  $\mathbf{X}$  according to the  $n$  subspaces, where subspace  $\mathbf{S}_i \in R^{D \times N_i}$  is the matrix containing  $N_i$  points  $\Gamma \in R^{n \times n}$  and is an unknown permutation matrix.  $\mathbf{S}_i$  can be factorized as  $\mathbf{s}_i = \mathbf{U}_i \mathbf{Y}_i$ , where  $\mathbf{U}_i \in R^{D \times d_i}$  is a basis of subspace  $i$  and  $\mathbf{Y} \in R^{d_i \times N_i}$  is the low-dimensional representation of  $\mathbf{S}_i$ . Substitute  $\mathbf{S}_i$  into  $\mathbf{X}\Gamma$  as follows:

$$\mathbf{X}\Gamma = [\mathbf{U}_1, \mathbf{U}_2, \dots, \mathbf{U}_n] \begin{bmatrix} \mathbf{Y}_1 & & \\ & \mathbf{Y}_2 & \\ & & \dots \\ & & & \mathbf{Y}_n \end{bmatrix} = \mathbf{U}\mathbf{Y}, \quad (20.17)$$

where  $\mathbf{U} \in R^{D \times r}$  and  $\mathbf{Y} \in R^{r \times N}$  with  $r = \text{rank}(X) = \sum_{i=1}^n d_i$ .

Algebraic clustering next involves trying to find matrix  $\Gamma$  such that  $\mathbf{X}\Gamma$  can be factorized to  $\mathbf{U}$  and  $\mathbf{Y}$ . This can be achieved using the linear algebra manipulation over  $\mathbf{X}$  [81,82].

#### 1.20.2.7.2.2 Iterative methods

Iterative algorithms are based on a two-step iteration. Given an initial clustering, we can fit each cluster into a subspace using PCA, and then assign a data point to each cluster based on its distance from the subspace. Iteration between the two steps occurs until convergence is achieved. These algorithms work in a way similar to k-means clustering. Algorithms such as the k-means projective algorithm [83] are based on this idea. In general, a  $K$ -subspace iterative method works by letting  $w_{ij}$  be the membership of data point  $j$  in cluster  $j$ ;  $w_{ij} = 1$  if  $j$  belongs to subspace  $i$ , and 0 otherwise. Minimizing the square distance allows us to find,  $\{\mu_i\}$ ,  $\{\mathbf{U}_i\}$ , and  $\{\mathbf{y}_j\}$ , as well as membership  $w_{ij}$ :

$$\min_{\{\mu_i\}, \{\mathbf{U}_i\}, \{\mathbf{y}_i\}, \{w_{ij}\}} \sum_{j=1}^N \sum_{i=1}^n w_{ij} \|\mathbf{x}_j - \mu_i - \mathbf{U}_i \mathbf{y}_j\|^2 \quad (20.18)$$

$$\text{s.t } w_{ij} \in \{0, 1\} \text{ and } \sum_{i=1}^n w_{ij} = 1.$$

We begin solving Eq. 20.18 by initializing  $\{\mu_i\}$ ,  $\{\mathbf{U}_i\}$  and  $\{\mathbf{y}_j\}$ , which allows us to find the optimal  $w_{ij}$  using:

$$w_{ij} = \begin{cases} 1 & \text{if } i = \text{argmin} \|\mathbf{x}_j - \mu_k - \mathbf{U}_k \mathbf{y}_j\| \\ 0 & \text{otherwise} \end{cases}. \quad (20.19)$$

Once  $w_{ij}$  is known,  $\mu_i$ ,  $\mathbf{U}_i$ , and  $\mathbf{y}_j$  can be recomputed using PCA for each cluster. This simple algorithm guarantees convergence but requires a good initialization and cannot handle outliers.

### 1.20.2.7.2.3 Statistical method

We start by building a generative model for the data. As in [84], data in a single subspace  $S$  can be modeled as a Gaussian:

$$\mathbf{x} = \boldsymbol{\mu} + \mathbf{U}\mathbf{y} + \mathbf{e}, \quad (20.20)$$

where  $\mathbf{y}$  is Gaussian with a mean of zero and a unit variance of  $\sim \mathcal{N}(0, \mathbf{I})$  and  $\mathbf{e}$  is also Gaussian with a mean of zero and a unit variance of  $\sim \mathcal{N}(0, \sigma^2 \mathbf{I})$ .

$\mathbf{x}$  is then normally distributed  $\sim \mathcal{N}(\boldsymbol{\mu}, \mathbf{U}\mathbf{U}^T + \sigma^2 \mathbf{I})$ .

Mixture probabilistic PCA extends the single Gaussian by regarding each subspace as Gaussian and the dataset as a mixture of Gaussians, which therefore can be clustered using an EM algorithm. Let  $p(x)$  be the Gaussian mixture of the dataset:

$$p(\mathbf{x}) = \sum_{i=1}^n \pi_i \mathcal{N}(\mathbf{x}; \boldsymbol{\mu}_i, \mathbf{U}_i \mathbf{U}_i^T + \sigma_i^2 \mathbf{I}), \quad (20.21)$$

where  $\pi_i$  is the weighted mixture.

Now we can iterate between steps E and M to compute the Gaussian parameters  $(\boldsymbol{\mu}_i, \mathbf{U}_i, \sigma_i, \pi_i)$  according to [80].

In step E:

$$R_{ij} = \frac{p(\mathbf{x}_j | i) \pi_i}{p(\mathbf{x}_j)}. \quad (20.22)$$

In step M:

$$\pi_i = \frac{1}{N} \sum_{j=1}^N R_{ij}, \quad (20.23)$$

$$\boldsymbol{\mu}_i = \frac{\sum_{j=1}^N R_{ij} \mathbf{x}_j}{\sum_{j=1}^N R_{ij}}. \quad (20.24)$$

$\mathbf{U}_i$  and noise variance  $\sigma_i^2$  are determined from the SVD of the local responsibility weighted covariance matrix:

$$\mathbf{s}_i = \frac{1}{\pi_i N} \sum_{j=1}^N R_{ij} (\mathbf{x}_j - \boldsymbol{\mu}_i)(\mathbf{x}_j - \boldsymbol{\mu}_i)^T. \quad (20.25)$$

These two steps are repeated until convergence occurs.

### 1.20.2.7.2.4 RANSAC method

RANSAC [85] is a powerful statistical method for fitting a model given a dataset that is corrupted by noise and outliers. This technique is used widely in computer vision when solving the fundamental matrix in a stereo correspondence problem. The basic idea of RANSAC is to pick  $d$  points from the dataset, enough to estimate and fit model, and then compute the residue of each point to this model,

choosing only points whose residue is lower than a certain threshold as inliers. These steps then are repeated with other randomly selected  $d$  points until enough samples are drawn. RANSAC can be applied in subspace clustering [86] by finding and situating one subspace as the model and then marking certain points in that subspace as inliers and the rest as outliers. After the first subspace is discovered, the inliers are removed from the dataset, and another RANSAC is repeated to discover the next subspace. This procedure is repeated until all the subspaces are recovered. PCA is used to compute the basis of the subspace for each set of inliers.

#### 1.20.2.7.2.5 Sparse subspace clustering

Sparse representation and compressive sensing are emerging areas in signal and image processing [87]. Due to the development of several efficient L1-norm solvers, sparse representation has been applied in many research areas, especially in clustering. The idea behind subspace clustering using compressed sensing [88] is that a point  $\mathbf{x}_j$  will have sparse representation in the sensing matrix  $\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2 \dots \mathbf{x}_{j-1}, \mathbf{x}_{j+1}, \dots, \mathbf{x}_N]$ , which means that the nonzero coefficients in sparse representation correspond to the points that lie in the same subspace as  $\mathbf{y}_j$ . After applying sparse representation to all the points, we build a matrix of sparse representation coefficients,  $C_{N \times N}$ . Subspace segmentation can be achieved by applying K-means to a subset of eigenvectors of the Laplacian of  $C$ .

Let  $w_{ij}$  be the linear combination of  $\mathbf{x}_j$ . If the data are noise-free,  $w_{ij}$  can be found using l1-optimization:

$$\begin{aligned} & \min \sum_{i \neq j} |w_{ij}| \\ & \text{s.t. } \mathbf{x}_j = \sum_{i \neq j} w_{ij} \mathbf{x}_i. \end{aligned} \quad (20.26)$$

If the data contain noise, a relaxation is added into the optimization:

$$\min_{w_{ij}} \sum_{i \neq j} |w_{ij}| + \mu \|\mathbf{x}_j - \sum_{i \neq j} w_{ij} \mathbf{x}_i\|^2, \quad (20.27)$$

where  $\mu$  is a positive relaxation coefficient.

In the case of outliers, sparse vector outliers are added to the sparse representation of

$$\mathbf{x}_j = \sum_{k \neq j} w_{kj} \mathbf{x}_k + \mathbf{e}_j. \quad (20.28)$$

The l1-norm optimization becomes:

$$\min_{w_{ij}, \mathbf{e}_j} \sum_{i \neq j} |w_{ij}| + \mu \left\| \mathbf{x}_j - \sum_{i \neq j} w_{ij} \mathbf{x}_i - \mathbf{e}_j \right\|^2. \quad (20.29)$$

The sparse representation of each data point then is used as the featured vector for spectral clustering [76].

In [89], Vidal extended the solution to disjointed subspaces and derived theoretical bounds relating the principal angles between the subspace and the distribution of the data points across all of the subspaces.

### 1.20.2.7.3 Biclustering algorithms

Let  $\mathbf{I} \subset \mathbf{G}$  and  $\mathbf{J} \subset \mathbf{S}$  be subsets of the rows and columns for the gene expression data matrix  $\mathbf{E}$ ;  $\mathbf{E}_{IJ} = (\mathbf{I}, \mathbf{J})$  is then the submatrix with rows  $\mathbf{I}$  and columns  $\mathbf{J}$ . A bicluster corresponds to such a submatrix that exhibits certain homogeneity. The goal of a biclustering algorithm, then, is to identify a set of biclusters with pairs of row and column subsets. The complexity of the biclustering problem has been shown to be NP-complete [31], which leads to many heuristics falling into the five major categories summarized in Table 20.2, according to Madeira and Oliveira.

The first biclustering research was presented by Cheng and Church [77]. The mean squared residue is used to measure the coherence of the rows and columns in a bicluster, which is defined as:

$$H(\mathbf{I}, \mathbf{J}) = \frac{1}{|\mathbf{I}||\mathbf{J}|} \sum_{i \in \mathbf{I}, j \in \mathbf{J}} (e_{ij} - e_{iJ} - e_{IJ} + e_{IJ})^2, \quad (20.30)$$

**Table 20.2** Biclustering Algorithms

Algorithm category	Description	Examples
Combination of iterative row and column clustering	Also known as two-way clustering. Uses existing clustering algorithms for the row and column dimensions separately. Combines the one-way results to produce biclusters.	Interrelated two-way clustering (ITWC) [90]; Double conjugated clustering (DCC) [91]; Coupled two-way clustering (CTWC) [92]; Fuzzy adaptive subspace iteration-based two-way clustering (FASIC) [93]
Divide and conquer	Divides the original problem into a set of smaller subproblems. Solves the subproblems and combines the solutions to obtain the final solution to the original problem.	Block clustering and its variants [94, 95]
Greedy iterative search	Iteratively inserts or removes rows or columns from the biclusters, guided with some criterion function.	$\delta$ -biclusters [77]; Flexible overlapped biclustering (FLOC) [96]; xMOTIF [95]; Order preserving submatrices (OPSM) [97]
Exhaustive bicluster enumeration	Performs exhaustive enumeration but with some restrictions on the size of biclusters.	Statistical algorithmic method for bicluster analysis (SAMBA) [98]; pclusters [99]
Distribution parameter identification	Considers underlying statistical models for biclusters. Estimates model parameters that best fit the data.	Probabilistic relational models [99]; Plaid models [100]

where  $e_{iJ}$  is the mean of the  $i$ th row,  $e_{Ij}$  is the mean of the  $j$ th column, and  $e_{IJ}$  is the mean of the bicluster. A submatrix  $\mathbf{E}_{IJ}$  is called a  $\delta$ -bicluster if  $\mathbf{H}(\mathbf{I}, \mathbf{J}) \leq \delta$  for some  $\delta \geq 0$ . Possible ways to find the largest  $\delta$ -biclusters, which should also have relatively high row variance, include the evolutionary algorithm [101], multi-objective particle swarm optimization [102], and other greedy iterative search approaches.

Another popular biclustering algorithm is the interrelated two-way clustering (ITWC) algorithm. ITWC generates biclusters by combining clustering results from each dimension of the data matrix in an iterative way. Within each iteration, a set of gene clusters first is created by standard clustering algorithms, e.g.,  $K$ -means or SOFM, followed by the independent clustering of the sample dimension based on each gene cluster. The clustering results from the previous steps then are combined, and heterogeneous groups, which are pairs of columns that do not share gene features used for clustering, are identified. Finally, the genes are sorted in descending order of the cosine distance, and only the first one-third of sorted genes is kept so that a reduced gene set is obtained for each heterogeneous group. The above steps then are repeated using the reduced gene set until some stopping conditions are satisfied. Other two-way clustering algorithms include the coupled two-way clustering (CTWC) algorithm [92], which uses hierarchical clustering with the Euclidean distance, the double conjugated clustering (DCC) algorithm [91], which uses SOFM with the dot product for similarity, and the fuzzy adaptive subspace iteration-based two-way clustering (FASIC) algorithm, which is integrated with the concept of fuzzy membership.

Xu and Wunsch [37] developed a new two-way clustering technique called BARTMAP, the structure of which consists of two Fuzzy ART modules, ARTa and ARTb, which communicate through the inter-ART module. The inputs of the ARTa module are samples, and the inputs of ARTb are genes. The goal of BARTMAP is to integrate the clustering results on the dimensions of columns and rows of the data matrix to create biclusters that capture the local relationships between genes and samples. More concretely, the first step of BARTMAP is to create a set of  $K_g$  gene clusters  $\mathbf{G}_i, i = 1, \dots, K_g$ , for  $N$  genes by using the ARTb module. Then, upon the presentation of a new sample in ARTa, the candidate sample cluster that is eligible to represent this sample is decided based on the winner take all rule. If this candidate cluster corresponds to an uncommitted neuron, a new one-element cluster is created. However, if a committed neuron is picked, the weights of this winning neuron are only updated if it displays behaviors similar to those of other members in the cluster formed in the ARTb module, as measured by the Pearson correlation coefficient.

Lazzeroni and Owen [100] developed a plaid model, treating the matrix as the sum of additive layers. This model was extended further to combine external grouping information and to generate biclusters of profiles of repeated measures [103]. Gu and Liu [104] proposed a Bayesian biclustering model with a Gibbs sampling procedure for statistical inference. McAllister et al. [105] considered modeling biclustering as either a network flow problem or a traveling salesman problem. A systematic comparison of five greedy search-based biclustering algorithms, together with a reference method (Bimax), was presented by Prelić et al. [106].

CTWC uses hierarchical clustering with the Euclidean distance, while DCC relies on self-organizing maps with the dot product for similarity [91]. FASIC adopts the concept of fuzzy set theory and applies the fuzzy-adaptive subspace iteration algorithm to generate gene clusters under a progressive clustering framework. Those clusters then are scored to generate  $p$ -values indicating the significance of the differential expression [93]. Tchagang et al. [107] demonstrated the effectiveness of biclustering

for detecting and diagnosing ovarian cancer. Mitra et al. [108] showed a biclustering application for microRNA expression profile-based cancer classification of multiple cancer types, including melanoma, ovarian, renal, colon, and leukemia.

### 1.20.2.8 Deep learning clustering

All of the clustering algorithms presented so far have not required any explicit feedback, i.e., they all engage in unsupervised learning. In contrast to this is supervised learning, in which the program learns to map functions from input to output by training data with labels. However, in practice, the available data will include some labeled samples and a large collection of unlabeled samples. Algorithms that work with such a mix of data are said to engage in semi-supervised learning; one of the most powerful semi-supervised clustering techniques is deep learning.

As human-computer interaction (HCI) continues to develop, more and more images and data will be created. A large and rapidly-growing demand exists for the ability to search, organize and recognize media content. The most popular methods are based on hand-crafted features and therefore are very time and resource consuming [109, 110]. On the other hand, researchers such as Andrew Ng [34] have suggested the novel idea of achieving best performance in classification using unsupervised methods. This idea combines both supervised and unsupervised learning to accomplish recognition tasks.

The central idea behind unsupervised feature learning is the sparse coding neural network [111]. Sparse coding retains only the characteristic structure of the image at the input of the network. In short, the goal of sparse coding is as follows:

*Input:* given images  $\mathbf{X}_1, \mathbf{X}_2, \dots, \mathbf{X}_m \in R^{n \times n}$ .

*Output:* dictionary bases  $\phi_1, \phi_2, \dots, \phi_k \in R^{n \times n}$ .

So that in every image  $\mathbf{X} = \sum_{j=1}^n a_j \phi_j$ , most  $a_j$ 's are 0.

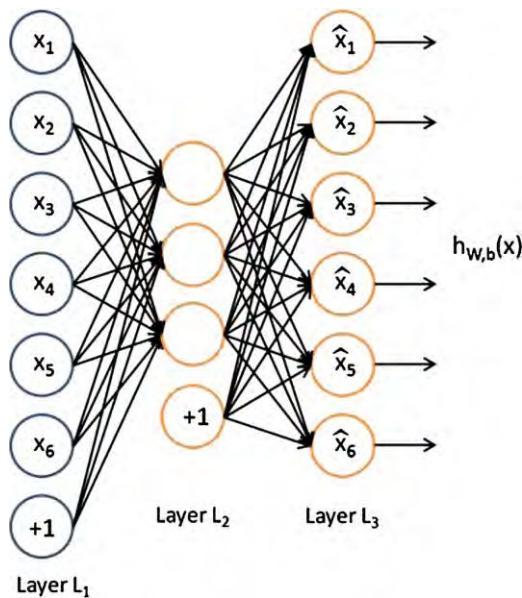

#### 1.20.2.8.1 Sparse auto-coding network

Sparse auto-coding uses a 3-layer neural network with input, hidden and output layers. The terminology *auto sparse encoder* implies something about this network's structure. The value at the output layer is exactly the same as at the input layer. The input and output layers have the same number of neurons, which differs from the hidden layer, in which the interesting structure of the data is retained (see Figure 20.6).

When training the sparse auto-coding network, a sparse constraint is imposed on the hidden layer in order to force the network to reflect the structure of the input. We denote the average activation of hidden unit  $j$  (over the entire training set) as  $\rho_j$  and the number of neurons in the hidden layer as  $s$ . We will enforce  $\rho_j = \rho$ , where  $\rho$  is a sparsity parameter, by adding the penalty term  $\sum_{j=1}^s KL(\rho \parallel \hat{\rho}_j)$  in the objective function of backpropagation [112]:

$$J_{\text{sparse}}(\mathbf{W}, \mathbf{b}) = J(\mathbf{W}, \mathbf{b}) + \beta \sum_{j=1}^s KL(\rho \parallel \hat{\rho}_j), \quad (20.31)$$

where  $\mathbf{W}$  represents the weight of the connections in the network,  $J(\mathbf{W}, \mathbf{b})$  is the sum of the square-error cost function of training the neural network, and KL refers to Kullback-Leiber [113], which measures

**FIGURE 20.6**

Example structure of a sparse auto-coding network.

the difference in the distribution of  $\rho$  and  $\rho_j$ .

$$KL(\rho \parallel \hat{\rho}_j) = \rho \log \frac{\rho}{\hat{\rho}_j} + (1 - \rho) \log \frac{1 - \rho}{1 - \hat{\rho}_j}. \quad (20.32)$$

To clarify the result of training the sparse auto-encoder network, we investigate the hidden layer:

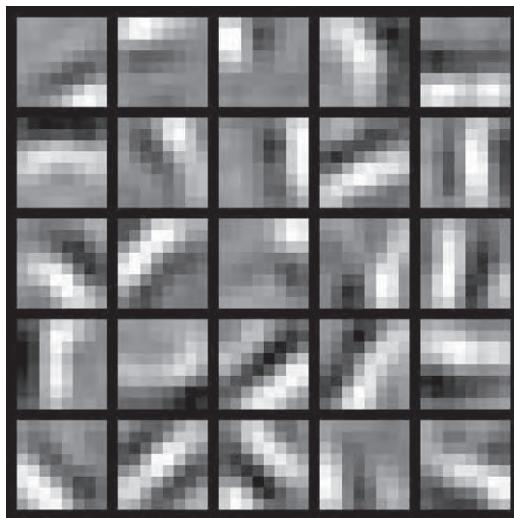

$$a_i = f \left( \sum_{j=1}^n W_{ij} x_j \right), \quad (20.33)$$

where  $a_i$  is the output of neuron  $i$  in the hidden layer, and  $w_{ij}$  is the weight of the connection from input  $x_j$  to neuron  $i$ , by which we can determine the maximum value of  $a_i$ . To avoid arriving at a trivial solution, we force  $\|\mathbf{x}\| \leq 1$  (by normalization).  $a_i$  obtains the maximum when:

$$x_{j \max} = \frac{W_{ij}}{\sum_{j=1}^n W_{ij}^2}, \quad (20.34)$$

which indicates that the image with the structure  $W_{ij}$  will be fired maximally on  $a_i$ . Due to the properties of the backpropagation algorithm, the weights connecting the hidden layer to the output layer are updated separately from those connecting the input layer to the hidden layer; those weights are not considered here because they do not have a specific meaning in sparse representation.

The result of training 200 images in a  $5 \times 5$  grid is shown in Figure 20.7.

**FIGURE 20.7**

Each cell represents features detected in the training data and stored in the hidden unit. The features detected here are edges at different positions and orientations (From Andrew Ng; Sparse autoencoder. CS 294A Machine Learning lecture notes).

#### 1.20.2.8.2 *Independent subspace analysis (ISA) network*

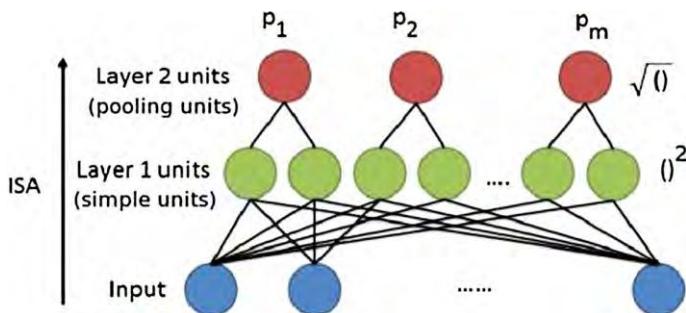

Another neural network that can be used to auto-learn features is the 3-layer independent subspace analysis network (ISA) [34]. The hidden layer has square nonlinearity, and the second layer has square root nonlinearity. The hidden layer is connected to the output layer via a few links of adjacent neighbors and represents the subspace structure of the neural network. The structure of an ISA network is illustrated in Figure 20.8a.

The output of the ISA network is:

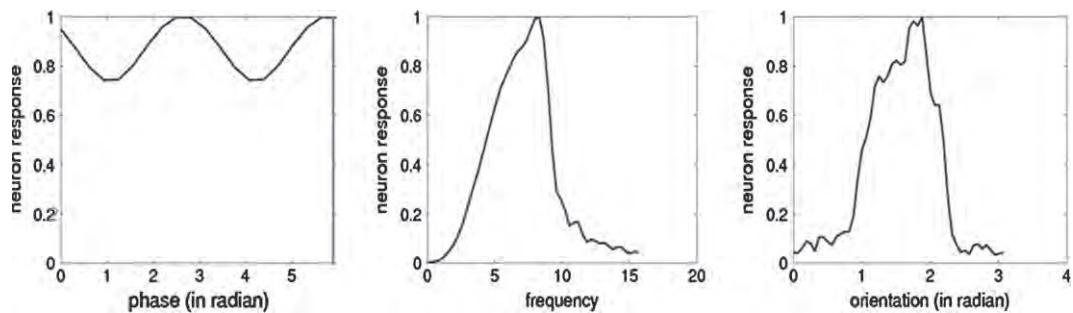

$$p_i = (x; \mathbf{W}, \mathbf{V}) = \sqrt{\sum_{k=1}^m \mathbf{V}_{ik} \left( \sum_{j=1}^n \mathbf{W}_{kj} x_j \right)^2}. \quad (20.35)$$

Similar to the sparse auto-encoding network, the ISA network learns the structure of the image by finding the sparse representation in the hidden layer by solving:

$$\begin{aligned} \min_{\mathbf{W}} \sum_{t=1}^T \sum_{i=1}^m p_i(x^t; \mathbf{W}, \mathbf{V}), \\ \text{subject } \mathbf{W}\mathbf{W}^T = \mathbf{I}, \end{aligned} \quad (20.36)$$

**FIGURE 20.8a**

ISA structure (from [34]).

**FIGURE 20.8b**

ISA response with image changes. These plots show that the ISA network is robust to translation (phase) and selective to frequency and rotation changes.

where  $\{\mathbf{x}^t\}$  are whitened input examples,  $\mathbf{W} \in R^{k \times n}$  represents the weights connecting the input layer to the hidden layer, and  $\mathbf{V} \in R^{m \times k}$  represents the weights connecting the hidden layer to the output layer.  $\mathbf{V}$  often is fixed in order to force the sparse representation of  $\mathbf{x}$ , and the orthogonal constraint ensures that feature learning is diverse (see Figure 20.8b).

The features learned by the ISA are invariant to translation, frequency and rotation and therefore are suitable for recognition tasks [114]. Many experiments have confirmed that ISA performs much better than sparse coding. However, to further extract features from large images or videos, those networks that auto-learn features can be stacked to form hierarchical networks.

After training the network, any image can be fed into it, and the output at both layers can be used as features for clustering. To process videos, features are extracted for each frame of the video and then quantized into visual words [115] using K-means clustering. A video is represented as a frequency histogram over those visual words by assigning features to the closest vocabulary word.

Based on unsupervised feature learning, several clustering applications have been developed, including speech processing. Lee et al. [116], action recognition [34], and character recognition [117].

### 1.20.3 Clustering validation

As Figure 20.1 depicted, the indispensable step in clustering is validation. Clustering validation is used to objectively and quantitatively evaluate the obtained clustering structure. There are three validation index categories: external indices, internal indices and relative indices [7].

Given a data set  $X$  and a clustering structure  $C$  obtained from a certain clustering algorithm on  $X$ , external criteria were used to compare  $C$  to a pre-specified structure containing a priori information about the data structure  $X$ . In contrast, internal criteria were used to evaluate the clustering structure exclusively from  $X$ . Relative criteria were used to compare  $C$  with other clustering structures from different clustering algorithms or from the same clustering algorithm with different parameters on  $X$ . The primary interest regarding relative criteria is how to estimate the optimal number of clusters. Xu and Wunsch [5] discussed those criteria in detail.

Another problem closely related to cluster validation is the assessment of clustering tendencies, in which the algorithm tries to determine whether clusters are present one step prior to actual clustering. Most assessment techniques utilize data visualization to present a view of the data structure. Yang et al. [96] proposed an interactive hierarchical display by which to look at the data at various levels. One of the most popular approaches comes from [118], in which the data are reordered according to their similarity, resulting in an intensity image display. This method has produced several derivatives, such as iVAT and reVAT [119, 120].

---

### 1.20.4 Applications

#### 1.20.4.1 Image segmentation

One of the broadest applications of clustering in image processing is image segmentation. The simplest approach to segmenting an image is using hierarchical clustering [121]. K-means can also be applied for segmentation. In many cases in which segments are not connected and can be very widely scattered, the feature vector in k-means will include pixel coordinates instead of just pixel colors. Segmentation also can be regarded as a graph cut problem in which spectral clustering has been developed, yielding very good results [74, 75].

#### 1.20.4.2 MRI images

Magnetic resonance imaging (MRI) provides a visualization of the internal structures of objects and living organisms. MRI images have better contrast than computerized tomography; therefore, most medical image segmentation research uses MRI images. Segmenting an MRI image is a key task in many medical applications, such as surgical planning and abnormality detection. MRI segmentation aims to partition an input image into significant anatomical areas, each of which is uniform according to certain image properties.

MRI segmentation can be formulated as a clustering problem in which a set of feature vectors obtained through transformation image measurements and pixel positions is grouped into a number of structures [14]. There are significantly fewer clusters than intensity levels in the original image, so this clustering process can be regarded as removing redundant information from the MRI.

Balaifar [122] used FCM for MRI segmentation. As FCM only considers image intensity, its results are not acceptable when working with noisy images. Many algorithms have been introduced to make FCM robust against noise [123, 124].

Another approach to image segmentation is to model each of the segments as a Gaussian distribution and apply mixture density-based clustering to the MRI images [125].

#### 1.20.4.3 Vision-guided robot

One of the main problems in robotics is enabling the robot to guide itself autonomously through the environment. A vision-guided robot equipped with a camera can attain that goal by clustering the images captured from the environment. Martinez and Vitria [126] found a successful solution, developing a normal mixture model-based (NMM) algorithm to cluster the images of the surrounding environment. This algorithm views images as column vectors whose dimensions are the intensities of the image pixels; this is the first clustering method projected to lower the dimensional space, which it accomplishes using principal component analysis. EM clustering then is applied to learn all the models in the mixtures in the PCA space. Each model corresponds to a different area of the environment. In order to improve the results, they employed a Genetic Algorithm that uses a population of mixture models rather than a single mixture. The resulting algorithm has a higher successful recognition rate than PCA or Fisher discriminant analysis.

#### 1.20.4.4 Motion clustering

One application of subspace clustering is motion clustering, in which rigid objects in a given video are segmented based on their motions in the scene. Features in the same object will have the same motion pattern with 3 degrees of freedom in space. Under an affine projection model, this motion was positioned in an affine subspace of 3 dimensions at most, i.e., in a linear 4-dimensional subspace. More specifically, suppose over  $F$  frames of the video, we successfully extract and track a set of  $N$  feature points  $\{x_{fi} \in R^2\}_{i=1\dots N, f=1\dots F}$ . The set of  $\{x_{fi} \in R^2\}, f = 1\dots F$  forms the trajectory; by stacking them, we obtain a data point  $y_i$  in  $2F$ -dimension. As noted previously, data point lies in a subspace of, at most, 3 dimensions. The problem of motion segmentation then becomes the problem of clustering those data points  $y_i$  in  $R^{2F}$ , which is the problem of subspace clustering. Vidal [127] contributed a significant amount of research exploring the use of different subspace clustering techniques on this application. Experiments were tested on the Hopkins 155 dataset, showing that sparse subspace clustering outperforms other subspace clustering algorithms.

---

### 1.20.5 Open issues and problems

Most clustering algorithms are available through software packages or are easy to implement. While offering substantial merits, they also have many disadvantages that make them inappropriate for some

signal and image processing needs. For example, the complexity of agglomerative hierarchical clustering is  $O(N^2)$ , which is not suitable for large-scale data clustering.

The typical clustering challenges are summarized as follows:

*Scalability:* Scalability in both time and memory is the most important challenge faced by clustering algorithms because of the ever-increasing amount of data from all applications. For example, some applications require the clustering of billions of images or documents available on the Internet. It is impractical for a clustering algorithm to run for several months to complete one run, especially if there is an extraordinary need for memory. Therefore, linear or near-linear complexity is very desirable.

*Dimensionality:* The algorithm should be able to handle data with many features, even more than the number of objects in the data set. Identifying relevant features and capturing the intrinsic dimension is important for describing the real data structure.

*Robustness:* Noise and outliers are always present in the data, so the clustering algorithm must be able to detect and remove them.

*Cluster number:* A classical clustering problem is to correctly identify the numbers of clusters, as many current algorithms require the user to input this parameter. This is difficult because a lack of prior knowledge or an incorrect estimation of the true number of clusters will prevent the clustering process from uncovering the real clustering structures.

*Parameter reliance:* Many algorithms, not just limited to clustering algorithms, require users to specify 3 or more parameters, which can decrease a user's confidence in utilizing the algorithm unless he knows the problem well enough to select these values within a sensible range. Thus, a good clustering algorithm should depend on only one parameter.

*Cluster shape:* Clustering algorithms should have the ability to detect all possible cluster shapes, rather than being confined to some particular shape, such as hyperspheres or hyper-rectangles.

*Order insensitivity:* One of the most important properties of a clustering algorithm, especially when being applied to large-scale data, is its online or incremental ability. However, the result of clustering may depend on the order of the presentation of input patterns. Decreasing the effects of the order of input patterns is a challenging problem.

*Good visualization:* Good visualization will help users understand the resulting clusters, allowing them to interpret and extract useful information to solve their problems.

---

## 1.20.6 Conclusion

This chapter has offered a review of emerging clustering algorithms with broad applications in computer science, machine learning, and statistics. While some of the clustering techniques, such as hierarchical, mixture, and fuzzy clustering, are suitable for typical data, biclustering and subspace clustering are very effective for high-dimensional datasets. To automatically learn features from a dataset, unsupervised feature learning clustering techniques may offer superior performance to hand-crafted feature selection.

---

## Glossary

ART (Adaptive Resonance Theory)	an unsupervised learning model in which learning occurs as a result of interaction between top-down observer expectations and bottom-up sensory information through a reset module, resulting in a theory that learning is mediated by resonance in a neural circuit
Affinity matrix	in the context of spectral clustering, an $N \times N$ matrix measures the affinity between data points. The measuring function is usually a Gaussian function
BIC (Bayesian Information Criterion)	a criterion for model selection when fitting data to a model, used to mitigate the problem of over fitting
Biclustering	a clustering approach that clusters the matrix of a data set in both columns and rows. Many clustering algorithms tessellate the data space. Biclustering selects data that is common to two subspaces, and can be considered as an unsupervised version of heteroassociative learning
Cluster	a group of objects that share some common property
Clustering	the process of dividing objects into clusters
Cluster validation	a post-processing step in clustering that objectively and qualitatively evaluates the resulting clusters
Competitive learning neuron network	a network in which the output nodes compete for the right to respond to a subset of the input data
Dendogram	a binary tree used to illustrate the arrangement of the clusters produced by hierarchical clustering
Dissimilarity	a proximity measurement of the difference between two data points
Eigenvalues, eigenvectors	in a square matrix, a non-zero vector when multiplied by the matrix yields a vector that lies parallel to the original
Expectation Maximization (EM)	an iterative method that finds the maximum likelihood of the estimate of parameters in statistical models, where the model has some latent variables. An iteration performs the Expectation step, which creates a function evaluating the expectation of the log-likelihood of the current parameters, and a Maximization step, which computes the parameters, thus maximizing the function in the Expectation step
Fuzzy clustering	a type of clustering in which the data point can belong to many different clusters denoted by its membership
Fuzzy c-means (FCM)	a partition-based clustering method in which a data point can belong to two or more clusters. The procedure is very similar to k-means clustering

Gaussian mixture	a probabilistic model in which a whole probability distribution is represented by the summation of several Gaussian distributions
Hard clustering	a type of clustering in which the data point can only belong to one cluster
Hierarchical clustering	a type of clustering that organizes data into hierarchical structures based on a proximity matrix
Image segmentation	the process of assigning a label to every pixel in an image such that pixels with the same label have the same visual characteristics
Independent component analysis	a method of finding a linear representation of non-Gaussian data so that the components are statistically independent
Kernel method	an approach in which a kernel function is used to map the data into a higher dimensional feature space and which allows a variety of clustering methods. The kernel functions allow computation through an inner product rather than on the coordinates of the data, thus resulting in a lower computational requirement
K-means	a classical clustering method of partitioning data into k clusters in which each data point belongs to the nearest mean
K-medoids	a process similar to k-means except that the mean is replaced by a data point as the center. K-medoids works with an arbitrary distance and is not limited to $L_2$
L1-norm	the sum of the absolute value of the components in a vector. The L1-norm is used widely in minimizing linear underestimated equations because of its property of sparse solutions
Large-scale data clustering	a special clustering problem in which the amount of data is extremely large (Big Data)
Learning rate	a parameter controlling the adjustments made during the training process. If the learning rate is large, the algorithm learns quickly; otherwise, the result in slow learning
Mahalanobis distance	a distance measure that takes into account the covariance among the dimensions
Maximum Likelihood Estimation (MLE)	A method of estimating the parameters of a statistical model in which the parameters are chosen to maximize the joint likelihood function
Online learning	a learning algorithm in which learning occurs sequentially as the data are introduced
Outlier	in statistics, a sample that lies far away from the rest of the data
Partitional clustering	as opposed to hierarchical clustering, this is the process of partitioning data into k clusters, which often is based on some optimized criterion function
Possibilistic c-means	a generalization of FCM, in which the membership of a data point in one cluster has nothing to do with other cluster. Membership is interpreted here as the degree of compatibility with the cluster prototype

Principle component analysis	a procedure that uses orthogonal transformation to extract a set of values of linearly uncorrelated variables called principle components
Prototype	a representation of a cluster, usually the means of data points in that cluster
Rand index	an external criterion for cluster validation
Self-organizing feature map	a neuron network trained using unsupervised learning to produce a low-dimensional, discrete representation of the training samples
Semi-supervised clustering	a type of clustering in which data are both labeled and unlabeled
Spectral clustering	a clustering technique making use of eigenvectors to perform dimension reduction before clustering in fewer dimensions
Subspace clustering	a type of clustering in which each cluster is a subspace
Unsupervised learning	a learning algorithm in which the data are not labeled
Vector quantization	a variant of k-means used in communications problems such as optimizing analog to digital conversion.
Vigilance parameter	a parameter that controls adaptation in ART

Wako-shi, Saitama 3510198, Japan*

## 1.21.1 Introduction and of problems statement

Matrix factorizations and their extensions to tensor (multiway arrays) factorizations and decompositions have become prominent techniques for Latent Variable Models (LVM), linear and Multiway or Multilinear Blind Source Separation (MBSS), and (multiway) Generalized Component Analysis (GCA) (especially, multilinear Independent Component Analysis (ICA), Nonnegative Matrix and Tensor Factorizations (NMF/NTF), Smooth Component Analysis (SmoCA), and Sparse Component Analysis (SCA)). Moreover, matrix and tensor decompositions have many other applications beyond blind source separation, especially for feature extraction, classification, dimensionality reduction and multiway clustering. The recent trends in MBSS and GCA are to consider problems in the framework of matrix and tensor factorizations or more general multi-dimensional data for signal decomposition within probabilistic generative models and exploit *a priori* knowledge about the true nature, diversities, morphology or structure of latent (hidden) variables or sources such as spatio-temporal-spectral decorrelation, statistical independence, nonnegativity, sparseness, smoothness or lowest possible complexity. The goal of MBSS can be considered as estimation of true physical sources and parameters of a mixing system, while the objective of GCA is to find a reduced (or hierarchical and structured) component representation for the observed (sensor) multi-dimensional data, that can be interpreted as physically or physiologically meaningful coding or blind signal decomposition. The key issue is to find such a transformation (or coding) which has true physical meaning and interpretation. In this chapter we briefly review some efficient unsupervised learning algorithms for linear and multilinear blind source separation, blind source extraction and blind signals decomposition, using various criteria, constraints and assumptions. Moreover, we briefly overview emerging models and approaches for constrained matrix/tensor decompositions with applications to group and linked multilinear BSS/ICA, feature extraction, multiway Canonical Correlation Analysis (CCA), and Partial Least Squares (PLS) regression problems.

Although the basic models for matrix and tensor (i.e., multiway array) decompositions and factorizations, such as Tucker and Canonical Polyadic (CP) decomposition models, were proposed long a time ago [1–7], they have recently emerged as promising tools for the exploratory analysis of large-scale and multi-dimensional data in diverse applications, especially, for dimensionality reduction, multilinear independent component analysis, feature extraction, classification, prediction, and multiway clustering [5,8–12]. By virtue of their multiway nature, tensors constitute powerful tools for the analysis and fusion

of large-scale, multi-modal massive data, together with a mathematical backbone for the discovery of underlying hidden complex data structures [8,13].

The problem of separating or extracting source signals from a sensor array, without knowing the transmission channel characteristics and the sources, is addressed by a number of related BSS or GCA methods such as ICA and its extensions: Topographic ICA, Multilinear ICA, Kernel ICA, Tree-dependent Component Analysis, Multi-resolution Subband Decomposition ICA [13–18], Non-negative Matrix Factorization (NMF) [19,20], Sparse Component Analysis (SCA) [21–25], and Multi-channel Morphological Component Analysis (MCA) [26,27].

The mixing and filtering processes of the unknown input sources  $x_j(t)$  ( $j = 1, 2, \dots, J$ ) may correspond to different mathematical or physical models, depending on the specific applications [17,28]. Most linear BSS models can be expressed algebraically in their simplest forms as some specific form of a constrained matrix factorization: Given observation (often called sensor or input) data matrix  $\mathbf{Y} = [y_{it}] = [\mathbf{y}(1), \dots, \mathbf{y}(T)] \in \mathbb{R}^{I \times T}$ , we perform the matrix factorization (see Figure 21.1a):

$$\boxed{\mathbf{Y} = \mathbf{AX} + \mathbf{E} = \mathbf{AB}^T + \mathbf{E},} \quad (21.1)$$

where  $\mathbf{A} \in \mathbb{R}^{I \times J}$  represents the unknown mixing matrix,  $\mathbf{E} \in \mathbb{R}^{I \times T}$  is an unknown matrix representing errors or noises,  $\mathbf{X} = \mathbf{B}^T = [\mathbf{x}(1), \mathbf{x}(2), \dots, \mathbf{x}(T)] \in \mathbb{R}^{J \times T}$  contains the corresponding latent (hidden) components that give the contribution of each basis vector,  $T$  is the number of available samples,  $I$  is the number of observations and  $J$  is the number of sources or components.

In general the number of source signals  $J$  is unknown, and it can be larger, equal or smaller than the number of observations. The above model can be written in an equivalent scalar (element-wise) form (see Figure 21.1b):

$$y_{it} = \sum_{j=1}^J a_{ij} x_{jt} + e_{it} \quad \text{or} \quad y_i(t) = \sum_{j=1}^J a_{ij} x_j(t) + e_i(t) \quad (t = 1, 2, \dots, T). \quad (21.2)$$

Usually, the latent components represent unknown source signals with specific statistical properties or temporal structures and matrices have clear statistical properties and meanings. For example, the rows of the matrix  $\mathbf{X}$  that represent unknown sources or components should be statistically independent for ICA, sparse for SCA [21–24,29], nonnegative for NMF [8], or have other specific and additional morphological properties such as smoothness, continuity, or orthogonality [14,16,27].

In many signal processing applications the data matrix  $\mathbf{Y} = [\mathbf{y}(1), \mathbf{y}(2), \dots, \mathbf{y}(T)] \in \mathbb{R}^{I \times T}$  is represented by vectors  $\mathbf{y}(t) \in \mathbb{R}^I$  ( $t = 1, 2, \dots, T$ ) of multiple measurements or recordings for a set of discrete time points  $t$ . As mentioned above, the compact aggregated matrix Eq. (21.1) can be written in a vector form as a system of linear equations (see Figure 21.1c), that is,

$$\mathbf{y}(t) = \mathbf{Ax}(t) + \mathbf{e}(t) \quad (t = 1, 2, \dots, T), \quad (21.3)$$

where  $\mathbf{y}(t) = [y_1(t), y_2(t), \dots, y_I(t)]^T$  is a vector of the observed signals at the discrete time point  $t$  whereas  $\mathbf{x}(t) = [x_1(t), x_2(t), \dots, x_J(t)]^T$  is a vector of unknown sources at the same time point.

In order to estimate sources, sometimes we try first to identify the mixing matrix  $\mathbf{A}$  or its (pseudo)-inverse (unmixing) matrix  $\mathbf{W}$  and then estimate the sources. Usually, the inverse (unmixing) system

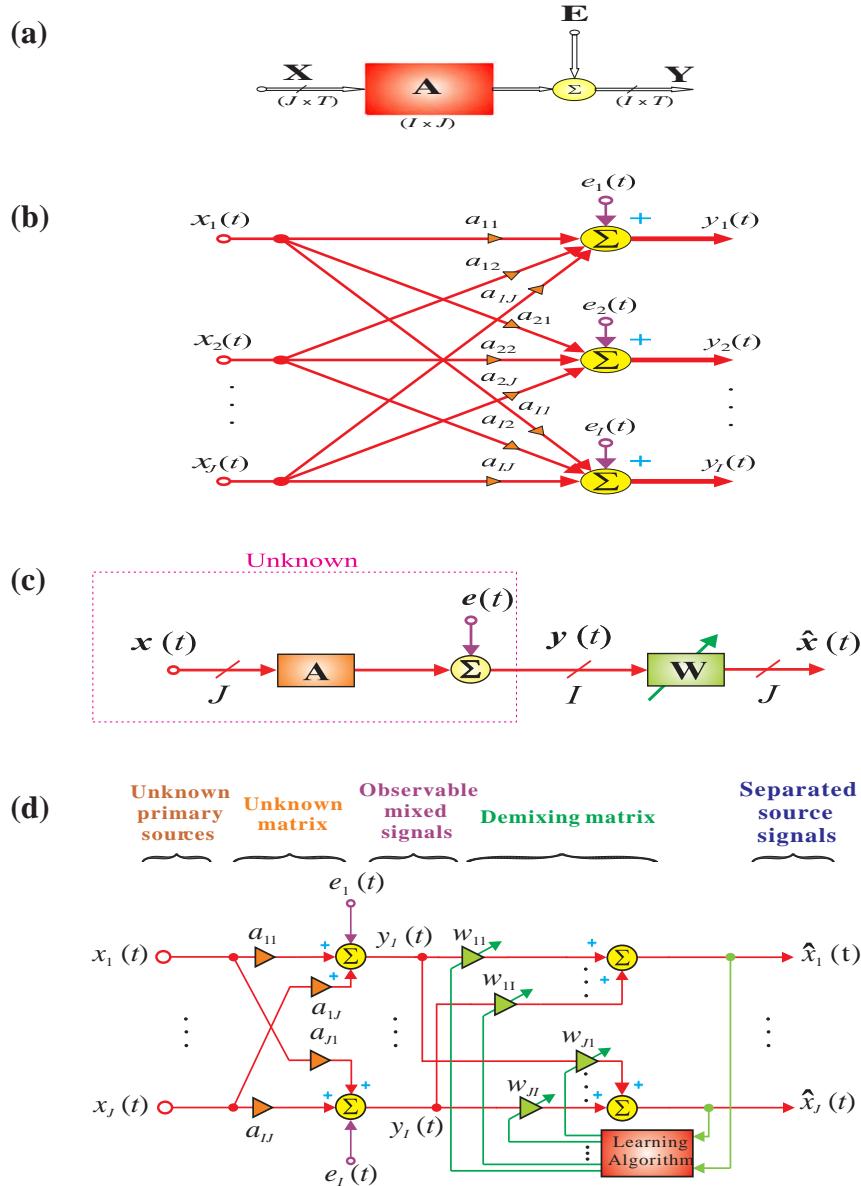

FIGURE 21.1

Basic linear (instantaneous) BSS model: (a) Block diagram expressed as a matrix factorization:  $\mathbf{Y} = \mathbf{AX} + \mathbf{E}$ , (b) its detailed model, (c) BSS via separating (demixing) matrix  $\mathbf{W} = \mathbf{A}^\dagger$ , and (d) its detailed model.

should be adaptive in such a way that it has some tracking capability in a nonstationary environment (see Figure 21.1d). We assume here that only the sensor vectors  $\mathbf{y}(t)$  are available and we need to estimate the parameters of the unmixing system online. This enables us to perform indirect identification of the mixing matrix  $\mathbf{A}$  (for  $I \geq J$ ) by estimating the separating matrix  $\mathbf{W} = \hat{\mathbf{A}}^\dagger$ , where the symbol  $(\cdot)^\dagger$  denotes the Moore–Penrose pseudo-inverse, and simultaneously estimate the sources. In other words, for  $I \geq J$  the original sources can be estimated by the linear transformation

$$\hat{\mathbf{x}}(t) = \mathbf{W}\mathbf{y}(t) \quad (t = 1, 2, \dots, T). \quad (21.4)$$

However, instead of estimating the source signals by projecting the observed signals by using the demixing matrix  $\mathbf{W}$ , it is often more convenient to identify an unknown mixing matrix  $\mathbf{A}$  (e.g., when the demixing system does not exist, especially when the system is underdetermined, i.e., the number of observations is lower than the number of source signals:  $I < J$ ) and then estimate the source signals by exploiting some *a priori* information about the source signals by applying a suitable optimization procedure.

There appears to be something magical about the BSS since we are estimating the original source signals without knowing the parameters of the mixing and/or filtering processes. It is difficult to imagine that one can estimate this at all. In fact, without some *a priori* knowledge it is not possible to *uniquely* estimate the original source signals. However, one can usually estimate them up to certain indeterminacies. In mathematical terms these indeterminacies and ambiguities can be expressed as arbitrary scaling and permutations of the estimated source signals. Let  $\Psi$  denote a specific BSS algorithm, then it holds that

$$\hat{\mathbf{X}} = \Psi(\mathbf{Y}) = \Psi(\mathbf{AX}) = \mathbf{PDX}, \quad (21.5)$$

where  $\mathbf{P}$  and  $\mathbf{D}$  are the permutation matrix and a diagonal scaling matrix (with nonzero entries), respectively. As a result, the original source signals represented by the rows of  $\mathbf{X}$  are recovered as  $\hat{\mathbf{X}}$  with the unavoidable ambiguities of scaling and permutations. If the BSS via constrained matrix factorization leads to the estimation of true components (sources) with arbitrary scaling and permutations, we call such factorization essentially unique. These indeterminacies preserve, however, the waveforms of the original sources. Although these indeterminacies seem to be rather severe limitations, in a great number of applications these limitations are not crucial, since the most relevant information about the source signals is contained in the temporal waveforms or time–frequency patterns of the source signals and usually not in their amplitudes or the order in which they are arranged in the system output. For some models, however, there is no guarantee that the estimated or extracted signals will have exactly the same waveforms as the source signals, and then the requirements must be sometimes further relaxed to the extent that the extracted waveforms are distorted (i.e., time delayed, filtered, or convolved) versions of the primary source signals.

In some applications the mixing matrix  $\mathbf{A}$  is ill-conditioned. In such cases some special models and algorithms should be applied. Although some decompositions or matrix factorizations provide an exact reconstruction of the data (i.e.,  $\mathbf{Y} = \mathbf{AX}$ ), we will consider here constrained factorizations which are approximative in nature. In fact, many problems in signal and image processing can be solved in terms of matrix factorizations. However, different cost functions and imposed constraints may lead to different types of matrix factorizations.

The BSS problems are closely related to the concept of linear inverse problems or more generally, to solving a large ill-conditioned system of linear equations (overdetermined or underdetermined), where

it is required to estimate the vectors  $\mathbf{x}(t)$  (also in some cases to identify the matrix  $\mathbf{A}$ ) from noisy data [14,30,31]. Physical systems are often contaminated by noise, thus, our task is generally to find an optimal and robust solution in a noisy environment. Wide classes of extrapolation, reconstruction, estimation, approximation, interpolation, and inverse problems can be converted into minimum norm problems of solving underdetermined systems of linear Eqs. (21.1) for  $J > I$  [14,31]. Generally speaking, in signal processing applications, an overdetermined ( $I > J$ ) system of linear Eqs. (21.1) describes filtering, enhancement, deconvolution and identification problems, while the underdetermined case describes inverse and extrapolation problems [14,30]. Although many different BSS criteria and algorithms are available, most of them exploit various diversities or constraints imposed for estimated components and/or factor matrices such as orthogonality, mutual independence, nonnegativity, sparsity, smoothness, predictability or lowest complexity. By diversities we usually mean different morphological characteristics or features of the signals.

More sophisticated or advanced approaches for GCA use combinations or the integration of various diversities, in order to separate or extract sources with various constraints, morphology, structures, or statistical properties, and to reduce the influence of noise and undesirable interferences [14,32].

All the above-mentioned BSS models are usually based on a wide class of unsupervised or semi-supervised learning algorithms. Unsupervised learning algorithms try to discover a structure underlying a data set, extract the meaningful features, and find useful representations of the given data. Since data can always be interpreted in many different ways, some knowledge is needed to determine which features or properties best represent true latent (hidden) components. For example, PCA finds a low-dimensional representation of the data that captures most of its variance. On the other hand, SCA tries to explain the data as a mixture of sparse components (usually, in the time–frequency domain), and NMF seeks to explain the data by parts-based localized additive representations (with nonnegativity constraints).

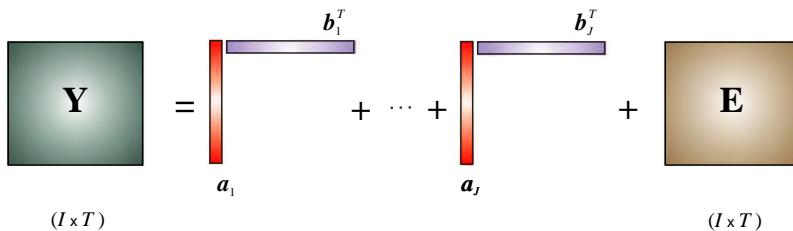

Most linear BSS or GCA models can be represented as constrained bilinear matrix factorization problems, with suitable constraints imposed on the component matrix:

$$\begin{aligned} \mathbf{Y} &= \mathbf{AB}^T + \mathbf{E} = \sum_{j=1}^J \mathbf{a}_j \mathbf{b}_j^T + \mathbf{E} \\ &= \sum_{j=1}^J \mathbf{a}_j \circ \mathbf{b}_j + \mathbf{E}, \end{aligned} \tag{21.6}$$

where  $\mathbf{Y} \in \mathbb{R}^{I \times T}$  is a known data matrix (representing observations or measurements),  $\mathbf{E} \in \mathbb{R}^{I \times T}$  represents errors or noise,  $\mathbf{A} = [\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_J] \in \mathbb{R}^{I \times J}$  is the unknown full column rank mixing (basis) matrix with  $J$  basis vectors  $\mathbf{a}_j \in \mathbb{R}^I$ , and  $\mathbf{B} = \mathbf{X}^T = [\mathbf{b}_1, \mathbf{b}_2, \dots, \mathbf{b}_J] \in \mathbb{R}^{T \times J}$  represent the unknown components, latent variables or sources  $\mathbf{b}_j \in \mathbb{R}^T$  (see Figure 21.2).

Note that we have symmetry of the factorization: For Eq. (21.6) we could write  $\mathbf{Y}^T \cong \mathbf{BA}^T$ , so the meaning of “sources” and “mixture” are often somewhat arbitrary.

The unknown components usually have clear statistical properties and meaning. For example, the columns of the matrix  $\mathbf{B}$  should be as statistically mutually independent as possible, or sparse, piecewise smooth, and/or nonnegative, etc., according to the physical meaning of the components, and to research

**FIGURE 21.2**

Bilinear BSS model. The data matrix  $\mathbf{Y} \in \mathbb{R}^{I \times T}$  is approximately represented by a sum or linear combination of rank-1 matrices  $\mathbf{Y}^{(j)} = \mathbf{a}_j \circ \mathbf{b}_j = \mathbf{a}_j \mathbf{b}_j^T \in \mathbb{R}^{I \times T}$ . The objective is to estimate all vectors  $\mathbf{a}_j$  and  $\mathbf{b}_j$  and the optimal index (rank)  $J$ . In general such decomposition is not unique, and we need to impose various constraints (e.g., nonnegativity, orthogonality, independence, or sparseness) to extract unique components with desired diversities or properties.

the field from which the data are collected. The BSS methods estimate these components maximizing the *a priori* information by imposing proper constraints on the components, then leading to various categories of BSS, such as ICA, SCA, SmoCA, NMF, etc. [8, 14, 33, 34].

Very often multiple subject, multiple task data sets can be represented by a set of data matrices  $\mathbf{Y}_n$ . It is therefore necessary to perform simultaneous constrained matrix factorizations:

$$\mathbf{Y}_n \approx \mathbf{A}_n \mathbf{B}_n^T \quad (n = 1, 2, \dots, N), \quad (21.7)$$

subject to various additional constraints (e.g.,  $\mathbf{A}_n = \mathbf{A}$  for all  $n$ , and their columns are mutually independent and/or sparse). This problem is related to various models of group ICA, with suitable pre-processing, dimensionality reduction and post-processing procedures [35–37]. This form of factorization is typical for EEG/MEG related data for multi-subjects, multi-tasks, while the factorization for the transposed of  $\mathbf{Y}$  is typical for fMRI data [35–38].

The multilinear BSS concept introduced in Section 1.21.5.4 is more general and flexible than the group ICA, since various constraints can be imposed on the component matrices for different modes (i.e., not only mutual independence but also nonnegativity, sparseness, smoothness or orthogonality). There are neither theoretical nor experimental reasons why statistical independence (used by ICA) should be the only one right concept to be used to extract latent components [33]. In real world scenarios, latent (hidden) components have various complex properties and features. In other words, true unknown components are seldom all statistically independent. Therefore, if we apply only one criterion like ICA, we may fail to extract all desired components with correct interpretations. Rather we need to apply the fusion of several strategies by employing several suitably chosen criteria and their associated learning algorithms to extract all desired components for specific modes [8, 33]. For these reasons we often consider the multilinear BSS methods, which exploit multiple criteria or diversities for the component matrices for various modes, rather than only statistical independence (see Section 1.21.5).

## 1.21.2 PCA/SVD and related problems

Principal Component Analysis (PCA) and Singular Value Decomposition (SVD) are well established tools with applications virtually in all areas of science, machine learning, signal processing, engineering,

genetics and neural computation, to name just a few, where large data sets are encountered [39, 40]. The basic aim of PCA is to find a few linear combinations of variables, called principal components, which point in orthogonal directions while explaining as much of the variance of the data as possible.

PCA is perhaps one of the oldest and best-known techniques from multivariate analysis and data mining. It was introduced by Pearson, who used it in a biological context and further developed by Hotelling in research work related to psychometry. PCA was also developed independently by Karhunen in the context of probability theory and was subsequently generalized by Loève (see [14, 39, 41] and references therein). The purpose of PCA is to derive a relatively small number of uncorrelated linear combinations (principal components) of a set of random zero-mean variables  $\mathbf{y}(t)$ , while retaining as much of the information from the original variables as possible.

Following are several of the objectives of PCA/SVD:

1. dimensionality reduction;
2. determination of linear combinations of variables;
3. feature selection: the choice of the most useful variables;
4. visualization of multi-dimensional data;
5. identification of underlying variables;
6. identification of groups of objects or of outliers.

Often the principal components (PCs) (i.e., directions on which the input data has the largest variance) are usually regarded as important or significant, while those components with the smallest variance called minor components (MCs) are usually regarded as unimportant or associated with noise. However, in some applications, the MCs are of the same importance as the PCs, for example, in the context of curve or surface fitting or total least squares (TLS) problems.

Generally speaking, PCA is often related and motivated by the following two problems:

1. Given random vectors  $\mathbf{y}(t) \in \mathbb{R}^I$  ( $t = 1, 2, \dots, T$ ), with finite second order moments and zero mean, find the reduced  $J$ -dimensional ( $J < I$ ) linear subspace that minimizes the expected distance of  $\mathbf{y}(t)$  from the subspace. This problem arises in the area of data compression, where the task is to represent all the data with a reduced number of parameters while assuring minimum distortion due to the projection.
2. Given random vectors  $\mathbf{y}(t) \in \mathbb{R}^I$ , find the  $J$ -dimensional linear subspace that captures most of the variance of the data. This problem is related to feature extraction, where the objective is to reduce the dimension of the data while retaining most of its information content.

It turns out that both problems have the same optimal solution (in the sense of least-squares error), which is based on the second order statistics (SOS), in particular, on the eigen structure of the data covariance matrix.

**Remark.** If the signals have standard deviation (SD) one, the covariance and correlation matrices are identical. The correlation matrix is the covariance matrix of the mean centered and scaled vectors. Since, we consider here zero mean signals with SD one, both matrices are equivalent.

PCA is designed for a general random variable regardless whether it is of zero mean or not. But at the first step we center the data, otherwise the first principal component will converge to its mean value.

### 1.21.2.1 Standard PCA

Without loss of generality let us consider a data matrix  $\mathbf{Y} \in \mathbb{R}^{T \times I}$  with  $T$  samples and  $I$  variables and with the columns centered (zero mean) and scaled. Equivalently, it is sometimes convenient to consider the data matrix  $\mathbf{Y}' = [\mathbf{y}(1), \mathbf{y}(2), \dots, \mathbf{y}(T)] \in \mathbb{R}^{I \times T}$ . The standard PCA can be written in terms of the scaled sample covariance matrix  $\mathbf{R}_{yy} = E\{\mathbf{y}\mathbf{y}^T\} \in \mathbb{R}^{I \times I}$  as follows: Find orthonormal vectors by solving the following optimization problem

$$\max_{\mathbf{v}_i} \{\mathbf{v}_i \mathbf{R}_{yy} \mathbf{v}_i^T\}, \quad \text{s.t. } \mathbf{v}_i^T \mathbf{v}_i = 1, \quad \mathbf{v}_i^T \mathbf{v}_k = 0 \quad \forall i > k \quad (i = 1, 2, \dots, I). \quad (21.8)$$

PCA can be converted to the eigenvalue problem of the covariance matrix of  $\mathbf{y}(t)$  ( $t = 1, 2, \dots, T$ ), and it is essentially equivalent to the Karhunen-Loëve transform used in image and signal processing. In other words, PCA is a technique for the computation of eigenvectors and eigenvalues for the scaled estimated covariance matrix

$$\mathbf{R}_{yy} = E\{\mathbf{y}(t)\mathbf{y}^T(t)\} = \mathbf{V}\Lambda\mathbf{V}^T = \sum_{i=1}^I \lambda_i \mathbf{v}_i \mathbf{v}_i^T, \quad (21.9)$$

where  $\Lambda = \text{diag}\{\lambda_1, \lambda_2, \dots, \lambda_I\}$  is a diagonal matrix containing the  $I$  eigenvalues (ordered in decreasing values) and  $\mathbf{V} = [\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_I] \in \mathbb{R}^{I \times I}$  is the corresponding orthogonal or unitary matrix consisting of the unit length eigenvectors referred to as principal eigenvectors. It should be noted that the covariance matrix is symmetric positive definite, that is why the eigenvalues are nonnegative. We assume that for noisy data all eigenvalues are positive and we put them in descending order.

The basic problem we try to solve is the standard eigenvalue problem which can be formulated using the equations

$$\mathbf{R}_{yy} \mathbf{v}_i = \lambda_i \mathbf{v}_i \quad (i = 1, 2, \dots, I), \quad (21.10)$$

where  $\mathbf{v}_i$  are the orthonormal eigenvectors,  $\lambda_i$  are the corresponding eigenvalues and  $\mathbf{R}_{yy} = E\{\mathbf{y}\mathbf{y}^T\}$  is the covariance matrix of zero-mean signals  $\mathbf{y}(t)$  and  $E$  is the expectation operator. Note that (21.10) can be written in matrix form as  $\mathbf{V}^T \mathbf{R}_{yy} \mathbf{V} = \Lambda$ , where  $\Lambda$  is the diagonal matrix of eigenvalues (ranked in descending order) of the estimated covariance matrix  $\mathbf{R}_{yy}$ .

The Karhunen-Loëve-transform determines a linear transformation of an input vector  $\mathbf{y}$  as

$$\tilde{\mathbf{y}}_P(t) = \mathbf{V}_S^T \mathbf{y}(t), \quad (21.11)$$

where  $\mathbf{y}(t) = [y_1(t), y_2(t), \dots, y_I(t)]^T$  is the zero-mean input vector,  $\tilde{\mathbf{y}}_P = [\tilde{y}_1(t), \tilde{y}_2(t), \dots, \tilde{y}_J(t)]^T$  is the output vector called the vector of principal components (PCs), and  $\mathbf{V}_S = [\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_J] \in \mathbb{R}^{I \times J}$ , with  $J < I$ , is the set of signal subspace eigenvectors, with the orthonormal vectors  $\mathbf{v}_j = [v_{j1}, v_{j2}, \dots, v_{jI}]^T$ , (i.e.,  $(\mathbf{v}_i^T \mathbf{v}_j = \delta_{ij})$  for  $j \leq i$ , where  $\delta_{ij}$  is the Kronecker delta that equals 1 for  $i = j$ , and zero otherwise. The vectors  $\mathbf{v}_j$  ( $j = 1, 2, \dots, J$ ) are eigenvectors of the covariance matrix, while the variances of the PCs  $\tilde{y}_j(t) = \mathbf{v}_j^T \mathbf{y}(t)$  are the corresponding principal eigenvalues, i.e.,  $\lambda_j = E\{\tilde{y}_j^2\}$ .

On the other hand, the  $(I - J)$  minor components are given by

$$\tilde{\mathbf{y}}_M(t) = \mathbf{V}_N^T \mathbf{y}(t), \quad (21.12)$$

where  $\mathbf{V}_N = [\mathbf{v}_{J+1}, \mathbf{v}_{J+2}, \dots, \mathbf{v}_I]$  consists of the  $(I - J)$  eigenvectors associated with the smallest eigenvalues.

### 1.21.2.2 Determining the number of principal components

A quite important problem arising in many application areas is the determination of the dimensions of the signal and noise subspaces. In other words, a central issue in PCA is choosing the number of principal components to be retained [42–44]. To solve this problem, we usually exploit a fundamental property of PCA: It projects the sensor data  $\mathbf{y}(t) \in \mathbb{R}^I$  from the original  $I$ -dimensional space onto a  $J$ -dimensional output subspace  $\tilde{\mathbf{y}}(t) \in \mathbb{R}^J$  (typically, with  $J \ll I$ ), thus performing a dimensionality reduction which retains most of the intrinsic information in the input data vectors. In other words, the principal components  $\tilde{\mathbf{y}}_j(t) = \mathbf{v}_j^T \mathbf{y}(t)$  are estimated in such a way that, for  $J \ll I$ , although the dimensionality of data is strongly reduced, the most relevant information is retained in the sense that the input data can be approximately reconstructed from the output data (signals) by using the transformation  $\hat{\mathbf{y}} = \mathbf{V}_S \tilde{\mathbf{y}}$ , that minimizes a suitable cost function. A commonly used criterion is the minimization of the mean squared error  $\|\mathbf{y} - \mathbf{V}_S \mathbf{V}_S^T \mathbf{y}\|_2^2$  subject to orthogonality constraint  $\mathbf{V}_S^T \mathbf{V}_S$ .

Under the assumption that the power of the signals is larger than the power of the noise, the PCA enables us to divide observed (measured) sensor signals:  $\mathbf{y}(t) = \mathbf{y}_s(t) + \mathbf{e}(t)$  into two subspaces: the *signal subspace* corresponding to principal components associated with the largest eigenvalues called the principal eigenvalues:  $\lambda_1, \lambda_2, \dots, \lambda_J$ , ( $I > J$ ) and associated eigenvectors  $\mathbf{V}_S = [\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_J]$  called the principal eigenvectors and the *noise subspace* corresponding to the minor components associated with the eigenvalues  $\lambda_{J+1}, \dots, \lambda_I$ . The subspace spanned by the  $J$  first eigenvectors  $\mathbf{v}_j$  can be considered as an approximation of the noiseless signal subspace. One important advantage of this approach is that it enables not only a reduction in the noise level, but also allows us to estimate the number of sources on the basis of distribution of the eigenvalues. However, a problem arising from this approach is how to correctly set or estimate the threshold which divides eigenvalues into the two subspaces, especially when the noise is large (i.e., the SNR is low). The scaled covariance matrix of the observed data can be written as

$$\begin{aligned} \mathbf{R}_{yy} &= [\mathbf{V}_S, \mathbf{V}_N] \begin{bmatrix} \mathbf{\Lambda}_S & \mathbf{0} \\ \mathbf{0} & \mathbf{\Lambda}_N \end{bmatrix} [\mathbf{V}_S, \mathbf{V}_N]^T \\ &= \mathbf{V}_S \mathbf{\Lambda}_S \mathbf{V}_S^T + \mathbf{V}_N \mathbf{\Lambda}_N \mathbf{V}_N^T, \end{aligned} \quad (21.13)$$

where  $\mathbf{V}_S \mathbf{\Lambda}_S \mathbf{V}_S^T$  is a rank- $J$  matrix,  $\mathbf{V}_S \in \mathbb{R}^{I \times J}$  contains the eigenvectors associated with  $J$  principal (signal + noise subspace) eigenvalues of  $\mathbf{\Lambda}_S = \text{diag}\{\lambda_1 \geq \lambda_2 \dots \geq \lambda_J\}$  in a descending order. Similarly, the matrix  $\mathbf{V}_N \in \mathbb{R}^{I \times (I-J)}$  contains the  $(I - J)$  (noise subspace) eigenvectors that correspond to the noise eigenvalues  $\mathbf{\Lambda}_N = \text{diag}\{\lambda_{J+1}, \dots, \lambda_I\} = \sigma_e^2 \mathbf{I}_{I-J}$ . This means that, theoretically, the  $(I - J)$  smallest eigenvalues of  $\mathbf{R}_{yy}$  are equal to  $\sigma_e^2$ , so we can theoretically (in the ideal case) determine the dimension of the signal subspace from the multiplicity of the smallest eigenvalues under the assumption that the variance of the noise is relatively low and we have a perfect estimate of the covariance matrix. However, in practice, we estimate the sample covariance matrix from a limited number of samples and the (estimated) smallest eigenvalues are usually different, so the determination of the dimension of the signal subspace is not an easy task. Usually we set the threshold between the signal and noise eigenvalues by using some heuristic procedure or a rule of thumb. A simple ad hoc rule is to plot the eigenvalues in decreasing order and search for an elbow, where the signal eigenvalues are on the left side and the noise eigenvalues are on the right side. Another simple technique is to compute the cumulative percentage of the total variation explained by the PCs and retain the number of PCs that represent, say

95% of the total variation. Such techniques often work well in practice, but their disadvantage is that they need a subjective decision from the user [44].

Alternatively, can use one of the several well-known information theoretic criteria, namely, Akaike's Information Criterion (AIC), the Minimum Description Length (MDL) criterion and Bayesian Information Criterion (BIC) [43,45,46]. To do this, we compute the probability distribution of the data for each possible dimension (see [46]).

Unfortunately, AIC and MDL criteria provide only rough estimates (of the number of sources) that are rather very sensitive to variations in the SNR and the number of available data samples.

Many sophisticated methods have been introduced such as a Bayesian model selection method, which is referred to as the Laplace method. It is based on computing the evidence for the data and it requires integrating out all the model parameters. The BIC method can be thought of as an approximation to the Laplace criterion. The calculation involves an integral over the Stiefel manifold which is approximated by the Laplace method [43]. One problem with the AIC, MDL and BIC criteria mentioned above is that they have been derived by assuming that the data vectors  $\mathbf{y}(t)$  have a Gaussian distribution [46]. This is done for mathematical tractability, by making it possible to derive closed form expressions. The Gaussianity assumption does not usually hold exactly in the BSS and other signal processing applications. For setting the threshold between the signal and noise eigenvalues, one might even suppose that the AIC, MDL and BIC criteria cannot be used for the BSS, particularly ICA problems, because in those cases we assume that the source signals  $x_j(t)$  are non-Gaussian. However, it should be noted that the components of the data vectors  $\mathbf{y}(t) = \mathbf{Ax}(t) + \mathbf{e}(t)$  are mixtures of the sources, and therefore they often have distributions that are not too far from a Gaussian distribution.

An alternative simple heuristic method [42,47] computes the GAP (smoothness) index between consecutive eigenvalues defined as

$$\text{GAP}(p) = \frac{\text{var}[\{\tilde{\lambda}_i\}_{i=p+1}^{I-1}]}{\text{var}[\{\tilde{\lambda}_i\}_{i=p}^{I-1}]} = \frac{\hat{\sigma}_{p+1}^2}{\hat{\sigma}_p^2} \quad (p = 1, 2, \dots, I-2), \quad (21.14)$$

where  $\tilde{\lambda}_i = \lambda_i - \lambda_{i+1}$  and  $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_I > 0$  are the eigenvalues of the covariance matrix for the noisy data and the sample variances are computed as follows:

$$\hat{\sigma}_p^2 = \text{var}[\{\tilde{\lambda}_i\}_{i=p}^{I-1}] = \frac{1}{I-p} \sum_{i=p}^{I-1} \left( \tilde{\lambda}_i - \frac{1}{I-p} \sum_{i=p}^{I-1} \tilde{\lambda}_i \right)^2. \quad (21.15)$$

The number of components (for each mode) are selected using the following criterion:

$$\hat{J} = \arg \min_{p=1,2,\dots,I-3} \{\text{GAP}(p)\}. \quad (21.16)$$

Recently, Ulfarsson and Solo [44] proposed an alternative more sophisticated method called SURE (Stein's Unbiased Risk Estimator) which allows to estimate the number of PC components.

Extensive numerical experiments indicate that the Laplace method usually outperforms the BIC method while the GAP and SURE methods can often achieve significantly better performance than the Laplace method.

### 1.21.2.3 Whitening

Some adaptive algorithms for blind separation require prewhitening (also called sphering or normalized spatial decorrelation) of mixed (sensor) signals. A random, zero-mean vector  $\tilde{\mathbf{y}}$  is said to be white if its covariance matrix is an identity matrix, i.e.,  $\mathbf{R}_{\tilde{\mathbf{y}}\tilde{\mathbf{y}}} = E\{\tilde{\mathbf{y}}\tilde{\mathbf{y}}^T\} = \mathbf{I}_J$  or  $E\{\tilde{y}_i\tilde{y}_j\} = \delta_{ij}$ , where  $\delta_{ij}$  is the Kronecker delta. In whitening, the sensor vectors  $\mathbf{y}(t)$  are pre-processed using the following transformation:

$$\tilde{\mathbf{y}}(t) = \mathbf{Q}\mathbf{y}(t). \quad (21.17)$$

Here  $\tilde{\mathbf{y}}(t)$  denotes the whitened vector, and  $\mathbf{Q}$  is an  $J \times I$  whitening matrix. For  $J < I$ , where  $J$  is known in advance,  $\mathbf{Q}$  simultaneously reduces the dimension of the data vectors from  $I$  to  $J$ . In whitening, the matrix  $\mathbf{Q}$  is chosen such that the scaled covariance matrix  $E\{\tilde{\mathbf{y}}(t)\tilde{\mathbf{y}}(t)^T\}$  becomes the unit matrix  $\mathbf{I}_J$ . Thus, the components of the whitened vectors  $\tilde{\mathbf{y}}(t)$  are mutually uncorrelated and have unit variance, i.e.,

$$\mathbf{R}_{\tilde{\mathbf{y}}\tilde{\mathbf{y}}} = E\{\tilde{\mathbf{y}}\tilde{\mathbf{y}}^T\} = E\{\mathbf{Q}\mathbf{y}\mathbf{y}^T\mathbf{Q}^T\} = \mathbf{Q}\mathbf{R}_{\mathbf{y}\mathbf{y}}\mathbf{Q}^T = \mathbf{I}_J. \quad (21.18)$$

Generally, the sensor signals are mutually correlated, i.e., the covariance matrix  $\mathbf{R}_{\mathbf{y}\mathbf{y}} = E\{\mathbf{y}\mathbf{y}^T\}$  is a full (not diagonal) matrix. It should be noted that the matrix  $\mathbf{Q} \in \mathbb{R}^{J \times I}$  is not unique, since multiplying it by an arbitrary orthogonal matrix from the left still preserves property (21.18). Since the covariance matrix of sensor signals  $\mathbf{y}(t)$  is symmetric positive semi-definite, it can be decomposed as follows:

$$\mathbf{R}_{\mathbf{y}\mathbf{y}} = \mathbf{V}\Lambda\mathbf{V}^T = \mathbf{V}\Lambda^{1/2}\Lambda^{1/2}\mathbf{V}^T, \quad (21.19)$$

where  $\mathbf{V}$  is an orthogonal matrix and  $\Lambda = \text{diag}\{\lambda_1, \lambda_2, \dots, \lambda_J\}$  is a diagonal matrix with positive eigenvalues  $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_J > 0$ . Hence, under the condition that the covariance matrix is positive definite, the required decorrelation matrix  $\mathbf{Q}$  (also called a whitening matrix or Mahalanobis transform) can be computed as follows:

$$\mathbf{Q} = \Lambda^{-1/2}\mathbf{V}^T = \text{diag}\left\{\frac{1}{\sqrt{\lambda_1}}, \frac{1}{\sqrt{\lambda_2}}, \dots, \frac{1}{\sqrt{\lambda_J}}\right\}\mathbf{V}^T \quad (21.20)$$

or

$$\mathbf{Q} = \mathbf{U}\Lambda^{-1/2}\mathbf{V}^T, \quad (21.21)$$

where  $\mathbf{U}$  is an arbitrary orthogonal matrix. This can be easily verified by substituting (21.20) or (21.21) into (21.18):

$$\mathbf{R}_{\mathbf{y}\mathbf{y}} = E\{\mathbf{y}\mathbf{y}^T\} = \Lambda^{-1/2}\mathbf{V}^T\mathbf{V}\Lambda\mathbf{V}^T\mathbf{V}\Lambda^{-1/2} = \mathbf{I}_J, \quad (21.22)$$

or

$$\mathbf{R}_{\mathbf{y}\mathbf{y}} = \mathbf{U}\Lambda^{-1/2}\mathbf{V}^T\mathbf{V}\Lambda\mathbf{V}^T\mathbf{V}\Lambda^{-1/2}\mathbf{U}^T = \mathbf{I}_J. \quad (21.23)$$

Alternatively, we can apply the Cholesky decomposition

$$\mathbf{R}_{\mathbf{y}\mathbf{y}} = \mathbf{L}\mathbf{L}^T, \quad (21.24)$$

where  $\mathbf{L}$  is a lower triangular matrix. The whitening (decorrelation) matrix in this case is

$$\mathbf{Q} = \mathbf{U}\mathbf{L}^{-1}, \quad (21.25)$$

where  $\mathbf{U}$  is an arbitrary orthogonal matrix, since

$$\mathbf{R}_{yy} = E\{yy^T\} = \mathbf{Q}\mathbf{R}_{yy}\mathbf{Q}^T = \mathbf{U}\mathbf{L}^{-1}\mathbf{L}\mathbf{L}^T(\mathbf{L}^{-1})^T\mathbf{U}^T = \mathbf{I}_J. \quad (21.26)$$

In the special case when  $y(t) = \mathbf{e}(t)$  is colored Gaussian noise with  $\mathbf{R}_{ee} = E\{\mathbf{e}\mathbf{e}^T\} \neq \sigma_e^2 \mathbf{I}_J$ , the whitening transform converts it into a white noise (i.i.d.) process. If the covariance matrix is positive semi-definite, we can take only the positive eigenvalues and the associated eigenvectors.

It should be noted that after pre-whitening of sensor signals  $y(t)$ , in the model  $\mathbf{Y} \cong \mathbf{AX}$ , the new mixing matrix defined as  $\mathbf{A}_* = \mathbf{QA}$  is orthogonal (i.e.,  $\mathbf{A}_*\mathbf{A}_*^T = \mathbf{I}_J$ ), if source signals are uncorrelated (i.e.,  $\mathbf{R}_{xx} = E\{\mathbf{xx}^T\} = \mathbf{I}_J$ ), since we can write  $\mathbf{R}_{\tilde{y}\tilde{y}} = E\{\tilde{y}\tilde{y}^T\} = \mathbf{A}_*E\{\mathbf{xx}^T\}\mathbf{A}_*^T = \mathbf{I}_J$ .

#### 1.21.2.4 SVD

The Singular Value Decomposition (SVD) is a tool of both great practical and theoretical importance in signal processing and data analysis [40]. The SVD of a data matrix  $\mathbf{Y} \in \mathbb{R}^{T \times I}$  of rank- $J$  with  $J \leq I$ , assuming without loss of generality that  $T > I$ , leads to the following matrix factorization

$$\boxed{\mathbf{Y} = \mathbf{U}\Sigma\mathbf{V}^T = \sum_{j=1}^J \sigma_j \mathbf{u}_j \mathbf{v}_j^T}, \quad (21.27)$$

where the matrix  $\mathbf{U} = [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_T] \in \mathbb{R}^{T \times T}$  contains the  $T$  left singular vectors,  $\Sigma \in \mathbb{R}_+^{T \times I}$  has nonnegative elements on the main diagonal representing the singular values  $\sigma_j$  and the matrix  $\mathbf{V} = [\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_I] \in \mathbb{R}^{I \times I}$  represents the  $I$  right singular vectors called the loading factors. The nonnegative quantities  $\sigma_j$ , sorted as  $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_J > \sigma_{J+1} = \sigma_{J+2} = \dots = \sigma_I = 0$  can be shown to be the square roots of the eigenvalues of the symmetric matrix  $\mathbf{Y}^T \mathbf{y} \in \mathbb{R}^{I \times I}$ . The term  $\mathbf{u}_j \mathbf{v}_j^T$  is a  $T \times I$  rank-1 matrix often called the  $j$ th eigenimage of  $\mathbf{Y}$ . Orthogonality of the SVD expansion ensures that the left and right singular vectors are orthogonal, i.e.,  $\mathbf{u}_i^T \mathbf{u}_j = \delta_{ij}$  and  $\mathbf{v}_i^T \mathbf{v}_j = \delta_{ij}$ , with  $\delta_{ij}$  the Kronecker delta (or equivalently  $\mathbf{U}^T \mathbf{U} = \mathbf{I}$  and  $\mathbf{V}^T \mathbf{V} = \mathbf{I}$ ).

In many applications, it is more practical to work with the truncated form of the SVD, where only the first  $P \leq J$ , (where  $J$  is the rank of  $\mathbf{Y}$ , with  $J < I$ ) singular values are used, so that

$$\mathbf{Y} \cong \mathbf{U}_P \Sigma_P \mathbf{V}_P^T = \sum_{j=1}^P \sigma_j \mathbf{u}_j \mathbf{v}_j^T, \quad (21.28)$$

where  $\mathbf{U}_P = [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_P] \in \mathbb{R}^{T \times P}$ ,  $\Sigma_P = \text{diag}\{\sigma_1, \sigma_2, \dots, \sigma_P\}$  and  $\mathbf{V} = [\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_P] \in \mathbb{R}^{I \times P}$ . This is no longer an exact decomposition of the data matrix  $\mathbf{Y}$ , but according to the **Eckart-Young** theorem it is the best rank- $P$  approximation in the least-squares sense and it is still unique (neglecting signs of vectors ambiguity) if the singular values are distinct.

For noiseless data, we can use the following decomposition:

$$\mathbf{Y} = [\mathbf{U}_S, \mathbf{U}_N] \begin{bmatrix} \Sigma_S & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} [\mathbf{V}_S, \mathbf{V}_N]^T, \quad (21.29)$$

where  $\mathbf{U}_S = [\mathbf{u}_1, \dots, \mathbf{u}_J] \in \mathbb{R}^{T \times J}$ ,  $\Sigma_S = \text{diag}\{\sigma_1, \dots, \sigma_J\}$  and  $\mathbf{U}_N = [\mathbf{u}_{J+1}, \dots, \mathbf{u}_I]$ . The set of matrices  $\{\mathbf{U}_S, \Sigma_S, \mathbf{V}_S\}$  represents this signal subspace and the set of matrices  $\{\mathbf{U}_N, \Sigma_N, \mathbf{V}_N\}$

represents the null subspace or, in practice for noisy data, the noise subspace. The  $J$  columns of  $\mathbf{U}$ , corresponding to these non-zero singular values that span the column space of  $\mathbf{Y}$ , are called the left singular vectors. Similarly, the  $J$  columns of  $\mathbf{V}$  are called the right singular vectors and they span the row space of  $\mathbf{Y}$ . Using these terms the SVD of  $\mathbf{Y}$  can be written in a more compact form as:

$$\mathbf{Y} = \mathbf{U}_{\mathcal{S}} \boldsymbol{\Sigma}_{\mathcal{S}} \mathbf{V}_{\mathcal{S}}^T = \sum_{j=1}^J \sigma_j \mathbf{u}_j \mathbf{v}_j^T. \quad (21.30)$$

Perturbation theory for the SVD is partially based on the link between the SVD and the PCA and symmetric Eigenvalue Decomposition (EVD). It is evident, that from the SVD of the matrix  $\mathbf{Y} = \mathbf{U} \boldsymbol{\Sigma} \mathbf{V}^T$  with rank- $J \leq I \leq T$ , we have

$$\boxed{\mathbf{Y} \mathbf{Y}^T = \mathbf{U} \boldsymbol{\Sigma}_1^2 \mathbf{U}^T}, \quad (21.31)$$

$$\boxed{\mathbf{Y}^T \mathbf{Y} = \mathbf{V} \boldsymbol{\Sigma}_2^2 \mathbf{V}^T}, \quad (21.32)$$

where  $\boldsymbol{\Sigma}_1 = \text{diag}\{\sigma_1, \dots, \sigma_I\}$  and  $\boldsymbol{\Sigma}_2 = \text{diag}\{\sigma_1, \dots, \sigma_I\}$ . This means that the singular values of  $\mathbf{Y}$  are the positive square roots of the eigenvalues of  $\mathbf{Y}^T \mathbf{Y}$  and the eigenvectors  $\mathbf{U}$  of  $\mathbf{Y} \mathbf{Y}^T$  are the left singular vectors of  $\mathbf{Y}$ . Note that if  $I < T$ , the matrix  $\mathbf{Y} \mathbf{Y}^T$  will contain at least  $T - I$  additional eigenvalues that are not included as singular values of  $\mathbf{Y}$ .

An estimate  $\hat{\mathbf{R}}_{yy}$  of the covariance matrix corresponding to a set of (zero-mean) observed vectors  $\mathbf{y}(t) \in \mathbb{R}^I$  may be computed as  $\hat{\mathbf{R}}_{yy} = (1/T) \sum_{t=1}^T \mathbf{y}(t) \mathbf{y}^T(t)$ . An alternative equivalent way of computing  $\hat{\mathbf{R}}_{yy}$  is to form a data matrix  $\mathbf{y}^T = [\mathbf{y}(1), \mathbf{y}(2), \dots, \mathbf{y}(T)] \in \mathbb{R}^{I \times T}$  and represent the estimated covariance matrix by  $\hat{\mathbf{R}}_{yy} = \frac{1}{T} \mathbf{y} \mathbf{y}^T$ . Hence, the eigenvectors of the sample covariance matrix  $\hat{\mathbf{R}}_{yy}$  are the left singular vectors  $\mathbf{U}$  of  $\mathbf{y}$  and the singular values  $\sigma_j$  of  $\mathbf{y}$  are the positive square roots of the eigenvalues of  $\hat{\mathbf{R}}_{yy}$ .

From this discussion it follows that all the algorithms for PCA and EVD can be applied (after some simple tricks) to the SVD of an arbitrary matrix  $\mathbf{Y}$  without any need to directly compute or estimate the covariance matrix. The opposite is also true; the PCA or EVD of the covariance matrix  $\hat{\mathbf{R}}_{yy}$  can be performed via the SVD numerical algorithms. However, for large data matrices  $\mathbf{Y}$ , the SVD algorithms usually become more costly, than the relatively efficient and fast PCA adaptive algorithms. Several reliable and efficient numerical algorithms for the SVD do however, exist [48].

The approximation of the matrix  $\mathbf{Y}$  by a rank-1 matrix  $\sigma \mathbf{u} \mathbf{v}^T$  of two unknown vectors  $\mathbf{u} = [u_1, u_2, \dots, u_T]^T \in \mathbb{R}^T$  and  $\mathbf{v} = [v_1, v_2, \dots, v_I]^T \in \mathbb{R}^I$ , normalized to unit length, with an unknown scaling constant term  $\sigma$ , can be presented as follows:

$$\mathbf{Y} = \sigma \mathbf{u} \mathbf{v}^T + \mathbf{E}, \quad (21.33)$$

where  $\mathbf{E} \in \mathbb{R}^{T \times I}$  is the matrix of the residual errors  $e_{it}$ . In order to compute the unknown vectors we minimize the squared Euclidean error as [49]

$$D_1(\mathbf{Y} \| \sigma \mathbf{u} \mathbf{v}^T) = \|\mathbf{E}\|_F^2 = \sum_{it} e_{it}^2 = \sum_{i=1}^I \sum_{t=1}^T (y_{ti} - \sigma u_t v_i)^2. \quad (21.34)$$

The necessary conditions for the minimization of (21.34) are obtained by equating the gradients to zero:

$$\frac{\partial D_1}{\partial u_t} = -2\sigma \sum_{i=1}^I (y_{ti} - \sigma u_t v_i) v_i = 0, \quad (21.35)$$

$$\frac{\partial D_1}{\partial v_i} = -2\sigma \sum_{t=1}^T (y_{ti} - \sigma u_t v_i) u_t = 0. \quad (21.36)$$

These equations can be expressed as follows:

$$\sum_{i=1}^I y_{ti} v_i = \sigma u_t \sum_{i=1}^I v_i^2, \quad \sum_{t=1}^T y_{ti} u_t = \sigma v_i \sum_{t=1}^T u_t^2. \quad (21.37)$$

It is interesting to note that (taking into account that  $\sigma u_t = \sum_{i=1}^I y_{ti} v_i / \sum_{i=1}^I v_i^2$  (see Eq. (21.37)) the cost function (21.34) can be expressed as [49]

$$\begin{aligned} D_1 &= \|\mathbf{E}\|_F^2 = \sum_{i=1}^I \sum_{t=1}^T (y_{ti} - \sigma u_t v_i)^2 \\ &= \sum_{i=1}^I \sum_{t=1}^T y_{ti}^2 - 2 \sum_{t=1}^T (\sigma u_t) \sum_{i=1}^I (y_{ti} v_i) + \sum_{t=1}^T (\sigma u_t)^2 \sum_{i=1}^I v_i^2 \\ &= \sum_{i=1}^I \sum_{t=1}^T y_{ti}^2 - \frac{\sum_{i=1}^I (\sum_{t=1}^T y_{ti} v_i)^2}{\sum_{i=1}^I v_i^2}. \end{aligned} \quad (21.38)$$

In matrix notation the cost function can be written as

$$\|\mathbf{E}\|_F^2 = \|\mathbf{Y}\|_F^2 - \frac{\mathbf{v}^T \mathbf{Y}^T \mathbf{Y} \mathbf{v}}{\|\mathbf{v}\|_2^2} = \|\mathbf{Y}\|_F^2 - \sigma^2, \quad (21.39)$$

where the second term is called the Rayleigh quotient. The maximum value of the Rayleigh quotient is exactly equal to the maximum eigenvalue  $\lambda_1 = \sigma_1^2$ .

Taking into account that the vectors are normalized to unit length, that is,  $\mathbf{u}^T \mathbf{u} = \sum_{t=1}^T u_t^2 = 1$  and  $\mathbf{v}^T \mathbf{v} = \sum_{i=1}^I v_i^2 = 1$ , we can write the above equations in a compact matrix form as

$$\mathbf{Y} \mathbf{v} = \sigma \mathbf{u}, \quad \mathbf{Y}^T \mathbf{u} = \sigma \mathbf{v} \quad (21.40)$$

or equivalently (by substituting one of Eq. (21.40) into another)

$$\mathbf{Y}^T \mathbf{Y} \mathbf{v} = \sigma^2 \mathbf{v}, \quad \mathbf{Y} \mathbf{Y}^T \mathbf{u} = \sigma^2 \mathbf{u}, \quad (21.41)$$

which are classical eigenvalue problems which estimate the maximum eigenvalue  $\lambda_1 = \sigma_1^2 = \sigma_{\max}^2$  with the corresponding eigenvectors  $\mathbf{u}_1 = \mathbf{u}$  and  $\mathbf{v}_1 = \mathbf{v}$ . The solutions of these problems give the best first rank-1 approximation of Eq. (21.27).

In order to estimate the next singular values and the corresponding singular vectors, we may apply a deflation approach, that is,

$$\mathbf{Y}_j = \mathbf{Y}_{j-1} - \sigma_j \mathbf{u}_j \mathbf{v}_j^T \quad (j = 1, 2, \dots, J), \quad (21.42)$$

where  $\mathbf{Y}_0 = \mathbf{Y}$ . Solving the same optimization problem (21.34) for the residual matrix  $\mathbf{Y}_j$  yields the set of consecutive singular values and corresponding singular vectors. Repeating the reduction of the matrix yields the next set of solution until the deflation matrix  $\mathbf{Y}_{J+1}$  becomes zero. In the general case, we have:

$$\mathbf{Y}\mathbf{v}_j = \sigma_j \mathbf{u}_j, \quad \mathbf{Y}^T \mathbf{u}_j = \sigma_j \mathbf{v}_j \quad (j = 1, 2, \dots, J). \quad (21.43)$$

Using the property of orthogonality of the eigenvectors and the equality  $\mathbf{u}^T \mathbf{Y} \mathbf{v} = \mathbf{v}^T \mathbf{Y}^T \mathbf{u} = \sigma$ , we can estimate the precision of the matrix approximation with the first  $P \leq J$  pairs of singular vectors [49]:

$$\begin{aligned} \|\mathbf{Y} - \sum_{j=1}^P \sigma_j \mathbf{u}_j \mathbf{v}_j^T\|_F^2 &= \sum_{t=1}^T \sum_{i=1}^I (y_{ti} - \sum_{j=1}^J \sigma_j u_{tj} v_{ij})^2 \\ &= \|\mathbf{Y}\|_F^2 - \sum_{j=1}^P \sigma_j^2, \end{aligned} \quad (21.44)$$

and the residual error reduces exactly to zero when the number of singular values is equal to the matrix rank, that is, for  $P = J$ . Thus, we can write for the rank- $J$  matrix:

$$\|\mathbf{Y}\|_F^2 = \sum_{j=1}^J \sigma_j^2. \quad (21.45)$$

Note that the SVD can be formulated as the following constrained optimization problem:

$$\min_{\mathbf{U}, \mathbf{V}, \Sigma} \{\|\mathbf{Y} - \mathbf{U}\Sigma\mathbf{V}^T\|_F^2\}, \quad \text{s.t. } \mathbf{U}^T \mathbf{U} = \mathbf{I}, \quad \mathbf{V}^T \mathbf{V} = \mathbf{I}, \quad \text{diag}(\Sigma) \geq 0. \quad (21.46)$$

The cost function can be expressed as follows:

$$\begin{aligned} \|\mathbf{Y} - \mathbf{U}\Sigma\mathbf{V}^T\|_F^2 &= \text{tr}(\mathbf{Y} - \mathbf{U}\Sigma\mathbf{V}^T)^T \text{tr}(\mathbf{Y} - \mathbf{U}\Sigma\mathbf{V}^T) \\ &= \|\mathbf{Y}\|_F^2 - 2 \sum_{j=1}^J \sigma_j \mathbf{u}_j^T \mathbf{Y} \mathbf{v}_j + \sum_{j=1}^J \sigma_j^2. \end{aligned} \quad (21.47)$$

Hence, for  $J = 1$  (with  $\mathbf{u}_1 = \mathbf{u}$  and  $\mathbf{v}_1 = \mathbf{v}$ ) the problem (21.46) (called the best rank-1 approximation):

$$\min_{\mathbf{u}, \mathbf{v}} \{\|\mathbf{Y} - \sigma \mathbf{u} \mathbf{v}^T\|_F^2\}, \quad \|\mathbf{u}\|_2 = \|\mathbf{v}\|_2 = 1, \quad \sigma > 0, \quad (21.48)$$

can be reformulated as an equivalent maximization problem (called the maximization variance approach):

$$\max_{\mathbf{u}, \mathbf{v}} \{\mathbf{u}^T \mathbf{Y} \mathbf{v}\}, \quad \text{s.t. } \|\mathbf{u}\|_2 = \|\mathbf{v}\|_2 = 1, \quad (21.49)$$

with a maximal singular value  $\sigma = \mathbf{u}^T \mathbf{Y} \mathbf{v}$ .

### 1.21.2.5 Very large-scale PCA/SVD

Suppose that  $\mathbf{Y} = \mathbf{U}\Sigma\mathbf{V}^T$  is the SVD decomposition of an  $T \times I$ -dimensional matrix, where  $T$  is very large and  $I$  is moderate. Then matrices  $\Sigma$  and  $\mathbf{V}$  can be obtained from EDV/PCA decomposition of the  $I \times I$ -dimensional matrix  $\mathbf{Y}^T\mathbf{Y} = \mathbf{V}\Sigma^2\mathbf{V}^T$ . The orthogonal matrix  $\mathbf{U}$  can be then obtained from  $\mathbf{U} = \mathbf{Y}\mathbf{V}\Sigma^{-1}$ .

**Remark.** It should be noted that for moderate large-scale problems with  $I \gg T$  and typically  $I < 10^4$  we can more efficiently solve the SVD problem by noting that the PCA/SVD of a semi-positive definite matrix (of much smaller dimension)

$$\mathbf{R}_{\mathbf{YY}'} = \mathbf{YY}^T = \mathbf{U}\Lambda\mathbf{U}^T \in \mathbb{R}^{T \times T}, \quad (21.50)$$

with  $\mathbf{U} \in \mathbb{R}^{T \times J}$ , has the same eigenvalues as the matrix  $\mathbf{R}_{\mathbf{YY}'} = \mathbf{Y}^T\mathbf{Y}$ , since we can write  $\mathbf{R}_{\mathbf{YY}'} = \mathbf{YY}^T = \mathbf{U}\Sigma\mathbf{V}^T\mathbf{V}\Sigma\mathbf{U}^T = \mathbf{U}\Sigma^2\mathbf{U}^T$  and  $\mathbf{R}_{\mathbf{YY}'} = \mathbf{Y}^T\mathbf{Y} = \mathbf{V}\Sigma\mathbf{U}^T\mathbf{U}\Sigma\mathbf{V}^T = \mathbf{V}\Sigma^2\mathbf{V}^T$  and  $\Sigma = \text{diag}\{\sigma_1, \dots, \sigma_J\}$ .

Moreover, if the vector  $\mathbf{v}$  is an eigenvector of the matrix  $\mathbf{R}_{\mathbf{YY}'} = \mathbf{Y}^T\mathbf{Y}$ , then  $\mathbf{Y}\mathbf{v}$  is an eigenvector of  $\mathbf{R}_{\mathbf{YY}'}$ , since we can write

$$\mathbf{Y}^T\mathbf{Y}\mathbf{v} = \lambda\mathbf{v}, \quad (\mathbf{YY}^T)(\mathbf{Y}\mathbf{v}) = \lambda(\mathbf{Y}\mathbf{v}). \quad (21.51)$$

In many practical applications dimension  $I \gg T$  could be so large that the data matrix  $\mathbf{Y} \in \mathbb{R}^{T \times I}$  can not be loaded into the memory of moderate class of computers. The simple solution is to partition of data matrix  $\mathbf{Y}$  into, say,  $Q$  slices as  $\mathbf{Y} = [\mathbf{Y}_1, \mathbf{Y}_2, \dots, \mathbf{Y}_Q]$ , where the size of the  $q$ th slice  $\mathbf{Y}_q \in \mathbb{R}^{T \times (I/Q)}$  and can be optimized depending on the available computer memory [50, 51]. The scaled covariance matrix (cross matrix product) can be then calculated as

$$\mathbf{YY}^T = \frac{1}{Q} \sum_{q=1}^Q \mathbf{Y}_q \mathbf{Y}_q^T = \mathbf{U}\Sigma^2\mathbf{U}^T \in \mathbb{R}^{T \times T}, \quad (21.52)$$

since  $\mathbf{Y}_q = \mathbf{U}\Sigma\mathbf{V}_q^T$ , where  $\mathbf{V}_q \in \mathbb{R}^{(I/Q) \times J}$  are orthogonal matrices. Instead of computing the whole right singular matrix  $\mathbf{V} = \mathbf{Y}^T\mathbf{U}\Sigma^{-1} \in \mathbb{R}^{I \times J}$ , we can perform calculations on the slices of the partitioned data matrix  $\mathbf{Y}$  as  $\mathbf{V}_q^T = \Sigma^{-1}\mathbf{U}^T\mathbf{Y}_q$  for  $q = 1, 2, \dots, Q$ . The concatenated slices  $[\mathbf{V}_1^T, \mathbf{V}_2^T, \dots, \mathbf{V}_Q^T]^T$  form the matrix of the right singular vectors  $\mathbf{V}^T$ . Such approach do not require loading the entire data matrix  $\mathbf{Y}$  at once in the computer memory but instead use a sequential access to dataset. Of course, this method will work only if the dimension  $T$  is moderate, typically less than 10,000 and the dimension  $I$  can be theoretically arbitrary large.

### 1.21.2.6 Basic algorithms for PCA/SVD

There are three basic or fundamental methods to compute PCA/SVD:

- The minimal reconstruction error approach:

$$\mathbf{v}^* = \underset{\mathbf{v}^T\mathbf{v}=1}{\operatorname{argmin}} \left\{ \sum_{t=1}^T [y(t) - (\mathbf{v}^T \mathbf{y}(t))\mathbf{v}]^2 \right\}. \quad (21.53)$$

- The best rank-1 approximation approach:

$$(\mathbf{u}^*, \mathbf{v}^*, \sigma^*) = \underset{\mathbf{u}, \mathbf{v}, \sigma}{\operatorname{argmin}} \left\{ \|\mathbf{Y} - \sigma \mathbf{u} \mathbf{v}^T\|_F^2 \right\} \quad \text{s.t. } \|\mathbf{u}\|_2 = \|\mathbf{v}\|_2 = 1, \quad \sigma > 0. \quad (21.54)$$

- The maximal variance approach:

$$\mathbf{v}^* = \underset{\mathbf{v}}{\operatorname{argmax}} \{ \mathbf{v}^T \mathbf{Y}^T \mathbf{Y} \mathbf{v} \} \quad \text{s.t. } \|\mathbf{v}\|_2 = 1. \quad (21.55)$$

or in the more general form (for  $j = 1, 2, \dots, J$ ):

$$\begin{aligned} (\mathbf{u}_j^*, \mathbf{v}_j^*) &= \underset{\mathbf{u}_j, \mathbf{v}_j}{\operatorname{argmax}} \{ \mathbf{u}_j^T \mathbf{Y} \mathbf{v}_j \}, \\ \text{s.t. } \|\mathbf{u}_j\|_2 &= \|\mathbf{v}_j\|_2 = 1 \quad \mathbf{u}_j^T \mathbf{u}_i = 0, \quad \mathbf{v}_j^T \mathbf{v}_i = 0, \quad \forall i < j. \end{aligned} \quad (21.56)$$

All the above approaches are connected or linked and almost equivalent. Often we impose additional constraints such as sparseness and/or nonnegativity (see Section 1.21.2.6.3).

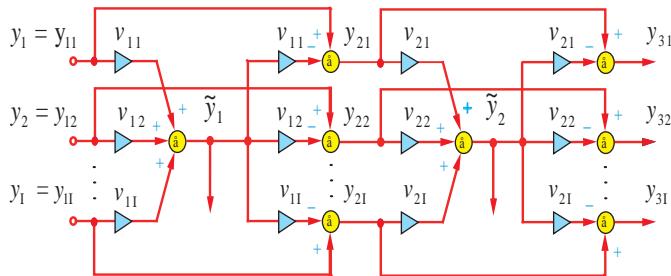

### 1.21.2.6.1 Simple iterative algorithm using minimal reconstruction error approach

One of the simplest and intuitively understandable approaches to the derivation of adaptive algorithms for the extraction of true principal components without need to compute explicitly the covariance matrix is based on self-association (also called self-supervising or the replicator principle) [30, 52]. According to this approach, we first compress the data vector  $\mathbf{y}(t)$  to one variable  $\tilde{y}_1(t) = \mathbf{v}_1^T \mathbf{y}(t)$  and next we attempt to reconstruct the original data from  $\tilde{y}_1(t)$  by using the transformation  $\hat{\mathbf{y}}(t) = \mathbf{v}_1 \tilde{y}_1(t)$ . Let us assume, that we wish to extract principal components (PCs) sequentially by employing the self-supervising principle (replicator) and a deflation procedure [30].

Let us consider a simple processing unit (see Figure 21.3)

$$\tilde{y}_1(t) = \mathbf{v}_1^T \mathbf{y}(t) = \sum_{i=1}^I v_{1i} y_i(t), \quad (21.57)$$

which extracts the first principal component, with  $\lambda_1 = E\{y_1^2(t)\}$ . Strictly speaking, the factor  $\tilde{y}_1(t)$  is called the first principal component of  $\mathbf{y}(t)$ , if the variance of  $\tilde{y}_1(t)$  is maximally large under the constraint that the principal vector  $\mathbf{v}_1$  has unit length.

**FIGURE 21.3**

The sequential extraction of principal components and the deflation procedure.

The vector  $\mathbf{v}_1 = [v_{11}, v_{12}, \dots, v_{1I}]^T$  should be determined in such a way that the reconstruction vector  $\hat{\mathbf{y}}(t) = \mathbf{v}_1 \tilde{\mathbf{y}}_1(t)$  will reproduce (reconstruct) the training vectors  $\mathbf{y}(t)$  as correctly as possible, according to the following cost function  $J(\mathbf{v}_1) = E\{\|\mathbf{e}_1(t)\|_2^2\} \approx \sum_{t=1}^T \|\mathbf{e}_1(t)\|_2^2$ , where  $\mathbf{e}_1(t) = \mathbf{y}(t) - \mathbf{v}_1 \tilde{\mathbf{y}}_1(t)$ .

In general, the loss (cost) function is expressed as

$$D_i(\mathbf{v}_i) = \sum_{t=1}^T \|\mathbf{e}_i(t)\|_2^2, \quad (21.58)$$

where

$$\mathbf{e}_j = \mathbf{y}_{j+1} = \mathbf{y}_j - \mathbf{v}_j \tilde{\mathbf{y}}_j, \quad \tilde{\mathbf{y}}_j = \mathbf{v}_j^T \mathbf{y}_j, \quad \mathbf{y}_1(t) = \mathbf{y}(t).$$

In order to increase the convergence speed, we can minimize the cost function (21.58) by employing the cascade recursive least-squares (CRLS) approach for optimal updating of the learning rate  $\eta_i$  [52,53]:

$$\mathbf{y}_1(t) = \mathbf{y}(t), \quad (21.59)$$

$$\tilde{\mathbf{y}}_j(t) = \mathbf{v}_j^T(t) \mathbf{y}_j(t) \quad (j = 1, 2, \dots, J), \quad (21.60)$$

$$\mathbf{v}_j(t+1) = \mathbf{v}_j(t) + \frac{\tilde{\mathbf{y}}_j(t)}{\eta_j(t)} [\mathbf{y}_j(t) - \tilde{\mathbf{y}}_j(t) \mathbf{v}_j(t)], \quad (21.61)$$

$$\eta_j(t+1) = \eta_j(t) + |\tilde{\mathbf{y}}_j(t)|^2, \quad \eta_j(0) = \frac{1}{T} \sum_{i=1}^I \sum_{t=1}^T y_{ji}^2(t), \quad (21.62)$$

$$\mathbf{y}_{j+1}(t) = \mathbf{y}_j(t) - \tilde{\mathbf{y}}_j(t) \mathbf{v}_{j*}, \quad (21.63)$$

$$\mathbf{v}_{j+1}(0) = \mathbf{v}_j - [\mathbf{v}_{1*}, \dots, \mathbf{v}_{j*}] [\mathbf{v}_1, \dots, \mathbf{v}_{j*}]^T \mathbf{v}_j, \quad (21.64)$$

where  $\mathbf{v}_{i*}$  denotes the vector  $\mathbf{v}_j(t)$  after achieving convergence. The above algorithm is fast and accurate for extracting sequentially an arbitrary number of eigenvectors in PCA.

### 1.21.2.6.2 Power methods for standard PCA

Many iterative algorithms for PCA exploit the Rayleigh quotient (RQ) of the specific covariance matrix as the cost function and power methods [54, 55]. The Rayleigh quotient  $R(\mathbf{v})$  is defined for  $\mathbf{v} \neq \mathbf{0}$ , as

$$R(\mathbf{v}) = R(\mathbf{v}, \mathbf{R}_{yy}) = \frac{\mathbf{v}^T \mathbf{R}_{yy} \mathbf{v}}{\mathbf{v}^T \mathbf{v}}, \quad (21.65)$$

It is worth to note that

$$\lambda_{\max} = \max R(\mathbf{v}, \mathbf{R}_{yy}), \quad \lambda_{\min} = \min R(\mathbf{v}, \mathbf{R}_{yy}), \quad (21.66)$$

where  $\lambda_{\max}$  and  $\lambda_{\min}$  denote the largest and the smallest eigenvalues of the covariance matrix  $\mathbf{R}_{yy}$ , respectively.

More generally, the critical points and critical values of  $R(\mathbf{v}, \mathbf{R}_{yy})$  are the eigenvectors and eigenvalues of  $\mathbf{R}_{yy}$ . Assuming that the eigenvalues of the covariance matrix can be ordered as  $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_J$ , and that the principal eigenvector  $\mathbf{v}_1$  has unit length, i.e.,  $\mathbf{v}_1^T \mathbf{v}_1 = 1$ , we can estimate it using the following iterations

$$\mathbf{v}_1(k+1) = \frac{\mathbf{R}_{yy} \mathbf{v}_1(k)}{\mathbf{v}_1^T(k) \mathbf{R}_{yy} \mathbf{v}_1(k)}. \quad (21.67)$$

Taking into account that  $\tilde{\mathbf{y}}_1^{(k)}(t) = \mathbf{v}_1^T(k) \mathbf{y}(t)$  and  $\widehat{\mathbf{R}}_{yy} = \langle \mathbf{y}(t) \mathbf{y}^T(t) \rangle$ , we can then use the following simplified formula

$$\mathbf{v}_1(k+1) = \frac{\sum_{t=1}^T \tilde{\mathbf{y}}_1^{(k)}(t) \mathbf{y}(t)}{\sum_{t=1}^T [\tilde{\mathbf{y}}_1^{(k)}(t)]^2} \quad (21.68)$$

or more generally, for a number of higher PCs, we may use the deflation approach as

$$\mathbf{v}_j(k+1) = \frac{\sum_{t=1}^T \tilde{\mathbf{y}}_j^{(k)}(t) \mathbf{y}_j(t)}{\sum_{t=1}^T [\tilde{\mathbf{y}}_j^{(k)}(t)]^2} \quad (j = 1, 2, \dots, J), \quad (21.69)$$

where  $\tilde{\mathbf{y}}_j^{(t)}(t) = \mathbf{v}_j^T(k) \mathbf{y}_j(t)$ . After the convergence of the vector  $\mathbf{v}_j(k)$  to  $\mathbf{v}_{j*}$ , we perform the deflation as:  $\mathbf{y}_{j+1} = \mathbf{y}_j - \mathbf{v}_{j*} \tilde{\mathbf{y}}_j$ ,  $\mathbf{y}_1 = \mathbf{y}$ .

The above fast PCA algorithm can be derived also in a slightly modified form by minimizing the cost function:

$$\begin{aligned} D(\mathbf{v}, \mathbf{y}^{(k)}) &= \sum_{t=1}^T \|\mathbf{y}(t) - \tilde{\mathbf{y}}^{(k)} \mathbf{v}\|_2^2 \\ &= \sum_{t=1}^T \|\mathbf{y}(t)\|_2^2 + \|\mathbf{v}\|_2^2 \sum_{t=1}^T [\tilde{\mathbf{y}}^{(k)}(t)]^2 - 2\mathbf{v}^T \sum_{t=1}^T \tilde{\mathbf{y}}^{(k)}(t) \mathbf{y}(t), \end{aligned} \quad (21.70)$$

subject to the constraint  $\|\mathbf{v}\|_2 = 1$ . The cost function achieves equilibrium when the gradient of  $D$  is zero, i.e.,

$$\mathbf{v}_* = \frac{\sum_{t=1}^T \tilde{\mathbf{y}}_*(t) \mathbf{y}(t)}{\sum_{t=1}^T \tilde{\mathbf{y}}_*^2(t)}. \quad (21.71)$$

This suggests the following iteration formula [55,56]:

$$\mathbf{v}(k+1) = \frac{\sum_{t=1}^T \tilde{y}^{(k)}(t) \mathbf{y}(t)}{\|\sum_{t=1}^T \tilde{y}^{(k)}(t) \mathbf{y}(t)\|_2}. \quad (21.72)$$

**Remark.** It should be noted that the convergence rate of the power algorithm depends on a ratio  $\lambda_2/\lambda_1$ , where  $\lambda_2$  is the second largest eigenvalue of  $\mathbf{R}_{yy}$ . This ratio is generally smaller than one, allowing adequate convergence of the algorithm. However, if the eigenvalue  $\lambda_1 = \lambda_{\max}$  has one or more other eigenvalues of  $\mathbf{R}_{yy}$  close by, in other words, when  $\lambda_1$  belongs to a cluster of eigenvalues then the ratio can be very close to one, causing very slow convergence, and as a consequence, the estimated eigenvector  $\mathbf{v}$  may be inaccurate for noisy data or collinear components. For multiple eigenvalues, the power method will fail to converge.

### 1.21.2.6.3 Extensions of standard PCA

#### 1.21.2.6.3.1 Sparse PCA

The importance of the standard PCA is mainly due to the following three important properties:

1. The principal components sequentially capture the maximum variability (variance) of the data matrix  $\mathbf{Y}$ , thus guaranteeing minimal information loss in the sense of mean squared errors.
2. The principal components are uncorrelated, i.e.,  $E\{\tilde{y}_i \tilde{y}_j\} = \delta_{ij} \lambda_j$ .
3. The PCs are hierarchically organized with the respect to decreasing values of their variances (eigenvalues of the covariance matrix).

The standard PCA/SVD has also several disadvantages, especially for large-scale and noisy problems. A particular disadvantage that the standard principal components  $\tilde{y}_j(t) = \mathbf{v}_j^T \mathbf{y}(t) = \sum_{i=1}^I v_{ij} y_i(t)$  are usually a linear combination of all the variables  $y_j(t)$ . In other words, all weights  $v_{ij}$  (referred as loadings) are not zero. This means that the principal vectors  $\mathbf{v}_j$  are dense (not sparse) what makes often the physical interpretation of the principal components difficult in many applications. For example, in many applications (from biology to image understanding) the coordinate axes have a physical interpretations (each axis might correspond to a specific feature), but only if the components are sparsely represented, i.e., by a very few non zero loadings (coordinates). Recently several modifications of PCA have been proposed which impose some sparseness for the principal (basis) vectors and corresponding components are called sparse principal components [54,57–62]. The main idea in SPCA is to force the basis vectors to be sparse, however the sparsity profile should be adjustable or well controlled via some parameters in order to discover specific features in the observed data. In other words, our objective is to estimate sparse principal components, i.e., the sets of sparse vectors  $\mathbf{v}_j$  spanning a low-dimensional space that represent most of the variance present in the data  $\mathbf{Y}$ .

Many methods have been proposed for estimating sparse principal components, based on either the maximum-variance property of the principal components, or on the regression/reconstruction error property. The most important approaches which extract the principal eigenvectors sequentially can be summarized as the following constrained or penalized optimization problems [54,57,59–63]:

1.  $l_1$ -norm constrained SPCA or the SCoTLASS procedure [59] uses the maximal variance characterization for the principal components. The first sparse principal component solves the optimization problem:

$$\max_{\mathbf{v}} \{\mathbf{v}^T \mathbf{Y}^T \mathbf{Y} \mathbf{v}\} \quad \text{s.t. } \|\mathbf{v}\|_2^2 \leq 1, \quad \|\mathbf{v}\|_1 \leq c_1 \quad (21.73)$$

and subsequent components solve the same problem but with the additional constraint that they must be orthogonal to the previous components. When the parameter  $c_1$  is sufficiently large, then the optimization problem (21.73) simply yields the first standard principal component of  $\mathbf{Y}$ , and when  $c_1$  is small, then the solution is sparse.

2.  $l_1$ -norm penalized SPCA [64]

$$\max_{\mathbf{v}} \{\mathbf{v}^T \mathbf{Y}^T \mathbf{Y} \mathbf{v} - \alpha \|\mathbf{v}\|_1\} \quad \text{s.t. } \|\mathbf{v}\|_2^2 \leq 1, \quad (21.74)$$

where the penalty parameter  $\alpha \geq 0$  controls the level of sparseness.

3.  $l_0$ -norm penalized SPCA [57]

$$\max_{\mathbf{v}} \{\mathbf{v}^T \mathbf{Y}^T \mathbf{Y} \mathbf{v} - \alpha \|\mathbf{v}\|_0\} \quad \text{s.t. } \|\mathbf{v}\|_2^2 \leq 1, \quad (21.75)$$

4. SPCA using Penalized Matrix decomposition (PMD) [61, 64]

$$\max_{\mathbf{u}, \mathbf{v}} \{\mathbf{u}^T \mathbf{Y} \mathbf{v}\}, \quad \text{s.t. } \|\mathbf{u}\|_2^2 \leq 1, \quad \|\mathbf{v}\|_2^2 \leq 1, \quad P_1(\mathbf{u}) \leq c_1, \quad P_2(\mathbf{v}) \leq c_2, \quad (21.76)$$

where positive parameters  $c_1, c_2$  control sparsity level and the convex penalty functions  $P_1(\mathbf{u})$  and  $P_2(\mathbf{v})$  can take a variety of different forms. Useful examples are:

$$\begin{aligned} P(\mathbf{v}) &= \|\mathbf{v}\|_1 = \sum_{i=1}^I |v_i| \quad \text{LASSO,} \\ P(\mathbf{v}) &= \|\mathbf{v}\|_0 = \sum_{i=1}^I |\text{sign}(v_i)| \quad \text{CARDINALITY PENALTY,} \\ P(\mathbf{v}) &= \sum_{i=1}^I |v_i| + \lambda \sum_{i=2}^I |v_i - v_{i-1}| \quad \text{FUSED LASSO.} \end{aligned}$$

5. SPCA via regularized SVD (sPCA-rSVD) [54, 65]

$$\max_{\mathbf{u}, \mathbf{v}} \{\mathbf{u}^T \mathbf{Y} \mathbf{v} - \alpha P(\mathbf{v})\} \quad \text{s.t. } \|\mathbf{u}\|_2^2 \leq 1, \quad \|\mathbf{v}\|_2^2 \leq 1, \quad (21.77)$$

6. Two-way functional PCA/SVD [66]

$$\max_{\mathbf{u}, \mathbf{v}} \{\mathbf{u}^T \mathbf{Y} \mathbf{v} - \frac{\alpha}{2} P_1(\mathbf{u}) P_2(\mathbf{v})\}, \quad \text{s.t. } \|\mathbf{u}\|_2^2 \leq 1, \quad \|\mathbf{v}\|_2^2 \leq 1. \quad (21.78)$$

## 7. Sparse SVD [67]

$$\max_{\mathbf{u}, \mathbf{v}} \left\{ \mathbf{u}^T \mathbf{Y} \mathbf{v} - \frac{1}{2} \mathbf{u}^T \mathbf{u} \mathbf{v}^T \mathbf{v} - \frac{\alpha_1}{2} P_1(\mathbf{u}) - \frac{\alpha_2}{2} P_2(\mathbf{v}) \right\}. \quad (21.79)$$

## 8. Generalized SPCA [68]

$$\max_{\mathbf{u}, \mathbf{v}} \left\{ \mathbf{u}^T \mathbf{Q} \mathbf{Y} \mathbf{R} \mathbf{v} - \frac{\alpha_1}{2} P_1(\mathbf{u}) - \frac{\alpha_2}{2} P_2(\mathbf{v}) \right\}, \quad \text{s.t. } \mathbf{u}^T \mathbf{Q} \mathbf{u} \leq 1, \mathbf{v}^T \mathbf{R} \mathbf{v} \leq 1, \quad (21.80)$$

where  $\mathbf{Q} \in \mathbb{R}^{T \times T}$  and  $\mathbf{R} \in \mathbb{R}^{I \times I}$  are symmetric positive definite matrices.

## 9. Generalized nonnegative SPCA [63]

$$\max_{\mathbf{u}, \mathbf{v}} \{ \mathbf{u}^T \mathbf{Y} \mathbf{R} \mathbf{v} - \alpha \|\mathbf{v}\|_1 \}, \quad \text{s.t. } \mathbf{u}^T \mathbf{u} \leq 1, \mathbf{v}^T \mathbf{R} \mathbf{v} \leq 1, \mathbf{v} \geq 0. \quad (21.81)$$

## 10. Robust SPCA [69]

$$\max_{\mathbf{v}} \{ Var(\mathbf{v}^T \mathbf{y}(1), \mathbf{v}^T \mathbf{y}(2), \dots, \mathbf{v}^T \mathbf{y}(T)) - \alpha \|\mathbf{v}\|_1 \}, \quad \text{s.t. } \mathbf{v}^T \mathbf{v} = 1, \quad (21.82)$$

where  $\mathbf{y}(t) \in \mathbb{R}^I$  ( $t = 1, 2, \dots, T$ ) are multivariate observations collected in the rows of the data matrix  $\mathbf{Y} \in \mathbb{R}^{T \times I}$  and  $Var$  is a robust variance measure.

There exist some connections between the above listed optimizations problems, and in fact they often deliver almost identical or at least similar solutions. All the optimization problems addressed here are rather difficult, generally non-convex maximization problems, and we can not make a claim with respect their global optimality. Even if the goal of obtaining a local minimizer is, in general, unattainable we must be content with convergence to a stationary point. However, using so formulated optimization problems, the common and interesting feature of the resulting algorithms is, that they provide a closed-form iterative updates (which is a generalized power method):

$$\mathbf{v} = \frac{\mathcal{S}(\mathbf{Y}^T \mathbf{Y} \mathbf{v})}{\|\mathcal{S}(\mathbf{Y}^T \mathbf{Y} \mathbf{v})\|_2}, \quad (21.83)$$

or

$$\mathbf{u} = \frac{\mathcal{S}(\mathbf{Y} \mathbf{v})}{\|\mathcal{S}(\mathbf{Y} \mathbf{v})\|_2}, \quad \mathbf{v} = \frac{\mathcal{S}(\mathbf{Y}^T \mathbf{u})}{\|\mathcal{S}(\mathbf{Y}^T \mathbf{u})\|_2}, \quad (21.84)$$

where  $\mathcal{S}$  is a simple operator (shrinkage) which can be written in explicit form and can be efficiently computed [54, 60].

For example, by applying the optimization problem (21.77) we obtain the sparse SVD algorithm. Sparse SVD can be performed by solving the following optimization problem:

$$\max_{\mathbf{u}, \mathbf{v}} \{ \mathbf{u}^T \mathbf{Y} \mathbf{v} - \alpha_1 \|\mathbf{u}\|_1 - \alpha_2 \|\mathbf{v}\|_1 \} \quad (21.85)$$

$$\text{s.t. } \mathbf{u}^T \mathbf{u} \leq 1, \mathbf{v}^T \mathbf{v} \leq 1, \quad (21.86)$$

which leads to the following update formulas:

$$\mathbf{u} = \frac{\mathcal{S}_1(\mathbf{Y}\mathbf{v}, \alpha_1)}{\|\mathcal{S}_1(\mathbf{Y}\mathbf{v}, \alpha_1)\|_2}, \quad \mathbf{v} = \frac{\mathcal{S}_1(\mathbf{Y}^T\mathbf{u}, \alpha_2)}{\|\mathcal{S}_1(\mathbf{Y}^T\mathbf{u}, \alpha_2)\|_2}, \quad (21.87)$$

where the non-negative parameters  $\alpha_1\alpha_2$  control sparsity level and the operator  $\mathcal{S}_1$  means the shrinkage function defined as

$$\mathcal{S}_1(\mathbf{Y}\mathbf{v}, \alpha) = \text{sign}(\mathbf{Y}\mathbf{v})[|\mathbf{Y}\mathbf{v}| - \alpha]_+. \quad (21.88)$$

In fact, when  $\mathcal{S}$  is the identity operator, the above update schemes are nothing else but power method for the standard PCA/SVD (see Algorithm 1).

---

**Algorithm 1.** Power Method for Sparse PCA/SVD

---

**Require:** Data matrix  $\mathbf{Y}^{(1)} = \mathbf{Y}$ ,

sparsity coefficients  $\alpha_n \geq 0$ , ( $n = 1, 2$ ), initial vectors  $\mathbf{u}$  and  $\mathbf{v}$

1: For  $j = 1, 2, \dots, J$ :

    Repeat until convergence of  $\mathbf{u}_j$  and  $\mathbf{v}_j$ ;

$$2: \quad \mathbf{u}_j = \frac{\mathcal{S}_1(\mathbf{Y}^{(j)}\mathbf{v}_j, \alpha_1)}{\|\mathcal{S}_1(\mathbf{Y}^{(j)}\mathbf{v}_j, \alpha_1)\|_2};$$

$$3: \quad \mathbf{v}_j = \frac{\mathcal{S}_1(\mathbf{Y}^{(j)T}\mathbf{u}_j, \alpha_2)}{\|\mathcal{S}_1(\mathbf{Y}^{(j)T}\mathbf{u}_j, \alpha_2)\|_2};$$

$$4: \quad \sigma_j = \mathbf{u}_j^T \mathbf{Y}^{(j)} \mathbf{v}_j;$$

$$5: \quad \mathbf{Y}^{(j+1)} = \mathbf{Y}^{(j)} - \sigma_j \mathbf{u}_j \mathbf{v}_j^T;$$

6: **return**  $\mathbf{U}^* = [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_J]$ ,  $\mathbf{V}^* = [\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_J]$ ,  $\Sigma^* = \text{diag}\{\sigma_1, \dots, \sigma_J\}$ .

---

In contrast to standard PCA, SPCA enables to reveal often multi-scale hierarchical structures from the data [62]. For example, for EEG data the SPCA generates spatially localized, narrow bandpass functions as basis vectors, thereby achieving a joint space and frequency representation, what is impossible to obtain by using standard PCA. The algorithm for sparse PCA/SVD can be easily extended to sparse CCA/PLS (see Section 1.21.2.6.6).

#### 1.21.2.6.4 Deflation techniques for SPCA

In sparse PCA the eigenvectors are not necessary mutually orthogonal. In fact, we usually alleviate or even completely ignore the orthogonality constraints. Due to this reason the standard Hotelling deflation procedure:

$$\mathbf{R}_{yy}^{(j+1)} \leftarrow \mathbf{R}_{yy}^{(j)} - \lambda_j \mathbf{v}_j \mathbf{v}_j^T \quad (j = 1, 2, \dots, J), \quad (21.89)$$

does not guarantee the positive semi-definiteness of the covariance matrix.

Due to this reason we usually use the Schur compliment deflation [70]:

$$\mathbf{R}_{yy}^{(j+1)} \leftarrow \mathbf{R}_{yy}^{(j)} - \mathbf{R}_{yy}^{(j)} \mathbf{v}_j \mathbf{v}_j^T \mathbf{R}_{yy}^{(j)} / \lambda_j \quad (21.90)$$

or alternatively the projection deflation

$$\mathbf{R}_{yy}^{(j+1)} \leftarrow (\mathbf{I} - \mathbf{v}_j \mathbf{v}_j^T) \mathbf{R}_{yy}^{(j)} (\mathbf{I} - \mathbf{v}_j \mathbf{v}_j^T). \quad (21.91)$$

Empirical studies by Mackey [70] indicate that the Schur deflation and the projection deflation outperform the standard Hotelling's deflation consistently for SPCA, and usually the projection deflation is even better than (or at least comparable with) the Schur deflation.

---

**Algorithm 2.** Deflation Algorithm for Sparse PCA [70]

---

**Require:** Covariance matrix  $\mathbf{R}_{yy}^{(0)} = \mathbf{R}_{yy}$  and  $J$ ,  
 1: (1)  $\mathbf{Q}_0 \leftarrow \mathbf{I}$ ,  
 2: For  $j = 1, 2, \dots, J$ :  
 3:    $\mathbf{v}_j = \operatorname{argmax}\{\mathbf{v}^T \mathbf{R}^{(j-1)} \mathbf{v}\} \quad \text{s.t. } \|\mathbf{v}\|_1 \leq 1$ ;  
 4:    $\mathbf{q}_j = \mathbf{Q}_{j-1} \mathbf{v}_j$ ;  
 5:    $\mathbf{R}^{(j)} \leftarrow (\mathbf{I} - \mathbf{q}_j \mathbf{q}_j^T) \mathbf{R}_{yy}^{(j-1)} (\mathbf{I} - \mathbf{q}_j \mathbf{q}_j^T)$ ;  
 6:    $\mathbf{Q}^{(j)} = \mathbf{Q}^{(j-1)} (\mathbf{I} - \mathbf{q}_j \mathbf{q}_j^T)$ ;  
 7:    $\mathbf{v}^{(j)} = \mathbf{v}^{(j)}/\|\mathbf{v}^{(j)}\|_2$ ;  
 8: **return**  $\mathbf{V}^* = [\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_J]$ .

---

### 1.21.2.6.5 Kernel PCA

Standard PCA applies linear transformation for dimensionality reduction and may not be effective for nonlinear data. In kernel PCA we apply implicitly nonlinear transformation to potentially very high dimensional feature space  $\mathcal{F}$ .

Let consider a data matrix  $\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N] \in \mathbb{R}^{I \times N}$  with vectors  $\mathbf{x}_n \in \mathbb{R}^I$  (typically, with  $N < I$ ), which are nonlinearly projected feature subspace

$$\phi : \mathbf{x}_n \in \mathbb{R}^I \rightarrow \phi(\mathbf{x}_n) \in \mathcal{F}. \quad (21.92)$$

The covariance matrix in the feature space can be expressed as

$$\hat{\mathbf{C}} = \frac{1}{N} \Phi(\mathbf{X}) \Phi^T(\mathbf{X}) = \frac{1}{N} \sum_{n=1}^N \phi(\mathbf{x}_n) \phi^T(\mathbf{x}_n), \quad (21.93)$$

where  $\Phi(\mathbf{X}) = [\phi(\mathbf{x}_1), \phi(\mathbf{x}_2), \dots, \phi(\mathbf{x}_N)]$  (we assume without loss of generality that  $\sum_n \phi(\mathbf{x}_n) = \mathbf{0}$ ). However, in practice, we almost never compute the nonlinear mapping  $\phi(\mathbf{x})$  explicitly, since the feature space can be very high dimensional in the kernel method, but rather exploit so called "kernel trick", i.e., employ the nonlinear mapping implicitly [71].

Let  $\mathbf{v}_j$  be eigenvector of the covariance matrix  $\hat{\mathbf{R}}_{\mathbf{xx}} = 1/N \sum_{n=1}^N \mathbf{x}_n \mathbf{x}_n^T$ , then the vector  $\mathbf{v}_j$  belongs to linear space spanned by the data points  $\mathbf{x}_n$  ( $n = 1, 2, \dots, N$ ) since  $\hat{\mathbf{R}}_{\mathbf{xx}} \mathbf{v}_j = \lambda_j \mathbf{v}_j$  implies that  $\mathbf{v}_j = 1/(\lambda_j N) \sum_{n=1}^N \mathbf{x}_n (\mathbf{x}_n^T \mathbf{v}) = \sum_{n=1}^N \alpha_{jn} \mathbf{x}_n$ . So, the standard PCA can be formulated in dual form as  $\mathbf{X}^T \mathbf{X} \boldsymbol{\alpha}_j = N \lambda_j \boldsymbol{\alpha}_j$ , where  $\mathbf{K} = \mathbf{X}^T \mathbf{X} \in \mathbb{R}^{N \times N}$  is referred to as linear kernel matrix with entries  $k_{nm} = \mathbf{x}_n^T \mathbf{x}_m$  expressed by inner products.

Similarly, eigenvector  $\mathbf{v}_j$  of the covariance matrix  $\hat{\mathbf{C}}$  defined by Eq. (21.93) can be written as  $\mathbf{v}_j = \sum_{n=1}^N \alpha_{jn} \phi(\mathbf{x}_n)$ . Taking into account that

$$\hat{\mathbf{C}} \mathbf{v}_j = \lambda_j \mathbf{v}_j \quad (j = 1, 2, \dots, J) \quad (21.94)$$

we can write

$$\left( \sum_{n=1}^N \phi(\mathbf{x}_n) \phi^T(\mathbf{x}_n) \right) \left( \sum_{m=1}^N \alpha_m \phi(\mathbf{x}_m) \right) = \lambda_j \left( \sum_{m=1}^N \alpha_{jm} \phi(\mathbf{x}_m) \right). \quad (21.95)$$

By multiplying the both side of the above equation by  $\phi^T(\mathbf{x}_n)$ , we obtain

$$\sum_{n=1}^N \sum_{m=1}^N \phi^T(\mathbf{x}_n) \phi(\mathbf{x}_n) \phi^T(\mathbf{x}_n) \phi(\mathbf{x}_m) \alpha_{jm} = \lambda_j \sum_{m=1}^N \alpha_{jm} \phi^T(\mathbf{x}_n) \phi(\mathbf{x}_m), \quad (21.96)$$

which can be written in a compact matrix form as  $\mathbf{K}^2 \boldsymbol{\alpha}_j = \lambda_j \mathbf{K} \boldsymbol{\alpha}_j$  or equivalently

$$\mathbf{K} \boldsymbol{\alpha}_j = \lambda_j \boldsymbol{\alpha}_j, \quad (21.97)$$

where  $\mathbf{K}$  is a kernel positive definite symmetric matrix with entries defined as  $k_{nm} = \phi^T(\mathbf{x}_n) \phi(\mathbf{x}_m)$ . We can estimate the kernel PCA features for new sample as

$$y_j(\mathbf{x}) = \phi^T(\mathbf{x}) \mathbf{v}_j = \sum_{n=1}^N \alpha_{jn} k(\mathbf{x}, \mathbf{x}_n) \quad (21.98)$$

Summarizing, the Kernel PCA algorithm can be formulated as follows:

1. Step 1: Select kernel function (e.g., Gaussian kernel:  $k_{nm}(\mathbf{x}_n, \mathbf{x}_m) = \exp(-\|\mathbf{x}_n - \mathbf{x}_m\|^2/2\sigma^2)$  or polynomial kernel:  $k_{nm}(\mathbf{x}_n, \mathbf{x}_m) = (\mathbf{x}_n^T \mathbf{x}_m + c)^d$ ) and compute the kernel matrix with entries  $k_{nm} = \phi^T(\mathbf{x}_n) \phi(\mathbf{x}_m)$  ( $n, m = 1, 2, \dots, N$ ) for training set.
2. Step 2: Compute eigenvalues and eigenvectors pairs of  $\mathbf{K}$  as  $\{\lambda_j, \boldsymbol{\alpha}_j\}$  ( $j = 1, 2, \dots, J$ ).
3. Step 3: Normalize the eigenvectors  $\boldsymbol{\alpha}_j \leftarrow \boldsymbol{\alpha}_j / \lambda_j$ .
4. Step 4: To project a test feature  $\phi(\mathbf{x})$  onto  $\mathbf{v}_j$  we need to compute  $y_j(\mathbf{x}) = \phi^T(\mathbf{x}) \mathbf{v}_j = \phi^T(\mathbf{x}) (\sum_{n=1}^N \alpha_{jn} \phi(\mathbf{x}_n)) = \sum_{n=1}^N \alpha_{jn} k(\mathbf{x}, \mathbf{x}_n)$ . So, explicit nonlinear mapping  $\phi(\cdot)$  is not required here.

### 1.21.2.6.6 Sparse CCA

The Canonical Correlation Analysis (CCA), introduced by Hotelling [72], can be considered as a generalization or extension of PCA (see [73, 74]). The standard CCA is a classical method for determining the relationship between two sets of variables. Given two zero-mean (i.e., centered) data sets  $\mathbf{X} \in \mathbb{R}^{I \times N}$  and  $\mathbf{Y} \in \mathbb{R}^{I \times M}$  on the same set of  $I$  observations, CCA seeks linear combinations of the variables in  $\mathbf{X}$  and the variables in  $\mathbf{Y}$  that are maximally correlated with each other. Formally, the classical CCA computes two projection vectors  $\mathbf{w}_x^{(1)} = \mathbf{w}_x \in \mathbb{R}^N$  and  $\mathbf{w}_y^{(1)} = \mathbf{w}_y \in \mathbb{R}^M$  such that the correlation coefficient

$$\rho = \frac{\mathbf{w}_x^T \mathbf{X}^T \mathbf{Y} \mathbf{w}_y}{\sqrt{(\mathbf{w}_x^T \mathbf{X}^T \mathbf{X} \mathbf{w}_x)(\mathbf{w}_y^T \mathbf{Y}^T \mathbf{Y} \mathbf{w}_y)}} \quad (21.99)$$

is maximized.

In a similar way, we can formulate a kernel CCA by replacing inner product matrices by kernel matrices:

$$\rho = \max_{\alpha_x, \alpha_y} \frac{\alpha_x^T \mathbf{K}_x^T \mathbf{K}_y \alpha_y}{\sqrt{(\alpha_x^T \mathbf{K}_x^T \mathbf{K}_x \alpha_x)(\alpha_y^T \mathbf{K}_y^T \mathbf{K}_y \alpha_y)}}, \quad (21.100)$$

where  $\mathbf{K}_x \in \mathbb{R}^{I \times I}$  and  $\mathbf{K}_y \in \mathbb{R}^{I \times I}$  are suitably designed kernel matrices. The above optimization problem can be solved by generalized eigenvalue decomposition.

Since  $\rho$  is invariant to the scaling of the vectors  $\mathbf{w}_x$  and  $\mathbf{w}_y$ , the standard CCA can be formulated equivalently as the following constrained optimization problem:

$$\max_{\mathbf{w}_x, \mathbf{w}_y} \{(\mathbf{w}_x^T \mathbf{X}^T \mathbf{Y} \mathbf{w}_y)^2\} \quad \text{s.t. } \mathbf{w}_x^T \mathbf{X}^T \mathbf{X} \mathbf{w}_x = \mathbf{w}_y^T \mathbf{Y}^T \mathbf{Y} \mathbf{w}_y = 1. \quad (21.101)$$

We will refer to  $\mathbf{t}_1 = \mathbf{X} \mathbf{w}_x$  and  $\mathbf{u}_1 = \mathbf{Y} \mathbf{w}_y$  as the canonical variables.

For sparse CCA we usually assume that the columns of  $\mathbf{X}$  and  $\mathbf{Y}$  have been standardized to have mean zero and standard deviation one.

In order to obtain sparse CCA we must impose suitable sparsity constraints on the canonical vectors, for example by applying the PMD approach [61, 64]:

$$\max_{\mathbf{w}_x, \mathbf{w}_y} \{(\mathbf{w}_x^T \mathbf{X}^T \mathbf{Y} \mathbf{w}_y)^2\} \quad \text{s.t. } \|\mathbf{w}_x\|_2^2 \leq 1, \|\mathbf{w}_y\|_2^2 \leq 1, P_1(\mathbf{w}_x) \leq c_1, P_2(\mathbf{w}_y) \leq c_2, \quad (21.102)$$

where  $P_1$  and  $P_2$  are convex penalty functions and positive parameters  $c_1, c_2$  control sparsity level (see Section 1.21.2.6.3). Since  $P_1$  and  $P_2$  are generally chosen to yield sparse canonical vectors  $\mathbf{w}_x$  and  $\mathbf{w}_y$ , we call this criterion the sparse CCA.

Note that since the data are standardized, cross product matrices  $\mathbf{X}^T \mathbf{X}$  and  $\mathbf{Y}^T \mathbf{Y}$  are approximated by identity matrices, and consequently the constraints  $\mathbf{w}_x^T \mathbf{X}^T \mathbf{X} \mathbf{w}_x \leq 1$  and  $\mathbf{w}_y^T \mathbf{Y}^T \mathbf{Y} \mathbf{w}_y \leq 1$  may be replaced by  $\|\mathbf{w}_x\|_2^2 \leq 1$  and  $\|\mathbf{w}_y\|_2^2 \leq 1$ , respectively [64].

The algorithms for the sparse CCA will be similar to sparse SVD/PCA (see Algorithm 3) in which the data matrix  $\mathbf{Y}$  in the SPCA should be replaced by  $\mathbf{Z} = \mathbf{X}^T \mathbf{Y}$  in the SCCA and the vectors  $\mathbf{u}$  and  $\mathbf{v}$  by the vectors  $\mathbf{w}_x$  and  $\mathbf{w}_y$ , respectively.

In order to compute multiple canonical vectors for CCA we need to apply a suitable deflation in a similar way as for SPCA. For example, we can compute the vectors  $\mathbf{w}_x^{(j)}$  and  $\mathbf{w}_y^{(j)}$  for  $j = 1, 2, \dots, J$  by applying criterion (21.102) to the data sets:

$$\mathbf{Z}^{(1)} = \mathbf{X}^T \mathbf{Y}, \quad \mathbf{Z}^{(j+1)} = \mathbf{Z}^{(j)} - (\mathbf{w}_x^{(j)T} \mathbf{Z}^{(j)} \mathbf{w}_y^{(j)}) \mathbf{w}_x^{(j)} \mathbf{w}_y^{(j)T}. \quad (21.103)$$

Note that the deflation and generalized power method do not impose automatically orthogonality constraints vectors  $\mathbf{w}_x^{(j)}$  and  $\mathbf{w}_y^{(j)}$ . In order to enforce orthogonality for the subsequently computed on the vectors  $\mathbf{w}_x^{(j+1)}$ , we can apply the Gram-Schmidt orthogonalization method [68]:

$$\mathbf{w}_x^{(j+1)} = \frac{(\mathbf{I} - \mathbf{W}_x^{(j)} \mathbf{W}_x^{(j)T})(\mathbf{X}^T \mathbf{Y} \mathbf{w}_y^{(j)})}{\|(\mathbf{I} - \mathbf{W}_x^{(j)} \mathbf{W}_x^{(j)T})(\mathbf{X}^T \mathbf{Y} \mathbf{w}_y^{(j)})\|_2} \quad (j = 1, 2, \dots), \quad (21.104)$$

where  $\mathbf{W}_x^{(j)} = [\mathbf{w}_x^{(1)}, \mathbf{w}_x^{(2)}, \dots, \mathbf{w}_x^{(j)}] \in \mathbb{R}^{N \times j}$ . Similar formulas can be written for  $\mathbf{w}_y^{(j+1)}$ .

### 1.21.2.6.7 Sparse partial least squares

The Partial Least Squares (PLS) methods, originally developed in chemometrics and econometrics by Herman Wold and his coworkers (see [75] and references therein) are particularly suitable for the analysis of relationships among multi-modal brain data (e.g., EEG, MEG, ECoG (electrocorticogram), fMRI) or relationships between measures of brain activity and behavior data [76,77]. The standard PLS approaches have been recently summarized in [75,78] and their suitability to model relationships between brain activity and behavior (experimental design) has been highlighted in [76].

There are two related basic PLS methods: PLS correlation (PLSC), which analyzes correlations or (associations) between two or more sets of data (e.g., two modalities brain data or brain and behavior data) and PLS regression (PLSR) methods, which attempt to predict one set of data from another independent set of data that constitutes the predictors (e.g., predict experimental behavior data from brain data such as multichannel ECoG or scalp EEG from ECoG by performing simultaneous recordings for epileptic patients).

In order to predict the response variables represented by the matrix  $\mathbf{Y}$  from the independent variables  $\mathbf{X}$ , the standard PLSR techniques find a set of common orthogonal latent variables (also called latent vectors, score vectors or components) by projecting both  $\mathbf{X}$  and  $\mathbf{Y}$  onto a subspace, which ensures a maximal covariance between the latent variables of  $\mathbf{X}$  and  $\mathbf{Y}$ . In other words, the prediction is achieved by simultaneous approximative decompositions training data sets:  $\mathbf{X} \in \mathbb{R}^{I \times N}$  and  $\mathbf{Y} \in \mathbb{R}^{I \times M}$  into factor matrices (components) ( $\mathbf{T} = [\mathbf{t}_1, \mathbf{t}_2, \dots, \mathbf{t}_J] \in \mathbb{R}^{I \times J}$ ,  $\mathbf{P} = [\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_J] \in \mathbb{R}^{N \times J}$  and  $\mathbf{U} = [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_J] \in \mathbb{R}^{I \times J}$ ,  $\mathbf{Q} = [\mathbf{q}_1, \mathbf{q}_2, \dots, \mathbf{q}_J] \in \mathbb{R}^{M \times J}$ ), respectively:

$$\boxed{\mathbf{X} = \mathbf{TP}^T + \mathbf{E} = \sum_{j=1}^J \mathbf{t}_j \mathbf{p}_j^T + \mathbf{E},} \quad (21.105)$$

$$\boxed{\mathbf{Y} = \mathbf{UQ}^T + \mathbf{F} = \sum_{j=1}^J \mathbf{u}_j \mathbf{q}_j^T + \mathbf{F},} \quad (21.106)$$

with the constraint that these components explain as much as possible of the covariance between  $\mathbf{X}$  and  $\mathbf{Y}$  [64,77]. In other words, the key concept of basic PLS algorithms is to maximize covariance between the vectors  $\mathbf{t}_j$  and  $\mathbf{u}_j$  expressed in a general form as:

$$\boxed{\max\{g(\mathbf{t}_j^T \mathbf{u}_j)\} \quad \forall j,} \quad (21.107)$$

subject to suitable constraints, where the function  $g(\cdot)$  may take different forms: the identity, the absolute value or the square function, and we define the vectors as  $\mathbf{t}_j = \mathbf{X}\mathbf{w}_x^{(j)}$  and  $\mathbf{u}_j = \mathbf{Y}\mathbf{w}_y^{(j)}$ .

More generally, the objective of the standard PLS is to find in the first step directions defined by  $\mathbf{W}_x = [\mathbf{w}_x^{(1)}, \mathbf{w}_x^{(2)}, \dots, \mathbf{w}_x^{(J)}] \in \mathbb{R}^{N \times J}$  and  $\mathbf{W}_y = [\mathbf{w}_y^{(1)}, \mathbf{w}_y^{(2)}, \dots, \mathbf{w}_y^{(J)}] \in \mathbb{R}^{M \times J}$  that maximize the set of cost functions (see Figure 21.4):

$$\max_{\mathbf{w}_x^{(j)}, \mathbf{w}_y^{(j)}} \{g(\mathbf{w}_x^{(j)T} \mathbf{X}^T \mathbf{Y} \mathbf{w}_y^{(j)})\} \quad \text{s.t. } \|\mathbf{w}_x^{(j)}\|_2 = 1, \quad \|\mathbf{w}_y^{(j)}\|_2 = 1, \quad (21.108)$$

$$\mathbf{w}_x^{(j)T} \mathbf{X}^T \mathbf{X} \mathbf{w}_x^{(k)} = 0, \quad \mathbf{w}_y^{(j)T} \mathbf{Y}^T \mathbf{Y} \mathbf{w}_y^{(k)} = 0 \quad \forall k < j \quad (j = 1, 2, \dots, J).$$

$$\mathbf{X} = \mathbf{T} \mathbf{P}^T + \mathbf{E} = \sum_{j=1}^J \mathbf{t}_j \mathbf{p}_j^T + \mathbf{E}$$

$$\mathbf{Y} = \mathbf{U} \mathbf{Q}^T + \mathbf{F} = \sum_{j=1}^J \mathbf{u}_j \mathbf{q}_j^T + \mathbf{F}$$

**FIGURE 21.4**

Illustration of a basic PLS model. In this model  $\mathbf{X}$  is a matrix of predictors,  $\mathbf{Y}$  is the response matrix,  $\mathbf{P}$  and  $\mathbf{Q}$  are loading matrices for the predictor and response with corresponding  $\mathbf{T}$  and  $\mathbf{U} \approx \mathbf{T}\mathbf{D}$  component matrices, and matrices  $\mathbf{E}$  and  $\mathbf{F}$  are corresponding error terms. Our objective is to perform approximative decompositions of the matrices  $\mathbf{X}$  and  $\mathbf{Y}$  and by imposing additional orthogonality and optional sparsity constraints.

In other words, the basic approach to the standard PLS is to find these direction vectors  $\mathbf{w}_x^{(j)}$  and  $\mathbf{w}_y^{(j)}$  from successive optimizations problems (see also Eq. (21.102)). The latent components can be defined as  $\mathbf{T} = \mathbf{XW}_x$  and  $\mathbf{U} = \mathbf{YW}_y$ , or equivalently  $\mathbf{t}_j = \mathbf{Xw}_x^{(j)}$  and  $\mathbf{u}_j = \mathbf{Yw}_y^{(j)}$  for  $j = 1, 2, \dots, J$ .

The main difference between PLS and CCA is that the CCA maximize the correlation while the PLS maximize the covariance. Moreover, in the PLS the primary objective is to estimate matrices  $\mathbf{T}$  and  $\mathbf{U}$  while in the CCA we estimate only projection matrices  $\mathbf{W}_x$  and  $\mathbf{W}_y$ . Anyway, the PLS and CCA are quite similar for the standardized data (that is after the columns of  $\mathbf{X}$  and  $\mathbf{Y}$  have been standardized to have mean zero and standard deviation one) the both method are equivalent.

The PLS decomposition allows us to find relationships between the components which can be used to predict the values of the dependent variables  $\mathbf{Y}_{\text{new}}$  for new situations, if the values of the corresponding independent variables  $\mathbf{X}_{\text{new}}$  are available:

$$\mathbf{T}_{\text{new}} = \mathbf{X}_{\text{new}}[\mathbf{P}^T]^\dagger, \quad \mathbf{Y}_{\text{new}} \approx \mathbf{T}_{\text{new}} \mathbf{D} \mathbf{Q}^T. \quad (21.109)$$

The predictive relationship between the two sets of data is driven by a linear regression model involving  $J$  pairs of latent variables:  $\mathbf{u}_j = d_j \mathbf{t}_j + \tilde{\mathbf{e}}_j$ , (or in a matrix form  $\mathbf{U} = \mathbf{T}\mathbf{D} + \tilde{\mathbf{E}}$ ), where  $d_j$  is a scaling regression coefficient and  $\tilde{\mathbf{e}}_j$  represents residual errors [79]. Using this basic inner regression model the standard PLS model can be expressed as

$$\mathbf{Y} = \sum_{j=1}^J d_j \mathbf{t}_j \mathbf{q}_j^T + \mathbf{E} = \mathbf{XB} + \mathbf{E} \quad (21.110)$$

where the regression coefficients matrix has been defined as  $\mathbf{B} = \sum_{j=1}^J d_j \mathbf{w}_x^{(j)} \mathbf{q}_j^T$ .

**Algorithm 3.** Power Method for Sparse CCA/PLS

---

**Require:** Normalized (standardized) data matrices  $\mathbf{X}^{(1)} = \mathbf{X}$ ,  $\mathbf{Y}^{(1)} = \mathbf{Y}$ , sparsity coefficients  $\alpha_n \geq 0$  ( $n = 1, 2$ ), initial vectors  $\mathbf{w}_x^{(1)}$  and  $\mathbf{w}_y^{(1)}$  and  $\mathbf{Z}^{(1)} = \mathbf{X}^{(1)T} \mathbf{Y}^{(1)}$ ,

1: For  $j = 1, 2, \dots, J$ :

- (a) Repeat until convergence of  $\mathbf{w}_x^{(j)}$  and  $\mathbf{w}_y^{(j)}$ ;
- 2:      $\mathbf{w}_x^{(j)} = \frac{\mathcal{S}_1(\mathbf{Z}^{(j)} \mathbf{w}_y^{(j)}, \alpha_1)}{\|\mathcal{S}_1(\mathbf{Z}^{(j)} \mathbf{w}_y^{(j)}, \alpha_1)\|_2};$
- 3:      $\mathbf{w}_y^{(j)} = \frac{\mathcal{S}_1(\mathbf{Z}^{(j)T} \mathbf{w}_x^{(j)}, \alpha_2)}{\|\mathcal{S}_1(\mathbf{Z}^{(j)T} \mathbf{w}_x^{(j)}, \alpha_2)\|_2};$
- 4: (b) Apply optional orthogonalization procedure according to Eq. (21.104)
- 5: (c)  $\sigma_j = |\mathbf{w}_x^{(j)T} \mathbf{Z}^{(j)} \mathbf{w}_y^{(j)}|$ ;
- 6: (d)  $\mathbf{Z}^{(j+1)} = \mathbf{Z}^{(j)} - \sigma_j \mathbf{w}_x^{(j)} \mathbf{w}_y^{(j)T};$
- 7: **return**  $\mathbf{W}_x^* = [\mathbf{w}_x^{(1)}, \mathbf{w}_x^{(2)}, \dots, \mathbf{w}_x^{(J)}]$ ,  $\mathbf{W}_y^* = [\mathbf{w}_y^{(1)}, \mathbf{w}_y^{(2)}, \dots, \mathbf{w}_y^{(J)}]$ ,  
 $\Sigma^* = \text{diag}\{\sigma_1, \dots, \sigma_J\};$
- 8: **return** Optional  $\mathbf{T} = \mathbf{X} \mathbf{W}_x$ ,  $\mathbf{U} = \mathbf{Y} \mathbf{W}_y$

---

Assuming that the vectors component matrices are estimated sequentially (using deflation approach), the loading factors and regression coefficient can be calculated as:

$$\mathbf{q}_j = \frac{\mathbf{Y}^T \mathbf{u}_j}{\mathbf{u}_j^T \mathbf{u}_j}, \quad d_j = \frac{\mathbf{t}_j^T \mathbf{u}_j}{\mathbf{t}_j^T \mathbf{t}_j} \quad (j = 1, 2, \dots, J). \quad (21.111)$$

Often, we impose additional (optional) sparseness and/or orthogonality constraints (imposed on components matrices  $\mathbf{T}$  and  $\mathbf{U}$  or the loading matrices), in order to achieve better predictive power. For high dimensional data sets, it is often appropriate to assume that independent and dependent data has unit covariance matrices, i.e.,  $\mathbf{X}^T \mathbf{X} \approx \mathbf{I}_N$  and  $\mathbf{Y}^T \mathbf{Y} \approx \mathbf{I}_M$ . In the case of the sparse PLS, we can formulate as the following optimization problem

$$\begin{aligned} & \max_{\mathbf{w}_x^{(1)}, \mathbf{w}_y^{(1)}} \left\{ g(\mathbf{w}_x^{(1)T} \mathbf{X}^T \mathbf{Y} \mathbf{w}_y^{(1)}) - \alpha_1 \|\mathbf{w}_x^{(1)}\|_1 - \alpha_2 \|\mathbf{w}_y^{(1)}\|_1 \right\} \\ & \text{s.t. } \|\mathbf{w}_x^{(1)}\|_2^2 \leq 1, \quad \|\mathbf{w}_y^{(1)}\|_2^2 \leq 1. \end{aligned} \quad (21.112)$$

The PLS algorithms have been proven to be particularly powerful for strongly collinear data and for underdetermined independent data (i.e., more variables than observations) [77]. The widely reported sensitivity to noise of the PLS regression is attributed to redundant (irrelevant) latent variables, their selection remains an open problem. Other problems include the difficulty of interpreting the loadings corresponding to the latent variables, and the fact that the number of latent variables cannot exceed the minimum number of predictors and observations.

Sparse PCA, CCA, and PLS deliver components (or latent vectors) that can be considered as a compromise between maximizing the variance, correlation or covariance, respectively and improving the interpretability of the data, especially for large-scale data with possibly fewer observations than

**Algorithm 4.** Alternative Algorithm for Sparse PLS

---

**Require:** Normalized (standardized) data matrices  $\mathbf{X}^{(1)} = \mathbf{X}$ ,  $\mathbf{Y}^{(1)} = \mathbf{Y}$ , sparsity coefficients  $\alpha_n \geq 0$ , ( $n = 1, 2$ );  
 1: For  $j = 1, 2, \dots, J$ :  
   Set (a)  $\mathbf{Z}^{(j)} = \mathbf{X}^{(j)T} \mathbf{Y}^{(j)}$  and use the SVD to compute the first pair of singular vectors:  
   the left singular vector  $\mathbf{w}_x^{(j)}$  and the right singular vector  $\mathbf{w}_y^{(j)}$ ;  
   (b) Repeat until the convergence of sparse  $\mathbf{w}_x^{(j)}$  and  $\mathbf{w}_y^{(j)}$ :  
     2:    $\mathbf{w}_x^{(j)} \leftarrow \mathcal{S}_1(\mathbf{Z}^{(j)} \mathbf{w}_y^{(j)}, \alpha_1)$ , normalize new vector  $\mathbf{w}_x^{(j)}$ ;  
     3:    $\mathbf{w}_y^{(j)} \leftarrow \mathcal{S}_1(\mathbf{Z}^{(j)T} \mathbf{w}_x^{(j)}, \alpha_2)$ , normalize new vector  $\mathbf{w}_y^{(j)}$ ;  
     4: (b) Apply optional orthogonalization procedure according to Eq. (21.104)  
     5: (c)  $\mathbf{t}_j = \frac{\mathbf{X}^{(j)} \mathbf{w}_x^{(j)}}{\mathbf{w}_x^{(j)T} \mathbf{w}_x^{(j)}}$ ,  $\mathbf{u}_j = \frac{\mathbf{Y}^{(j)} \mathbf{w}_y^{(j)}}{\mathbf{w}_y^{(j)T} \mathbf{w}_y^{(j)}}$ ;  
     6: (d)  $\mathbf{p}_j = \frac{\mathbf{X}^{(j)T} \mathbf{t}_j}{\mathbf{t}_j^T \mathbf{t}_j}$ ,  $\mathbf{q}_j = \frac{\mathbf{Y}^{(j)T} \mathbf{u}_j}{\mathbf{u}_j^T \mathbf{u}_j}$ ;  
     7: (e)  $\mathbf{X}^{(j+1)} = \mathbf{X}^{(j)} - \mathbf{t}_j \mathbf{p}_j^T$ ;  
     8:    $\mathbf{Y}^{(j+1)} = \mathbf{Y}^{(j)} - \mathbf{u}_j \mathbf{q}_j^T$ ;  
   9: **return**  $\mathbf{W}_x, \mathbf{W}_y, \mathbf{T}, \mathbf{P}, \mathbf{U}, \mathbf{Q}$ ;

---

variables. The extraction of components and latent variables sequentially, one by one, by applying deflation techniques, allows us to stop the algorithms after achieving the desired number of components and/or achieving an error measure below a specified threshold.

### 1.21.3 ICA and related problems

There are at least three basic approaches for ICA, coming from different models of source signals [13, 14, 17]. The first simple model considers weakly stationary Gaussian processes and exploits directly the second order statistics (SOS). These signals are separable if their spectra are distinct; therefore, the separation is based on the spectral diversity of the sources. The second approach takes the nonstationarity of the signals into account by modeling them as independently distributed Gaussian variables whose variance is changing in time. For the third basic approach one assumes that source signals are represented by sequence of identically and independently distributed random variables. The condition of separability of such source signals requires that at most only one signal is Gaussian, so the approach is said to be based on the non-Gaussianity and it exploits higher order statistics (HOS). Strictly speaking the first two approaches do not explicitly or implicitly assume statistical independence but rather generalized decorrelation via simultaneous joint diagonalization of time-delayed covariance matrices.

Spatial decorrelation (or prewhitening) is often considered a necessary (but not sufficient) condition for stronger stochastic independence criteria. After prewhitening ICA tasks usually become somewhat easier and well-posed (or less ill-conditioned), because the subsequent separating (unmixing) system is described by an orthogonal matrix for real-valued signals and by a unitary matrix for complex-valued signals and weights. Furthermore, the spatio-temporal and time-delayed decorrelation can be used to identify the mixing matrix and to perform blind source separation of colored sources under certain weak

conditions [13, 14, 17, 18, 80]. Temporal, spatial and spatio-temporal decorrelations play important roles in EEG/MEG data analysis. These techniques are based only on second-order statistics (SOS). They are the basis for modern subspace methods of spectrum analysis and array processing and are often used in a preprocessing stage in order to improve the convergence properties of adaptive systems, to eliminate redundancy or to reduce noise. Spatio-temporal data has both spatial (i.e., location) and temporal (i.e., time related) components.

One possible extension of the ICA is the so-called Independent Subspace Analysis (ISA). ISA can be applied to situations where not all source signals can be separated from each other by linear transformations. The goal here is to decompose the linear space spanned by rows of  $\mathbf{Y}$  to a direct (orthogonal) sum of linear subspaces, such that elements of each subspace are statistically independent of the others. The ISA problem can be approached by applying an ICA algorithm, which aims to separate each component from the others as much as possible. In the postprocessing step we usually perform clustering of the obtained components according to their residual mutual dependence.

### 1.21.3.1 The AMUSE algorithm and its properties

AMUSE (Algorithm for Multiple Unknown Signal Extraction) is probably the simplest BSS algorithm which belongs to the group of Second-Order Statistics Spatio-Temporal Decorrelation (SOS-STD) algorithms [14, 81]. It provides similar decompositions for noiseless data to the well known and popular SOBI and TDSEP algorithms [82, 83]. This class of algorithms are sometimes classified or referred to as ICA algorithms. However, these algorithms do not exploit implicitly or explicitly the statistical independence. Moreover, in contrast to standard higher order statistics ICA algorithms, they are able to estimate colored Gaussian distributed sources and their performance in estimation of original sources is usually better if the sources have temporal structures.

The AMUSE algorithm has some similarity with the standard PCA. The main difference is that the AMUSE employs PCA two times in two separate steps: In the first step, standard PCA is applied for the whitening (sphering) of the data and in the second step PCA is applied to the time delayed covariance matrix of the pre-whitened data. Mathematically the AMUSE algorithm consists of the following two stage procedure: In the first step we apply standard or robust prewhitening as a linear transformation  $\hat{\mathbf{y}}(t) = \mathbf{Q}\mathbf{y}(t)$ , where  $\mathbf{Q} = \mathbf{R}_{yy}^{-1/2} = (\mathbf{V}\Lambda\mathbf{V}^T)^{-1/2} = \mathbf{V}(\Lambda)^{-1/2}\mathbf{V}^T$  of the standard covariance matrix  $\mathbf{R}_{yy} = E\{\mathbf{y}(t)\mathbf{y}^T(t)\}$ , and  $\mathbf{y}(t)$  is a vector of observed data for time point  $t$ . Next, (for the pre-whitened data) the SVD is applied for the time-delayed covariance matrix  $\mathbf{R}_{\hat{\mathbf{y}}}(p) = E\{\hat{\mathbf{y}}(t)\hat{\mathbf{y}}^T(t-p)\} = \mathbf{U}_1\boldsymbol{\Sigma}_1\mathbf{V}_1^T$  (typically, with  $p = 1$ ), where  $\boldsymbol{\Sigma}_1$  is a diagonal matrix with decreasing singular values and  $\mathbf{U}_1, \mathbf{V}_1$  are orthogonal matrices containing the of left and right singular vectors. Then, an unmixing (separating) matrix is estimated as  $\mathbf{W} = \mathbf{U}_1^T\mathbf{Q}$ .

The main advantages of the AMUSE algorithm over the other BSS/ICA algorithms is its simplicity and that it allows the automatic ordering of the components, due to application of SVD. In fact, the components are ordered according to the decreasing values of the singular values of the time-delayed covariance matrix. In other words, the AMUSE algorithm exploits the simple principle that the estimated components tends to be less complex or more precisely that they have better linear predictability than any mixture of those sources. It should be emphasized that all components estimated by AMUSE are uniquely defined and consistently ranked. The consistent ranking is due to the fact that these singular values are always ordered in decreasing values. For real-world data probability that two singular values achieve

exactly the same value is very small, so ordering is consistent and unique [14]. The one disadvantage of the AMUSE algorithm it is that is very sensitive to additive noise since the algorithm exploits only one time delayed covariance matrix.

### 1.21.3.2 The SOBI algorithm and its extensions

The second-order blind identification (SOBI) algorithm is a classical blind source separation (BSS) algorithm for wide-sense stationary (WSS) processes with distinct spectra [82]. This algorithm has proven to be very useful in biomedical applications and it has became more popular than the other algorithms.

There is a common practice in ICA/BSS research to exploit the “average eigen-structure” of a large set of data matrices formed as functions of the available data (typically, covariance or cumulant matrices for different time delays). In other words, the objective is to extract reliable information (e.g., estimation of sources and/or of the mixing matrix) from the eigen-structure of a possibly large set of data matrices [14, 82, 84, 85]. However, since in practice we only have a finite number of samples of signals corrupted by noise, the data matrices do not exactly share the same eigen-structure. Furthermore, it should be noted that determining the eigen-structure on the basis of one or even two data matrices usually leads to poor or unsatisfactory results, because such matrices, based usually on an arbitrary choice, may have degenerate eigenvalues leading to loss of the information contained in other data matrices. Therefore, from a statistical point of view, in order to provide robustness and accuracy, it is necessary to consider the average eigen-structure by taking into account simultaneously a possibly large set of data matrices [14, 85].

The average eigen-structure can be easily implemented via the linear combination of several time-delayed covariance matrices and by applying the standard EVD or SVD. An alternative approach to EVD/SVD is to apply the approximate joint diagonalization procedure (JAD). The objective of this procedure is to find the orthogonal matrix  $\mathbf{U}$  which diagonalizes a set of matrices [82, 84, 85]:

$$\mathbf{R}_{\tilde{\mathbf{y}}}(p_r) = \mathbf{U} \mathbf{D}_r \mathbf{U}^T + \boldsymbol{\varepsilon}_r \quad (r = 1, 2, \dots, R), \quad (21.113)$$

where  $\mathbf{R}_{\tilde{\mathbf{y}}}(p_r) = E\{\tilde{\mathbf{y}}(t)\tilde{\mathbf{y}}^T(t - p_r)\} \in \mathbb{R}^{J \times J}$  are data matrices (for example, time-delayed covariance matrices), the  $\mathbf{D}_r$  are diagonal and real, and  $\boldsymbol{\varepsilon}_r$  represent additive errors (as small as possible). If  $R > 2$  for arbitrary matrices  $\mathbf{R}_x(p_r)$ , the problem becomes overdetermined and generally we can not find an exact diagonalizing matrix  $\mathbf{U}$  with  $\boldsymbol{\varepsilon}_r = \mathbf{0}, \forall r$ . An important advantage of the Joint Approximate Diagonalization (JAD) is that several numerically efficient algorithms exist for its computation, including Jacobi techniques (one sided and two sided), Alternating Least Squares (ALS), PARAFAC (Parallel Factor Analysis) and subspace fitting techniques employing the efficient Gauss–Newton optimization [85]. This idea has been implemented as a robust SOBI algorithm which can be briefly outlined as follows [14, 86]:

1. Perform robust orthogonalization  $\tilde{\mathbf{y}}(t) = \mathbf{Q}\mathbf{y}(t)$ , similar as to the AMUSE algorithm.
2. Estimate the set of covariance matrices:

$$\widehat{\mathbf{R}}_{\tilde{\mathbf{y}}}(p_r) = (1/T) \sum_{t=1}^T \tilde{\mathbf{y}}(t)\tilde{\mathbf{y}}^T(t - p_r) = \mathbf{Q}\widehat{\mathbf{R}}_{\tilde{\mathbf{y}}}(p_r)\mathbf{Q}^T \quad (21.114)$$

for a preselected set of time lags  $(p_1, p_2, \dots, p_R)$  or bandpass filters  $B_r$ .

3. Perform JAD:  $\mathbf{R}_{\hat{\mathbf{y}}}(p_r) = \mathbf{U}\mathbf{D}_r\mathbf{U}^T$ ,  $\forall r$ , i.e., estimate the orthogonal matrix  $\mathbf{U}$  using one of the available numerical algorithms.
4. Estimate the source signals as  $\hat{\mathbf{x}}(t) = \mathbf{U}^T \mathbf{Q} \mathbf{y}(t)$ , and then the mixing matrix as  $\hat{\mathbf{A}} = \mathbf{Q}^+ \mathbf{U}$ .

The main advantage of the SOBI algorithm is its robustness with respect to additive noise if number of covariance matrices is sufficiently large (typically,  $R > 100$ ).

Several extensions and modifications of the SOBI algorithm have been proposed, e.g., Robust SOBI [14], thinICA [87], and WASOBI [88,89] (the weights-adjusted variant of SOBI), which is asymptotically optimal (in separating Gaussian parametric processes). The WASOBI for the separation of independent stationary sources is modeled as Auto-Regressive (AR) random processes. The matrices are computed for the case of Gaussian sources, for which the resulting separation would be asymptotically optimal approaching the corresponding Cramer-Rao bound (CRB) for the best possible separation [88,90].

### 1.21.3.3 ICA based on higher order statistics (HOS)

The ICA of a random vector  $\mathbf{y}(t) \in \mathbb{R}^I$  can be performed by finding an  $J \times I$ , (with  $I \geq J$ ), full rank separating (transformation) matrix  $\mathbf{W}$ , such that the output signal vector  $\hat{\mathbf{x}}(t) = [\hat{x}_1(t), \hat{x}_2(t), \dots, \hat{x}_J(t)]^T$  (components) estimated by

$$\hat{\mathbf{x}}(t) = \mathbf{W}\mathbf{y}(t) = \mathbf{A}^\dagger \mathbf{y}, \quad (21.115)$$

are as independent as possible as evaluated by an information-theoretic cost function such as the minimum of the Kullback-Leibler divergence [14,17,91,92].

The statistical independence of random variables is a more general concept than decorrelation. Roughly speaking, we say that the random variables  $x_i$  and  $x_j$  are statistically independent if knowledge of the value of  $x_i$  provides no information about the values of  $x_j$ . Mathematically, the independence of  $x_i$  and  $x_j$  can be expressed by the relationship

$$p(x_i, x_j) = p(x_i)p(x_j), \quad (21.116)$$

where  $p(x)$  denotes the probability density function (pdf) of the random variable  $x$ . In other words, signals are independent if their joint pdf can be factorized.

If independent signals are zero-mean, then the generalized covariance matrix of  $f(x_i)$  and  $g(x_j)$ , where  $f(x)$  and  $g(x)$  are different, odd nonlinear activation functions (e.g.,  $f(x) = \tanh(x)$  and  $g(x) = x$  for super-Gaussian sources) is a non-singular diagonal matrix:

$$\mathbf{R}_{fg} = E\{\mathbf{f}(\hat{\mathbf{x}})\mathbf{g}^T(\hat{\mathbf{x}})\} = \begin{bmatrix} E\{f(\hat{x}_1)g(\hat{x}_1)\} & & 0 \\ & \ddots & \\ 0 & & E\{f(\hat{x}_J)g(\hat{x}_J)\} \end{bmatrix}, \quad (21.117)$$

i.e., the covariances  $E\{f(\hat{x}_i)g(\hat{x}_j)\}$  are all zero. It should be noted that for odd  $f(\hat{x})$  and  $g(\hat{x})$ , if the probability density function of each zero-mean source signal is even, then the terms of the form  $E\{f(\hat{x}_i)\}E\{g(\hat{x}_i)\}$  equal zero. The true general condition for the statistical independence of signals is the vanishing of all high-order cross-cumulants [93–95]. The diagonalization principle can be expressed as

$$\mathbf{R}_{fg}^{-1} = \mathbf{\Lambda}^{-1}, \quad (21.118)$$

where  $\Lambda$  is any diagonal positive definite matrix (typically,  $\Lambda = \mathbf{I}$ ). By pre-multiplying the above equation by the matrices  $\mathbf{W}$  and  $\Lambda$ , we obtain:

$$\Lambda \mathbf{R}_{fg}^{-1} \mathbf{W} = \mathbf{W}, \quad (21.119)$$

which suggests the following simple iterative multiplicative learning algorithm [96]

$$\tilde{\mathbf{W}}(k+1) = \Lambda \mathbf{R}_{fg}^{-1} \mathbf{W}(k), \quad (21.120)$$

$$\mathbf{W}(t+1) = \tilde{\mathbf{W}}(t+1) [\tilde{\mathbf{W}}^T(t+1) \tilde{\mathbf{W}}(t+1)]^{-1/2}, \quad (21.121)$$

where the last equation represents the symmetric orthogonalization that keeps the algorithm stable. The above algorithm is very simple, but it needs the prewhitening of the sensor data and it is sensitive to noise [14, 97].

Assuming prior knowledge of the source distributions  $p_j(x_j)$ , we can estimate  $\mathbf{W} = [\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_J]^T$  by using maximum likelihood (ML):

$$L = T \log |\det \mathbf{W}| + \sum_{t=1}^T \sum_{j=1}^J \log p_j(\mathbf{w}_j^T \mathbf{y}(t)). \quad (21.122)$$

Using the gradient descent of the likelihood we obtain the infomax update rule

$$\mathbf{W}(k+1) = \mathbf{W}(k) - \eta \frac{\partial L}{\partial \mathbf{W}} = \mathbf{W}(k) + \eta ([\mathbf{W}^T(k)]^{-1} - \frac{1}{T} \sum_{t=1}^T \mathbf{f}(\hat{\mathbf{x}}(t)) \mathbf{y}^T(t)), \quad (21.123)$$

where  $\hat{\mathbf{x}}(t) = \mathbf{W}(k) \mathbf{y}(t)$  and  $\mathbf{f}(\hat{\mathbf{x}}) = [f_1(\hat{x}_1), f_2(\hat{x}_2), \dots, f_J(\hat{x}_J)]^T$  is an entry-wise nonlinear score function defined by:

$$f_j(x_j) = -\frac{p'_j(x_j)}{p_j(x_j)} = -\frac{d \log(p_j(x_j))}{d(x_j)}. \quad (21.124)$$

Using the natural gradient descent to increase the likelihood we get [98]:

$$\begin{aligned} \Delta \mathbf{W} &= \mathbf{W}(k+1) - \mathbf{W}(k) = -\eta \frac{\partial L}{\partial \mathbf{W}} \mathbf{W}^T \mathbf{W} \\ &= \eta [\mathbf{I} - \langle \mathbf{f}(\hat{\mathbf{x}}) \hat{\mathbf{x}}^T \rangle] \mathbf{W}(k). \end{aligned} \quad (21.125)$$

Alternatively, for signals corrupted by additive Gaussian noise, we can use higher order matrix cumulants. As an illustrative example, let us consider the following cost function which is a measure of independence [99]:

$$J(\mathbf{W}, \hat{\mathbf{x}}) = -\frac{1}{2} \log |\det (\mathbf{W} \mathbf{W}^T)| - \frac{1}{1+q} \sum_{i=1}^n |C_{1+q}(\hat{x}_i)|, \quad (21.126)$$

where we use the following notations:  $C_q(\hat{x}_i)$  denotes the  $q$ -order cumulants of the signal  $\hat{x}_i$  and  $\mathbf{C}_{p,q}(\hat{\mathbf{x}}, \hat{\mathbf{x}})$  denotes the cross-cumulant matrix whose elements are  $[\mathbf{C}_{pq}(\hat{\mathbf{x}}, \hat{\mathbf{x}})]_{ij} = \text{Cum}(\underbrace{\hat{x}_i, \hat{x}_i, \dots, \hat{x}_i}_p, \underbrace{\hat{x}_j, \hat{x}_j, \dots, \hat{x}_j}_q)$ .

**Table 21.1** Basic Equivariant Adaptive Learning Algorithms for ICA.  $\hat{\mathbf{x}}(t) = \mathbf{W}\mathbf{y}(t) = \hat{\mathbf{A}}^\dagger \mathbf{y}(t)$ 

No.	Learning Algorithm	References
1.	$\Delta\mathbf{W} = \eta[\Lambda - \langle \mathbf{f}(\hat{\mathbf{x}})\mathbf{g}^T(\hat{\mathbf{x}}) \rangle]\mathbf{W}$ $\Delta\hat{\mathbf{A}} = -\eta\hat{\mathbf{A}}[\Lambda - \langle \mathbf{f}(\hat{\mathbf{x}})\mathbf{g}^T(\hat{\mathbf{x}}) \rangle]$	[93, 95]
2.	$\Delta\mathbf{W} = \eta[\Lambda - \langle \mathbf{f}(\hat{\mathbf{x}})\hat{\mathbf{x}}^T \rangle]\mathbf{W}, \quad f(y_i) = -p'(y_i)/p(y_i)$ $\lambda_{ii} = \langle f(y_i(k))y_i(k) \rangle$ or $\lambda_{ii} = 1, \forall i$	[91] [98]
3.	$\Delta\mathbf{W} = \eta[\mathbf{I} - \langle \hat{\mathbf{x}}\hat{\mathbf{x}}^T \rangle - \langle \mathbf{f}(\hat{\mathbf{x}})\hat{\mathbf{x}}^T \rangle + \langle \hat{\mathbf{x}}\mathbf{f}^T(\hat{\mathbf{x}}) \rangle]\mathbf{W}$	[100]
4.	$\Delta\mathbf{W} = \eta[\mathbf{I} - \langle \hat{\mathbf{x}}\hat{\mathbf{x}}^T \rangle - \langle \mathbf{f}(\hat{\mathbf{x}})\hat{\mathbf{x}}^T \rangle + \langle \mathbf{f}(\hat{\mathbf{x}})\mathbf{f}^T(\hat{\mathbf{x}}) \rangle]\mathbf{W}$	[45]
5.	$\tilde{\mathbf{W}} = \mathbf{W} + \eta[\Lambda - \langle \mathbf{f}(\hat{\mathbf{x}})\hat{\mathbf{x}}^T \rangle]\mathbf{W}, \quad \lambda_{ii} = \langle f(y_i)y_i \rangle$ $\eta_{ii} = [\lambda_{ii} + \langle f'(y_i) \rangle]^{-1}; \quad \mathbf{W} = (\tilde{\mathbf{W}}\tilde{\mathbf{W}}^T)^{-1/2}\tilde{\mathbf{W}}$	[17]
6.	$\Delta\mathbf{W} = \eta[\mathbf{I} - \Lambda^{-1}\langle \hat{\mathbf{x}}\hat{\mathbf{x}}^T \rangle]\mathbf{W}$ $\lambda_{ii}(k) = \langle \hat{x}_i^2(t) \rangle$	[101] [28]
7.	$\mathbf{W}(k+1) = [\mathbf{I} \mp \eta[\mathbf{I} - \langle \mathbf{f}(\hat{\mathbf{x}})\mathbf{g}^T(\hat{\mathbf{x}}) \rangle]]^{\mp 1}\mathbf{W}(k)$	[102]
8.	$\Delta\mathbf{W} = \eta[\mathbf{I} - \mathbf{C}_{1,q}(\hat{\mathbf{x}}, \hat{\mathbf{x}})\mathbf{S}_{q+1}(\hat{\mathbf{x}})]\mathbf{W}$ $\mathbf{C}_{1,q}(x_i, x_j) = \text{Cum}(y_i, \underbrace{x_j, \dots, x_j}_q)$	[99]

The first term in (21.126) assures that the determinant of the global matrix will not approach zero. By including this term we avoid the trivial solution  $\hat{x}_i = 0, \forall i$ . The second term forces the output signals to be as far as possible from Gaussianity, since the higher order cumulants are a natural measure of non-Gaussianity and they will vanish for Gaussian signals. It can be shown that for such a cost function, we can derive the following equivariant and robust (with respect to the Gaussian noise) algorithm [87, 99, 102]

$$\Delta\mathbf{W}(t) = \mathbf{W}(k+1) - \mathbf{W}(k) = \eta_l[\mathbf{I} - \mathbf{C}_{1,q}(\hat{\mathbf{x}}, \hat{\mathbf{x}})\mathbf{S}_{q+1}(\hat{\mathbf{x}})]\mathbf{W}(k), \quad (21.127)$$

where  $\mathbf{S}_{q+1}(\hat{\mathbf{x}}) = \text{sign}(\text{diag}(\mathbf{C}_{1,q}(\hat{\mathbf{x}}, \hat{\mathbf{x}})))$  and  $\mathbf{F}(\hat{\mathbf{x}}) = \mathbf{I} - \mathbf{C}_{1,q}(\hat{\mathbf{x}}, \hat{\mathbf{x}})\mathbf{S}_{q+1}(\hat{\mathbf{x}})$ .

A wide class of equivariant algorithms for ICA can be expressed in a general form as (see Table 21.1) [14]

$$\nabla\mathbf{W}(k) = \mathbf{W}(k+1) - \mathbf{W}(k) = \eta\mathbf{F}(\hat{\mathbf{x}})\mathbf{W}(k), \quad (21.128)$$

where  $\hat{\mathbf{x}}(t) = \mathbf{W}\mathbf{y}(t)$  and the matrix  $\mathbf{F}(\hat{\mathbf{x}})$  can take different forms, for example  $\mathbf{F}(\hat{\mathbf{x}}) = \Lambda - \langle \mathbf{f}(\hat{\mathbf{x}})\mathbf{g}^T(\hat{\mathbf{x}}) \rangle$  with suitably chosen nonlinearities  $\mathbf{f}(\hat{\mathbf{x}}) = [f(\hat{x}_1), \dots, f(\hat{x}_J)]$  and  $\mathbf{g}(\hat{\mathbf{x}}) = [g(\hat{x}_1), \dots, g(\hat{x}_J)]$  [14, 95, 96, 99].

It should be noted that ICA based on HOS can perform blind source separation, i.e., allows us to estimate the true sources only if they are all statistically independent and are non Gaussian (except possibly of one) [14, 91].

### 1.21.3.4 Blind source extraction

There are two main approaches to solve the problem of blind source separation. The first approach, which was mentioned briefly in the previous section, is to simultaneously separate all sources. In the second

approach, we extract the sources sequentially in a blind fashion, one by one, rather than separating them all simultaneously. In many applications a large number of sensors (electrodes, sensors, microphones or transducers) are available but only a very few source signals are the subject of interest. For example, in the modern EEG or MEG devices, we typically observe more than 100 sensor signals, but only a few source signals are interesting; the rest can be considered as interfering noise. In another example, the cocktail party problem, it is usually essential to extract the voices of specific persons rather than separate all the source signals of all speakers available (in mixing form) from an array of microphones. For such applications it is essential to apply reliable, robust and effective learning algorithms which enable us to extract only a small number of source signals that are potentially interesting and contain useful information.

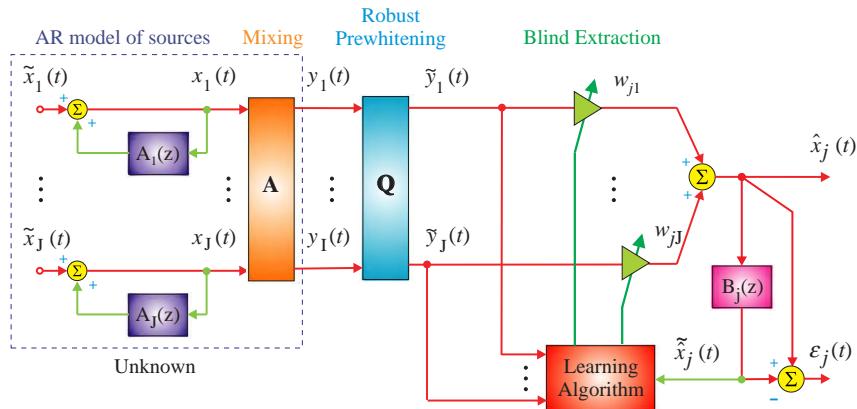

The blind source extraction (BSE) approach has several advantages over the simultaneous blind separation/deconvolution, such as

- Only the “interesting” signals need to be extracted. For example, if the source signals are mixed with a large number of noise terms, we may extract only the specific signals which possess some desired statistical properties.
- The signals can be extracted in a *specified order* according to the statistical features of the source signals, e.g., in the order determined by the absolute values of the generalized normalized kurtosis. Blind extraction of sources can be considered as a generalization of the sequential extraction of principal components, where uncorrelated output signals are extracted according to the decreasing order of their variances.
- The available unsupervised learning algorithms for BSE are local, stable and typically biologically plausible.

We can use two different criteria. The first criterion is based on higher order statistics (HOS), which assumes that the sources are mutually statistically independent and non-Gaussian (at most one can be Gaussian). For independence criteria we will use some measure of non-Gaussianity [14]. The second criterion is based on the concept of linear predictability and it assumes that the source signals have some temporal structure, i.e., the sources are colored with different autocorrelation functions, or equivalently they have different spectral shapes.

#### 1.21.3.4.1 *Blind extraction of sources with temporal structures*

In this approach we exploit the temporal structure of the signals rather than their statistical independence [103, 104]. Intuitively speaking, the source signals  $x_j(t)$  have less complexity than the mixed sensor signals  $y_j(t)$ . In other words, the degree of temporal predictability of any source signal is higher than (or equal to) that of any mixture. For example, waveforms of a mixture of two sine waves with different frequencies are more complex (or less predictable) than either of the original sine waves. This means that applying the standard linear predictor model and minimizing the mean squared error  $E\{\varepsilon^2\}$ , which is a measure of predictability, we can separate (or extract) signals with different temporal structures. More precisely, by minimizing the error, we maximize a measure of temporal predictability for each recovered signal [105].

**FIGURE 21.5**

Block diagram illustrating the implementation of learning algorithm for the blind extraction of temporally correlated sources.

It is worth noting that two criteria used in BSE, namely temporal linear predictability and non-Gaussianity based on kurtosis, may lead to different results. Temporal predictability forces the extracted signals to be smooth and possibly less structurally complex, while the non-Gaussianity measure forces the extracted signals to be as independent as possible, with sparse representation for the sources that have positive kurtosis.

Let us assume that temporally correlated source signals are modeled by autoregressive processes (AR) (see Figure 21.5) as

$$x_j(t) = \tilde{x}_j(t) + \sum_{p=1}^L \tilde{a}_{jp} x_j(t-p) = \tilde{x}_j(t) + A_j(z)x_j(t), \quad (j = 1, 2, \dots, J) \quad (21.129)$$

where \$A\_j(z) = \sum\_{p=1}^L \tilde{a}\_{jp} z^{-p}\$, \$z^{-p}x(t) = x(t-p)\$ and \$\tilde{x}\_j(t)\$ are i.i.d. unknown (innovative) processes. In practice, the AR model can be extended to more general models such as the Auto Regressive Moving Average (ARMA) model or the Hidden Markov Model (HMM) [14, 17, 101].

For ill-conditioned problems (when a mixing matrix is ill-conditioned and/or the source signals have different amplitudes), we can apply optional pre-whitening to the sensor signals \$\mathbf{y}(t)\$ in the form of \$\tilde{\mathbf{y}}(t) = \mathbf{Q}\mathbf{y}(t)\$, where \$\mathbf{Q} \in \mathbb{R}^{J \times J}\$ is a whitening matrix that ensures that the auto-correlation matrix is an identity matrix: \$\mathbf{R}\_{\tilde{\mathbf{y}}\tilde{\mathbf{y}}} = E\{\tilde{\mathbf{y}}\tilde{\mathbf{y}}^T\} = \mathbf{I}\_J\$.

To model temporal structures of source signals, we consider a linear processing unit with an adaptive filter with the transfer function \$B\_j(z)\$ (which estimates one \$A\_j(z)\$) as illustrated in Figure 21.5. Let us assume for simplicity, that we want to extract only one source signal, e.g., \$\hat{x}\_j(t)\$, from the available

sensor vector  $\tilde{\mathbf{y}}(t)$ . For this purpose, we employ a single processing unit described as

$$\hat{x}_j(t) = \mathbf{w}_j^T \tilde{\mathbf{y}}(t) = \sum_{i=1}^J w_{ji} \tilde{y}_j(t), \quad (21.130)$$

$$\varepsilon_j(t) = \hat{x}_j(t) - \sum_{p=1}^L b_{jp} \hat{x}_j(t-p) = \mathbf{w}^T \tilde{\mathbf{y}}(t) - \mathbf{b}_j^T \hat{\mathbf{x}}_j(t), \quad (21.131)$$

where  $\mathbf{w}_j = [w_{j1}, w_{j2}, \dots, w_{jJ}]^T$ ,  $\hat{\mathbf{x}}_j(t) = [\hat{x}_1(t-1), \hat{x}_2(t-2), \dots, \hat{x}_J(t-L)]^T$ ,  $\mathbf{b}_j = [b_{j1}, b_{j2}, \dots, b_{jL}]^T$  and  $B_j(z) = \sum_{p=1}^L b_{jp} z^{-p}$  is the transfer function of the corresponding FIR filter. It should be noted that the FIR (Finite Impulse Response) filter can have a sparse vector  $\mathbf{b}_j$ . In particular, only one single processing unit, e.g., with delay  $p$  and  $b_{jp} \neq 0$  can be used instead of the  $L$  parameters. The processing unit has two outputs:  $\hat{x}_j(t)$  which estimates the extracted source signals, and  $\varepsilon_j(t)$ , which represents a linear prediction error or estimation of the innovation, after passing the output signal  $\hat{x}_j(t)$  through the  $B_j(z)$  filter. Our objective is to estimate the optimal values of the vectors  $\mathbf{w}_1$  and  $\mathbf{b}_1$ , in such a way that the processing unit successfully extracts one of the sources. This is achieved if the global vector defined as  $\mathbf{g}_j = \mathbf{A}^T \mathbf{w}_j = (\mathbf{w}_j^T \mathbf{A})^T = c_j \mathbf{e}_i$  contains only one nonzero element, e.g., in the  $j$ th row, such that  $\hat{x}_j(t) = c_j x_i(t)$ , where  $c_j$  is an arbitrary nonzero scaling factor. For this purpose we reformulate the problem as a minimization of the cost function

$$D_j(\mathbf{w}_j, \mathbf{b}_j) = E\{\varepsilon_j^2\}. \quad (21.132)$$

The main motivation for applying such a cost function is the assumption that the primary source signals (signals of interest) have temporal structures and can be modeled by an autoregressive model [14, 106, 107].

According to the AR model of source signals, the filter output can be represented as  $\varepsilon_j(t) = \hat{x}_j(t) - \tilde{x}_j(t)$ , where  $\tilde{x}_j(t) = \sum_{p=1}^L b_{jp} \hat{x}_j(t-p)$  is defined as an error or estimator of the innovation source  $\tilde{x}_j(t)$ . The mean squared error  $E\{\varepsilon_j^2(t)\}$  achieves a minimum  $c_j^2 E\{\tilde{x}_j^2(t)\}$ , where  $c_j$  is a positive scaling constant, if and only if  $\hat{x}_1 = \pm c_1 x_j$  for any  $j \in \{1, 2, \dots, m\}$  or  $\hat{x}_j = 0$  holds.

The cost function (21.132) can be evaluated as follows:

$$E\{\varepsilon_j^2\} = \mathbf{w}_j^T \widehat{\mathbf{R}}_{\tilde{\mathbf{y}}\tilde{\mathbf{y}}} \mathbf{w}_j - 2\mathbf{w}_j^T \widehat{\mathbf{R}}_{\tilde{\mathbf{y}}\tilde{\mathbf{x}}_j} \mathbf{b}_j + \mathbf{b}_j^T \widehat{\mathbf{R}}_{\tilde{\mathbf{x}}_j\tilde{\mathbf{x}}_j} \mathbf{b}_j, \quad (21.133)$$

where  $\widehat{\mathbf{R}}_{\tilde{\mathbf{y}}\tilde{\mathbf{y}}} \approx E\{\tilde{\mathbf{y}}\tilde{\mathbf{y}}^T\}$ ,  $\widehat{\mathbf{R}}_{\tilde{\mathbf{y}}\tilde{\mathbf{x}}_j} \approx E\{\tilde{\mathbf{y}}\tilde{\mathbf{x}}_j^T\}$  and  $\widehat{\mathbf{R}}_{\tilde{\mathbf{x}}_j\tilde{\mathbf{x}}_j} \approx E\{\tilde{\mathbf{x}}_j\tilde{\mathbf{x}}_j^T\}$  are estimators of the true values of correlation and cross-correlation matrices:  $\mathbf{R}_{\tilde{\mathbf{y}}\tilde{\mathbf{y}}}$ ,  $\mathbf{R}_{\tilde{\mathbf{y}}\tilde{\mathbf{x}}_j}$ ,  $\mathbf{R}_{\tilde{\mathbf{x}}_j\tilde{\mathbf{x}}_j}$ , respectively.

In order to estimate the vectors  $\mathbf{w}_j$  and  $\mathbf{b}_j$ , we evaluate the gradients of the cost function and make them equal to zero as follows:

$$\frac{\partial D_j(\mathbf{w}_j, \mathbf{b}_j)}{\partial \mathbf{w}} = 2\widehat{\mathbf{R}}_{\tilde{\mathbf{y}}\tilde{\mathbf{y}}} \mathbf{w}_j - 2\widehat{\mathbf{R}}_{\tilde{\mathbf{y}}\tilde{\mathbf{x}}_j} \mathbf{b}_j = \mathbf{0}, \quad (21.134)$$

$$\frac{\partial D_j(\mathbf{w}_j, \mathbf{b}_j)}{\partial \mathbf{b}_j} = 2\widehat{\mathbf{R}}_{\tilde{\mathbf{x}}_j\tilde{\mathbf{x}}_j} \mathbf{b}_j - 2\widehat{\mathbf{R}}_{\tilde{\mathbf{x}}_j\tilde{\mathbf{y}}} \mathbf{w}_j = \mathbf{0}. \quad (21.135)$$

Solving the above matrix equations we obtain the iterative formulas:

$$\tilde{\mathbf{w}}_j = \widehat{\mathbf{R}}_{\tilde{\mathbf{y}}\tilde{\mathbf{y}}}^{-1} \widehat{\mathbf{R}}_{\tilde{\mathbf{y}}\tilde{\mathbf{x}}_j} \mathbf{b}_j, \quad \mathbf{w}_j = \frac{\tilde{\mathbf{w}}_j}{\|\tilde{\mathbf{w}}_j\|_2}, \quad (21.136)$$

$$\mathbf{b}_j = \widehat{\mathbf{R}}_{\tilde{\mathbf{x}}_j\tilde{\mathbf{x}}_j}^{-1} \widehat{\mathbf{R}}_{\tilde{\mathbf{x}}_j\tilde{\mathbf{y}}} \mathbf{w}_j = \widehat{\mathbf{R}}_{\tilde{\mathbf{x}}_j\tilde{\mathbf{y}}}^{-1} \widehat{\mathbf{R}}_{\tilde{\mathbf{x}}_jx_j}, \quad (21.137)$$

where in order to avoid the trivial solution  $\mathbf{w}_j = \mathbf{0}$ , we normalize the vector  $\mathbf{w}_j$  to unit length in each iteration step as  $\mathbf{w}_j(k+1) \leftarrow \mathbf{w}_j(k+1)/\|\mathbf{w}_j(k+1)\|_2$  (which ensures that  $E\{x_j^2\} = 1$ ). It is worth to note that in our derivation the matrices  $\widehat{\mathbf{R}}_{\tilde{\mathbf{x}}_j\tilde{\mathbf{x}}_j}$  and  $\widehat{\mathbf{R}}_{\tilde{\mathbf{x}}_j\tilde{\mathbf{x}}_j}$  are assumed to be independent of the vector  $\mathbf{w}_j(k+1)$ , i.e., they are estimated based on  $\mathbf{w}_j(k)$  from the previous iteration step. This two-phase procedure is similar to the expectation maximization (EM) scheme: (i) Freeze the correlation and cross-correlation matrices and learn the parameters of the processing unit ( $\mathbf{w}_j, \mathbf{b}_j$ ); (ii) freeze  $\mathbf{w}_j$  and  $\mathbf{b}_j$  and learn the new statistics (i.e., matrices  $\widehat{\mathbf{R}}_{\tilde{\mathbf{x}}_j\tilde{\mathbf{x}}_j}$  and  $\widehat{\mathbf{R}}_{\tilde{\mathbf{x}}_j\tilde{\mathbf{x}}_j}$ ) of the estimated source signal, then go back to (i) and repeat. Hence, in phase (i) our algorithm extracts a source signal, whereas in phase (ii) it learns the statistics of the source.

The above algorithm can be further simplified. It should be noted that in order to avoid the inversion of the autocorrelation matrix  $\widehat{\mathbf{R}}_{\tilde{\mathbf{y}}\tilde{\mathbf{y}}}$ , in each iteration step we can perform the standard prewhitening or standard PCA as a preprocessing step and then normalize the sensor signals to have unit variance. In such cases  $\widehat{\mathbf{R}}_{\tilde{\mathbf{y}}\tilde{\mathbf{y}}} = \mathbf{I}$  and the algorithm is considerably simplified to [106]

$$\mathbf{w}_j = \widehat{\mathbf{R}}_{\tilde{\mathbf{y}}\tilde{\mathbf{x}}_j} \mathbf{b}_j = \widehat{\mathbf{R}}_{\tilde{\mathbf{y}}\tilde{\mathbf{x}}_j}, \quad \mathbf{w}_j \leftarrow \frac{\mathbf{w}_j}{\|\mathbf{w}_j\|_2}, \quad (21.138)$$

where  $\widehat{\mathbf{R}}_{\tilde{\mathbf{y}}\tilde{\mathbf{x}}_j} = \frac{1}{T} \sum_{t=1}^T \tilde{\mathbf{y}}(t) \tilde{\mathbf{x}}_j(t) = \langle \tilde{\mathbf{y}}(t) \tilde{\mathbf{x}}_j(t) \rangle$  or in equivalent form

$$\boxed{\mathbf{w}_j(k+1) = \frac{\langle \tilde{\mathbf{y}}(t) \tilde{\mathbf{x}}_j(t) \rangle}{\langle \tilde{\mathbf{x}}_j^2(t) \rangle}}. \quad (21.139)$$

From (21.138) and (21.139) it follows that the derived update rules are similar to the power method in finding the eigenvector associated with the maximal eigenvalue of the matrix  $\mathbf{R}_{\tilde{\mathbf{y}}}(\mathbf{b}_j) = E\{\sum_{p=1}^L b_{jp} \tilde{\mathbf{y}}(t) \tilde{\mathbf{y}}^T(t-p)\}$ . This observation suggests that it is often not necessary to minimize the cost function with respect to the parameters  $\{b_{jp}\}$  but it is enough to choose a random set of them for which the largest eigenvalue is unique (single). More generally, if all eigenvalues of the generalized covariance matrix  $\mathbf{R}_{\tilde{\mathbf{y}}}(\mathbf{b}_j)$  are distinct, then we can extract all sources simultaneously by estimating the principal eigenvectors of  $\mathbf{R}_{\tilde{\mathbf{y}}}(\mathbf{b}_j)$ .

## 1.21.4 NMF and related problems

NMF has been investigated by many researchers, e.g., Paatero and Tapper [108], but it has gained popularity through the works of Lee and Seung published in Nature and NIPS [20, 109]. Based on the argument that the nonnegativity is important for human perception, they proposed simple algorithms (often called the Lee-Seung algorithms) for finding nonnegative representations of nonnegative data and images.

### 1.21.4.1 Why nonnegativity and sparsity constraints?

Many real-world data are nonnegative and the corresponding hidden components have a physical meaning only when nonnegative. In practice, both nonnegative and sparse decompositions of the data are often either desirable or necessary, when the underlying components have a physical interpretation. For example, in image processing and computer vision, the involved variables and parameters may correspond to pixels, and the nonnegative sparse decomposition is related to the extraction of relevant parts from the images [20, 109]. In computer vision and graphics, we often encounter multi-dimensional data, such as images, videos, and medical data, one type of which is MRI (magnetic resonance imaging). A color image can be considered as a 3D nonnegative data sets, two of the dimensions (rows and columns) being spatial, and the third one being a color plane (channel) depending on its color space, while a color video sequence can be considered as a 4D nonnegative data sets with time being the fourth dimension. A sparse representation of the data by a limited number of components is an important research problem. In machine learning sparseness is closely related to feature selection and certain generalizations of learning algorithms, while nonnegativity relates to probability distributions. Generally speaking, compositional data (i.e., positive sum of components or real vectors) are natural representations when the variables (features) are essentially the probabilities of complementary and mutually exclusive events. Furthermore, we may note that NMF is an additive model which does not allow subtraction; therefore it often describes quantitatively the parts that comprise the entire entity. In other words, NMF can be considered as a part-based representation in which a zero-value represents the absence and a positive number represents the presence of some event or component. Specifically, in the case of facial image data, the additive or part-based nature of NMF has been shown to result in a basis of facial features, such as eyes, nose, and lips [20]. Furthermore, the low-rank matrix factorization methods that exploit nonnegativity and sparsity constraints usually lead to estimation of the hidden components with specific structures and physical interpretations, in contrast to other blind source separation methods. In economics, variables and data such as volume, price and many other factors are nonnegative and sparse. Sparseness constraints may increase the efficiency of a portfolio, while nonnegativity both increases the efficiency and reduces the risk [110, 111]. In information retrieval the documents are usually represented as relative frequencies of words form a prescribed vocabulary. In environmental science the scientists investigate a relative proportion of different pollutants in water or air [112]. In biology each coordinate axis may correspond to a specific gene, and the sparseness is necessary for finding local patterns hidden in the data, whereas the nonnegativity is required to give physical or physiological meaning. This is also important for the robustness of biological systems, where any observed change in the expression level of a specific gene emerges from either positive or a negative influence, rather than a combination of both, which partly cancel each other [109, 111]. It is clear, however, that with constraints such as sparsity and nonnegativity some of the explained variance (fit) may decrease. In other words, it is natural to seek a trade-off between the two goals of interpretability (making sure that the estimated components have physical or physiological meaning) and statistical fidelity (explaining most of the variance of the data) if the data are consistent and do not contain too much noise.

### 1.21.4.2 Basic NMF models

The basic NMF problem can be stated as follows: Given a nonnegative data matrix  $\mathbf{Y} \in \mathbb{R}_+^{I \times T}$  (with  $y_{it} \geq 0 \forall it$  or compactly  $\mathbf{Y} \geq \mathbf{0}$ ) and a reduced rank- $J$  ( $J \leq \min(I, T)$ ), find two nonnegative

matrices  $\mathbf{A} = [\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_J] \in \mathbb{R}_+^{I \times J}$  and  $\mathbf{X} = \mathbf{B}^T = [\mathbf{b}_1, \mathbf{b}_2, \dots, \mathbf{b}_J]^T \in \mathbb{R}_+^{J \times T}$ , which factorize  $\mathbf{Y} = \mathbf{AX} + \mathbf{E} = \mathbf{AB}^T + \mathbf{E}$ , as well as possible in the sense that a norm or divergence of error matrix  $\mathbf{E}$  is minimized (see Figure 21.1). Since we usually operate on the column vectors of matrices (in order to avoid a complex or confusing notation) it is often convenient to use the matrix  $\mathbf{B} = \mathbf{X}^T$  instead of the matrix  $\mathbf{X}$ . The factors  $\mathbf{A}$  and  $\mathbf{B}$  may have different physical meaning in different applications. In a BSS problem,  $\mathbf{A}$  plays the role of a mixing matrix, while the columns of  $\mathbf{B}$  express source signals. In clustering problems,  $\mathbf{A}$  is the basis matrix while  $\mathbf{B}$  denotes the weight matrix. In acoustic analysis,  $\mathbf{A}$  represents the basis patterns, while each column of  $\mathbf{B}$  expresses the time points (positions) when the sound patterns are activated. In standard NMF we only assume nonnegativity of the factor matrices  $\mathbf{A}$  and  $\mathbf{B}$ . Unlike blind source separation methods based on independent component analysis (ICA), here we do not assume that the sources are independent, although we often impose additional constraints on  $\mathbf{A}$  and/or  $\mathbf{B}$ .

The NMF model can also be represented as a special form of the bilinear model (see Figure 21.2):  $\mathbf{Y} = \sum_{j=1}^J \mathbf{a}_j \circ \mathbf{b}_j + \mathbf{E} = \sum_{j=1}^J \mathbf{a}_j \mathbf{b}_j^T + \mathbf{E}$ . Thus, we can build an approximate representation of the nonnegative data matrix  $\mathbf{Y}$  as a sum of rank-1 nonnegative matrices  $\mathbf{a}_j \mathbf{b}_j^T$ . If such decomposition is exact (i.e.,  $\mathbf{E} = \mathbf{0}$ ) then it is called the Nonnegative Rank Factorization (NRF) [113]. Among the many possible series representations of the data matrix  $\mathbf{Y}$  by nonnegative rank-1 matrices, the smallest integer  $J$  for which such a nonnegative rank-1 series representation is attained is called the nonnegative rank of the nonnegative matrix  $\mathbf{Y}$  and it is denoted by  $\text{rank}_+(\mathbf{Y})$ . The nonnegative rank satisfies the following bounds [113]:

$$\text{rank}(\mathbf{Y}) \leq \text{rank}_+(\mathbf{Y}) \leq \min\{I, T\}. \quad (21.140)$$

Although the NMF can be applied to BSS problems for nonnegative sources and nonnegative mixing matrices, its application is not limited to BSS and it can be used for other diverse applications far beyond BSS. In many applications we require additional constraints on the elements of the matrices  $\mathbf{A}$  and/or  $\mathbf{B}$ , such as smoothness, sparsity, symmetry, and orthogonality.

#### 1.21.4.2.1 Special forms of NMF

The NMF models may take several different forms:

**Symmetric NMF:** In the special case when  $\mathbf{A} = \mathbf{B} \in \mathbb{R}_+^{I \times J}$  the NMF is called a symmetric NMF, given by

$$\mathbf{Y} = \mathbf{AA}^T + \mathbf{E}. \quad (21.141)$$

This model is also considered equivalent to Kernel K-means clustering and Laplace spectral clustering [114].

If the exact symmetric NMF exists ( $\mathbf{E} = \mathbf{0}$ ) then a nonnegative matrix  $\mathbf{Y} \in \mathbb{R}_+^{I \times I}$  is said to be completely positive (cp) and the smallest number of columns of  $\mathbf{A} \in \mathbb{R}_+^{I \times J}$  satisfying the exact factorization  $\mathbf{Y} = \mathbf{AA}^T$  is called the cp-rank of the matrix  $\mathbf{Y}$ , denoted by  $\text{rank}_{cp}(\mathbf{Y})$ . If  $\mathbf{Y}$  is cp, then the upper bound estimate for the cp-rank is given by [113]:

$$\text{rank}_{cp}(\mathbf{Y}) \leq \frac{\text{rank}(\mathbf{Y})(\text{rank}(\mathbf{Y}) + 1)}{2} - 1, \quad (21.142)$$

provided that  $\text{rank}(\mathbf{Y}) > 1$ .

**Orthogonal NMF:** The orthogonal or semi-orthogonal NMF can be defined as

$$\mathbf{Y} = \mathbf{AB}^T + \mathbf{E}, \quad (21.143)$$

subject to nonnegativity constraints  $\mathbf{A} \geq \mathbf{0}$  and  $\mathbf{B} \geq \mathbf{0}$  (component-wise) and an additional orthogonality constraint:  $\mathbf{A}^T \mathbf{A} = \mathbf{I}_J$  or  $\mathbf{B}^T \mathbf{B} = \mathbf{I}_J$ . It can be proved that the orthogonal NMF is equivalent to a weighted variant of spherical K-means clustering.

Probably the simplest and most efficient way to impose orthogonality for the matrix  $\mathbf{A}$  (or  $\mathbf{B}$ ) is to perform the following transformation after each iteration

$$\mathbf{A} \leftarrow \mathbf{A}[\mathbf{A}^T \mathbf{A}]^{-1/2} \quad \text{or} \quad \mathbf{B} \leftarrow [\mathbf{B}^T \mathbf{B}]^{-1/2} \mathbf{B}^T. \quad (21.144)$$

**Semi-NMF and Nonnegative Factorization of an Arbitrary Matrix:** In some applications the observed input data is unsigned (unconstrained or bipolar) as indicated by  $\mathbf{Y} = \mathbf{Y}_{\pm} \in \mathbb{R}^{I \times T}$  which allows us to relax the constraints regarding nonnegativity of one factor (or only specific vectors of a matrix). This leads to the approximative semi-NMF which can take the following form

$$\mathbf{Y}_{\pm} = \mathbf{A}_{\pm} \mathbf{B}_{\pm}^T + \mathbf{E} \quad \text{or} \quad \mathbf{Y}_{\pm} = \mathbf{A}_{+} \mathbf{B}_{\pm}^T + \mathbf{E}, \quad (21.145)$$

where the subscript in  $\mathbf{A}_{+}$  indicates that the matrix is constrained to be nonnegative. Usually, in order to provide uniqueness of the semi-NMF additional constraints must be imposed.

**Nonnegative Factorization (NF):** In some applications the data matrix  $\mathbf{Y}$  has some negative entries. Such case when the matrices  $\mathbf{A}$  and/or  $\mathbf{B}$  are restricted to contain nonnegative entries, but the data matrix  $\mathbf{Y}$  may have entries with mixed signs, is referred to as the Nonnegative Factorization (NF) [115, 116].

**NMF with Offset (Affine NMF):** In NMF with offset (also called affine NMF, aNMF), the goal is to remove the base line or constant bias from the matrix  $\mathbf{Y}$  by using a slightly modified NMF model:

$$\mathbf{Y} = \mathbf{AB}^T + \mathbf{a}_0 \mathbf{1}^T + \mathbf{E}, \quad (21.146)$$

where  $\mathbf{1} \in \mathbb{R}^T$  is a vector of all ones and  $\mathbf{a}_0 \in \mathbb{R}_+^I$  is a vector which is selected in such a way that the matrix  $\mathbf{B}$  is zero-grounded, that is, with a possibly large number of zero entries in each column (or for noisy data close to zero entries). The term  $\mathbf{Y}_0 = \mathbf{a}_0 \mathbf{1}^T$  denotes the offset, which together with the nonnegativity constraint often ensures the sparseness of the factored matrices. The main role of the offset is to absorb the constant values of a data matrix, thereby making the factorization sparser and therefore improving (relaxing) conditions for the uniqueness of NMF (see next sections).

**Three-factor NMF:** Three-factor NMF (also called the tri-NMF) can be considered as a special case of the multi-layer NMF, and it can take the following general form [117, 118]

$$\mathbf{Y} = \mathbf{ASB}^T + \mathbf{E}, \quad (21.147)$$

where the nonnegativity constraints are imposed on all or only on selected factor matrices:  $\mathbf{A} \in \mathbb{R}^{I \times J}$ ,  $\mathbf{S} \in \mathbb{R}^{J \times R}$ , and/or  $\mathbf{B} \in \mathbb{R}^{T \times R}$ .

It should be noted that if we do not impose any additional constraints to the factors (besides nonnegativity), the three-factor NMF can be reduced to the standard (two-factor) NMF by the transformation  $\mathbf{A} \leftarrow \mathbf{AS}$  or  $\mathbf{B} \leftarrow \mathbf{BS}^T$ . However, the three-factor NMF is not equivalent to the standard NMF if we apply special constraints or conditions as illustrated by the following special cases.

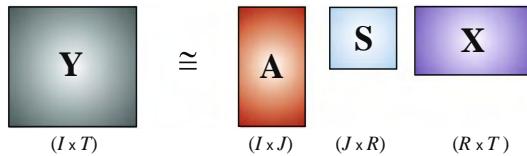

**FIGURE 21.6**

Illustration of three factor NMF (tri-NMF). The goal is to estimate two matrices  $\mathbf{A} \in \mathbb{R}_+^{I \times J}$  and  $\mathbf{B} = \mathbf{X}^T \in \mathbb{R}_+^{T \times R}$ , assuming that the matrix  $\mathbf{S} \in \mathbb{R}^{J \times R}$  is given, or to estimate all three factor matrices  $\mathbf{A}$ ,  $\mathbf{S}$ , and  $\mathbf{X}$ , subject to additional constraints such as orthogonality, smoothness or sparsity.

**Non-Smooth NMF:** Non-smooth NMF (nsNMF) was proposed by [119] and it is a special case of the three-factor NMF model in which the matrix  $\mathbf{S}$  is fixed and known, and it is used for controlling the sparsity or the smoothness of the matrix  $\mathbf{B}$  and/or  $\mathbf{A}$ . Typically, the smoothing matrix  $\mathbf{S} \in \mathbb{R}^{J \times J}$  takes the form:

$$\mathbf{S} = (1 - \Theta)\mathbf{I}_J + \frac{\Theta}{J}\mathbf{1}_{J \times J}, \quad (21.148)$$

where  $\mathbf{I}_J$  is the  $J \times J$  identity matrix and  $\mathbf{1}_{J \times J}$  is the square matrix of all ones. The scalar parameter  $0 \leq \Theta \leq 1$  controls the smoothness of the matrix operator  $\mathbf{S}$ . For  $\Theta = 0$ ,  $\mathbf{S} = \mathbf{I}_J$ , and the model reduces to the standard NMF for  $\Theta \rightarrow 1$  strong smoothing is imposed on  $\mathbf{S}$  causing increased sparseness of both  $\mathbf{A}$  and  $\mathbf{B}$ , in order to maintain the faithfulness of the model.

**CUR Decomposition:** In the CUR decomposition, a given data matrix  $\mathbf{Y} \in \mathbb{R}^{I \times T}$  is decomposed as follows [120–124]:

$$\mathbf{Y} = \mathbf{C}\mathbf{U}\mathbf{R} + \mathbf{E}, \quad (21.149)$$

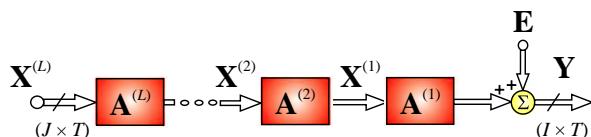

where  $\mathbf{C} \in \mathbb{R}^{I \times C}$  is a matrix constructed from  $C$  selected columns of  $\mathbf{Y}$ ,  $\mathbf{R} \in \mathbb{R}^{R \times T}$  consists of  $R$  rows of  $\mathbf{Y}$  and the matrix  $\mathbf{U} \in \mathbb{R}^{C \times R}$  is chosen to minimize the error  $\mathbf{E} \in \mathbb{R}^{I \times T}$ .

The CUR decomposition for data analysis can be considered as an alternative as low-rank approximation to PCA and SVD, specially for large-scale and sparse data sets. On this regard, the idea of the CUR decomposition is to provide a representation of the data as a linear combination of a few “meaningful” components which are exact replicas of columns and rows of the original data matrix. [121, 123–125]. Since typically,  $C \ll T$  and  $R \ll I$ , the objective is to find a matrix  $\mathbf{U}$  and select rows and columns of  $\mathbf{Y}$  such that the error cost function  $\|\mathbf{E}\|_F^2$  is minimized. There are several strategies for the selection of suitable columns and rows. The main principle is to select columns and rows that exhibit high “statistical leverage” and provide the best low-rank fit to the data matrix [120–122].

The core matrix  $\mathbf{U}$  can be easily computed as  $\mathbf{U} = \mathbf{W}^\dagger$ , where  $\mathbf{W} \in \mathbb{R}^{C \times R}$  is matrix build from entries of  $\mathbf{Y}$  located on the cross-intersections of selected rows and columns. In other words, the core matrix  $\mathbf{U}$  is the Moore–Penrose pseudo-inverse of a matrix  $\mathbf{W} \in \mathbb{R}^{R \times C}$ , i.e.,  $\mathbf{U} = \mathbf{W}^\dagger$ , which is defined by the intersections of the selected rows and columns. Alternatively, we can compute a core matrix  $\mathbf{U}$  as  $\mathbf{U} = \mathbf{C}^\dagger \mathbf{Y} \mathbf{R}^\dagger$ , but in this case the knowledge of the whole data matrix  $\mathbf{Y}$  is necessary (see Figure 21.6).

In the special case, when we assume that  $\mathbf{U}\mathbf{R} = \mathbf{X}$ , we have the CX decomposition:

$$\mathbf{Y} = \mathbf{C}\mathbf{X} + \mathbf{E}. \quad (21.150)$$

**FIGURE 21.7**

Multilayer NMF model. In this model the global factor matrix  $\mathbf{A} = \mathbf{A}^{(1)}\mathbf{A}^{(2)}\dots\mathbf{A}^{(L)}$  has a distributed sparse representation in which each matrix  $\mathbf{A}^{(l)}$  can be sparse.

The CX and CUR decompositions are low-rank matrix decompositions that are explicitly expressed in terms of a small number of actual columns and/or actual rows of the original data matrix and they have recently received increasing attention within the data analysis community, especially for nonnegative data, due to its many applications [121–124]. The CUR decomposition has the advantage that components (factor matrices  $\mathbf{C}$  and  $\mathbf{R}$ ) are directly obtained from the rows and columns of the data matrix  $\mathbf{Y}$ , preserving desired properties such as nonnegativity or sparsity. Because they are constructed from actual data elements, the CUR decomposition is often more easily interpretable by practitioners from the field from which the data are collected (to the extent that the original data points and/or features are interpretable) [123].

**Orthogonal Three-Factor NMF:** Orthogonal three-factor NMF imposes additional constraints upon the two matrices:  $\mathbf{A}^T\mathbf{A} = \mathbf{I}_J$  and  $\mathbf{B}^T\mathbf{B} = \mathbf{I}_R$  while the matrix  $\mathbf{S}$  can be an arbitrary unconstrained matrix (i.e., it has both positive and negative entries) [117, 118].

For the uni-orthogonal three-factor NMF only one matrix ( $\mathbf{A}$  or  $\mathbf{B}$ ) is orthogonal and all three matrices are usually nonnegative.

**Multi-layer NMF:** In multi-layer NMF the basic matrix  $\mathbf{A}$  is replaced by a set of cascaded (factor) matrices. Thus, the model can be described as (see Figure 21.7)

$$\mathbf{Y} = \mathbf{A}^{(1)}\mathbf{A}^{(2)}\dots\mathbf{A}^{(L)}\mathbf{X} + \mathbf{E}. \quad (21.151)$$

Since the model is linear, all the matrices can be merged into a single matrix  $\mathbf{A}$  if no special constraints are imposed upon the individual matrices  $\mathbf{A}^{(l)}$  ( $l = 1, 2, \dots, L$ ). However, multi-layer NMF can be used to considerably improve the performance of standard NMF algorithms due to its distributed structure and the alleviation the problem of local minima.

To improve the performance of the NMF algorithms (especially for ill-conditioned and badly-scaled data) and to reduce the risk of converging to local minima of a cost function due to nonconvex alternating minimization, we have developed a simple hierarchical multi-stage procedure [126] combined with a multi-start initialization, in which we perform a sequential decomposition of nonnegative matrices as follows. In the first step, we perform the basic approximate decomposition  $\mathbf{Y} \cong \mathbf{A}^{(1)}\mathbf{X}^{(1)} \in \mathbb{R}^{I \times T}$  using any available NMF algorithm. In the second stage, the results obtained from the first stage are used to build up an input data matrix  $\mathbf{Y} \leftarrow \mathbf{X}^{(1)}$ , that is, in the next step, we perform a similar decomposition  $\mathbf{X}^{(1)} \cong \mathbf{A}^{(2)}\mathbf{X}^{(2)} \in \mathbb{R}^{J \times T}$ , using the same or different update rules. We continue our decomposition by taking into account only the last obtained components. The process can be repeated for an arbitrary number of times until some stopping criterion is satisfied.

Thus, our multi-layer NMF model has the form:

$$\mathbf{Y} \cong \mathbf{A}^{(1)} \mathbf{A}^{(2)} \cdots \mathbf{A}^{(L)} \mathbf{X}^{(L)}, \quad (21.152)$$

with the final results  $\mathbf{A} = \mathbf{A}^{(1)} \mathbf{A}^{(2)} \cdots \mathbf{A}^{(L)}$  and  $\mathbf{X} = \mathbf{X}^{(L)}$ . Physically, this means that we build up a distributed system that has many layers or cascade connections of  $L$  mixing subsystems. The key point of this approach is that the learning (update) process to find the parameters of the matrices  $\mathbf{X}^{(l)}$  and  $\mathbf{A}^{(l)}$  ( $l = 1, 2, \dots, L$ ) is performed sequentially, layer-by-layer, where each layer is randomly initialized with different initial conditions. We have found that the hierarchical multi-layer approach can improve the performance of most NMF algorithms discussed in this chapter [8, 127].

**Simultaneous NMF:** In simultaneous NMF (siNMF) we have available two or more linked input data matrices (say,  $\mathbf{Y}_1$  and  $\mathbf{Y}_2$ ) and the objective is to decompose them into nonnegative factor matrices in such a way that one of the factor matrices is common (which is a special form of the Nonnegative Tensor Factorization (NTF) model, for example [8]

$$\mathbf{Y}_1 = \mathbf{A}_1 \mathbf{B}^T + \mathbf{E}_1, \quad \mathbf{Y}_2 = \mathbf{A}_2 \mathbf{B}^T + \mathbf{E}_2. \quad (21.153)$$

Such a problem arises, for example, in bio-informatics if we combine gene expression and transcription factor regulation [128]. In this application the data matrix  $\mathbf{Y}_1 \in \mathbb{R}^{I_1 \times T}$  is the expression level of gene  $t$  for the data sample  $i_1$  (i.e., the index  $i_1$  denotes the samples, while  $t$  stands for genes) and  $\mathbf{Y}_2 \in \mathbb{R}^{I_2 \times T}$  is the transcription matrix (which is 1 whenever transcription factor  $i_2$  regulates gene  $t$ ).

**Quadratic NMF:** Quadratic NMF (QNMF) has several forms [129]:

- 1) The asymmetric form (AQNMF)  $\mathbf{Y} \approx \mathbf{A}\mathbf{A}^T\mathbf{X}$ ,
- 2) The symmetric form (SQNMF):  $\mathbf{Y} \approx \mathbf{A}\mathbf{X}\mathbf{A}^T$ ,
- 3) Projective NMF (PNMF):  $\mathbf{Y} \approx \mathbf{A}\mathbf{A}^T\mathbf{Y}$ , for  $\mathbf{X} = \mathbf{Y}$ ,
- 4) Symmetric NMF (SNMF)  $\mathbf{Y} \approx \mathbf{A}\mathbf{A}^T$ , for  $\mathbf{X} = \mathbf{I}$ .

#### 1.21.4.3 Basic approaches to estimate parameters of the standard NMF

In order to estimate factor matrices  $\mathbf{A}$  and  $\mathbf{B}$  for the standard NMF, we need to consider the similarity measure or divergence to quantify the difference between the data matrix  $\mathbf{Y}$  and the approximative NMF model matrix  $\hat{\mathbf{Y}} = \mathbf{AB}^T$ . The choice of the similarity measure (also referred to as distance, divergence or measure of dissimilarity) depends mostly on the probability distribution of the estimated signals or components and on the structure of the data or the distribution of the noise [130]. The simplest and most often used measure is based on the Frobenius norm:

$$D_F(\mathbf{Y} \|\mathbf{AB}^T) = \frac{1}{2} \|\mathbf{Y} - \mathbf{AB}^T\|_F^2, \quad (21.154)$$

which is also referred to as the squared Euclidean distance. It should be noted that the above cost function is convex with respect to either one of the elements of the matrix  $\mathbf{A}$  or the matrix  $\mathbf{B}$ , but not with respect to both. Although the NMF optimization problem is not convex, the objective functions are separately convex in each of the two factors  $\mathbf{A}$  and  $\mathbf{B}$ , which implies that finding the optimal factor matrix  $\mathbf{A}$  corresponding to a fixed matrix  $\mathbf{B}$  reduces to a convex optimization problem and vice versa. However, the convexity is lost as soon as we try to optimize both factor matrices simultaneously [116].

Alternating minimization of such cost function leads to the ALS (Alternating Least Squares) algorithm which can be described as follows:

1. Initialize  $\mathbf{A}$  randomly or by using a specific deterministic strategy.
2. Estimate  $\mathbf{B}$  from the matrix equation  $\mathbf{A}^T \mathbf{AB}^T = \mathbf{A}^T \mathbf{Y}$  by solving

$$\min_{\mathbf{B}} \{D_F(\mathbf{Y} \|\mathbf{AB}^T)\} = \frac{1}{2} \|\mathbf{Y} - \mathbf{AB}^T\|_F^2, \quad \text{with fixed } \mathbf{A}. \quad (21.155)$$

3. Set all the negative elements of  $\mathbf{B}$  to zero or to some small positive value  $\varepsilon$ .
4. Estimate  $\mathbf{A}$  from the matrix equation  $\mathbf{B}^T \mathbf{BA}^T = \mathbf{B}^T \mathbf{Y}^T$  by solving

$$\min_{\mathbf{A}} \{D_F(\mathbf{Y} \|\mathbf{AB}^T)\} = \frac{1}{2} \|\mathbf{Y}^T - \mathbf{BA}^T\|_F^2, \quad \text{with fixed } \mathbf{B}. \quad (21.156)$$

5. Set all negative elements of  $\mathbf{A}$  to zero or to some small positive value  $\varepsilon$ .
6. Repeat the procedure till we achieve convergence.

The above ALS algorithm can be written in the following form (Note that the max operator is applied element-wise, that is, each element of a matrix is compared with the scalar parameter  $\varepsilon$ ):

$$\mathbf{B} \leftarrow \max\{\varepsilon, (\mathbf{Y}^T \mathbf{A}(\mathbf{A}^T \mathbf{A})^{-1})\}, \quad \mathbf{A} \leftarrow \max\{\varepsilon, \mathbf{Y}\mathbf{B}(\mathbf{B}^T \mathbf{B})^{-1}\}, \quad (21.157)$$

where  $\varepsilon$  is a small constant (typically,  $10^{-16}$ ) used to enforce positive entries. Various additional constraints (such as sparsity or smoothness) can also be imposed on either  $\mathbf{A}$  or  $\mathbf{B}$ .

Today the ALS method is considered as the basic “workhorse” approach, however it is not guaranteed to converge to a global minimum nor even to a stationary point, but only to a solution where the cost functions cease to decrease [5, 112]. Moreover, it is often not sufficiently accurate. The ALS method can be dramatically improved and its computational complexity reduced as it will be shown later.

It is interesting to note that the NMF problem can be considered as a natural extension of a Nonnegative Least Squares (NLS) problem formulated as the following optimization problem: given a matrix  $\mathbf{A} \in \mathbb{R}^{I \times J}$  and a set of observed values given by the vector  $\mathbf{y} \in \mathbb{R}^I$ , find a nonnegative vector  $\mathbf{x} \in \mathbb{R}^J$  which minimizes the cost function  $J(\mathbf{x}) = \frac{1}{2} \|\mathbf{y} - \mathbf{Ax}\|_2^2$ , i.e.,

$$\min_{\mathbf{x} \geq \mathbf{0}} \frac{1}{2} \|\mathbf{y} - \mathbf{Ax}\|_2^2, \quad (21.158)$$

subject to  $\mathbf{x} \geq \mathbf{0}$ . There is a large volume of literature devoted to NLS problems which can be exploited and adopted to NMF [8].

Most of the existing approaches minimize only one kind of cost function by alternately switching between the sets of parameters. However, we can adopt a more general and flexible approach in which, instead of one cost function, we exploit two or more cost functions (with the same global minima); one of them is minimized with respect to  $\mathbf{A}$  and the other one is minimized with respect to  $\mathbf{B}$ . Such an approach is fully justified as  $\mathbf{A}$  and  $\mathbf{B}$  may have different distributions or different statistical properties and therefore different cost functions may be optimal for each one of them.

Let us consider a basic penalized cost function by considering additional penalty terms:

$$\begin{aligned} D_{Fr}(\mathbf{Y} \|\mathbf{AB}^T) &= \frac{1}{2} \|\mathbf{Y} - \mathbf{AB}^T\|_F^2 + \alpha_{\mathbf{A}} D_{\mathbf{A}}(\mathbf{A}) + \alpha_{\mathbf{B}} D_{\mathbf{B}}(\mathbf{B}) \\ \text{s.t. } a_{ij} &\geq 0, \quad b_{tj} \geq 0, \quad \forall i, j, t, \end{aligned} \quad (21.159)$$

where  $\alpha_{\mathbf{A}}$  and  $\alpha_{\mathbf{B}}$  are nonnegative regularization parameters and the penalty terms  $D_{\mathbf{B}}(\mathbf{B})$ , and  $D_{\mathbf{A}}(\mathbf{A})$  are used to enforce certain application-dependent characteristics for the desired solution. As a special practical case, we have  $D_{\mathbf{B}}(\mathbf{B}) = \sum_{tj} \varphi_{\mathbf{B}}(b_{tj})$ , where  $\varphi(b_{tj})$  are suitably chosen functions which are measures of smoothness or sparsity. To achieve a sparse representation we usually chose  $\varphi_{\mathbf{B}}(b_{tj}) = |b_{tj}|$  or simply  $\varphi_{\mathbf{B}}(b_{tj}) = b_{tj}$  (since,  $b_{tj}$  are nonnegative). Similar regularization terms can also be implemented for the matrix  $\mathbf{A}$ . Note that we treat both matrices  $\mathbf{A}$  and  $\mathbf{B}$  in a similar way.

Applying the standard gradient descent approach, we have

$$a_{ij} \leftarrow a_{ij} - \eta_{ij} \frac{\partial D_{Fr}(\mathbf{A}, \mathbf{B})}{\partial a_{ij}}, \quad b_{tj} \leftarrow b_{tj} - \eta_{tj} \frac{\partial D_{Fr}(\mathbf{A}, \mathbf{B})}{\partial b_{tj}}, \quad (21.160)$$

where  $\eta_{ij}$  and  $\eta_{tj}$  are positive learning rates. The gradients above can be expressed in compact matrix form as

$$\frac{\partial D_{Fr}(\mathbf{A}, \mathbf{B})}{\partial a_{ij}} = [-\mathbf{Y}\mathbf{B} + \mathbf{AB}^T\mathbf{B}]_{ij} + \alpha_{\mathbf{A}} \frac{\partial D_{\mathbf{A}}(\mathbf{A})}{\partial a_{ij}}, \quad (21.161)$$

$$\frac{\partial D_{Fr}(\mathbf{A}, \mathbf{B})}{\partial b_{tj}} = [-\mathbf{Y}^T\mathbf{A} + \mathbf{BA}^T\mathbf{A}]_{tj} + \alpha_{\mathbf{B}} \frac{\partial D_{\mathbf{B}}(\mathbf{B})}{\partial b_{tj}}. \quad (21.162)$$

At this point we can follow the Lee and Seung approach to choose the learning rates [20, 109]

$$\eta_{ij} = \frac{a_{ij}}{[\mathbf{AB}^T\mathbf{B}]_{ij}}, \quad \eta_{tj} = \frac{b_{tj}}{[\mathbf{BA}^T\mathbf{A}]_{jt}}, \quad (21.163)$$

leading to multiplicative updates (refereed to as NMF\_MU):

$$a_{ij} \leftarrow a_{ij} \frac{[[\mathbf{Y}\mathbf{B}]_{ij} - \alpha_{\mathbf{A}} \Psi_{\mathbf{A}}(a_{ij})]_+}{[\mathbf{AB}^T\mathbf{B}]_{ij}}, \quad b_{tj} \leftarrow b_{tj} \frac{[[\mathbf{Y}^T\mathbf{A}]_{tj} - \alpha_{\mathbf{B}} \Psi_{\mathbf{B}}(b_{tj})]_+}{[\mathbf{BA}^T\mathbf{A}]_{jt}}, \quad (21.164)$$

where the functions  $\Psi_{\mathbf{A}}(a_{ij})$  and  $\Psi_{\mathbf{B}}(b_{tj})$  are defined as

$$\Psi_{\mathbf{A}}(a_{ij}) = \frac{\partial D_{\mathbf{A}}(\mathbf{A})}{\partial a_{ij}}, \quad \Psi_{\mathbf{B}}(b_{tj}) = \frac{\partial D_{\mathbf{B}}(\mathbf{B})}{\partial b_{tj}} \quad (21.165)$$

and the regularization parameters  $\alpha_{\mathbf{A}}$  and  $\alpha_{\mathbf{B}}$  should be sufficiently small to ensure the nonnegativity in (21.164) at each iteration, or we can avoid this problem by a half-wave rectifier  $[x]_+ = \max\{x, \varepsilon\}$  with a small  $\varepsilon$ .

The above update rules (21.164), (for  $\alpha_{\mathbf{A}} = \alpha_{\mathbf{B}} = 0$ ) often called Lee-Seung NMF algorithm can be considered as an extension of the well known ISRA (Image Space Reconstruction Algorithm) algorithm proposed first by Daube-Witherspoon and Muehllehner [131] and investigated by many researchers, especially by De Pierro and Byrne [132–136].

In order to impose sparsity, instead of using the  $\ell_2$ -norm, we can use regularization terms based on the  $\ell_1$ -norm, and minimize the cost function:

$$\begin{aligned} D_{F1}(\mathbf{A}, \mathbf{B}) &= \frac{1}{2} \|\mathbf{Y} - \mathbf{AB}^T\|_F^2 + \alpha_{\mathbf{A}} \|\mathbf{A}\|_1 + \alpha_{\mathbf{B}} \|\mathbf{B}\|_1, \\ \text{s.t. } a_{ij} &\geq 0, \quad b_{tj} \geq 0, \quad \forall i, j, t, \end{aligned} \quad (21.166)$$

where the  $\ell_1$ -norms for matrices are defined as  $\|\mathbf{A}\|_1 = \sum_{ij} |a_{ij}|$  and  $\|\mathbf{B}\|_1 = \sum_{tj} |b_{tj}|$ .

This way, the multiplicative learning rules (21.164) for sparse NMF (with controlled sparseness) can be simplified as

$$\boxed{a_{ij} \leftarrow a_{ij} \frac{[(\mathbf{YB})_{ij} - \alpha_{\mathbf{A}}]_+}{[\mathbf{AB}^T \mathbf{B}]_{ij}}, \quad b_{tj} \leftarrow b_{tj} \frac{[(\mathbf{Y}^T \mathbf{A})_{jt} - \alpha_{\mathbf{B}}]_+}{[\mathbf{B} \mathbf{A}^T]_{jt}}}, \quad (21.167)$$

where the normalization of the columns of the matrix  $\mathbf{A}$  at each iteration is performed as  $a_{ij} \leftarrow a_{ij}/\sum_p a_{pj}$ . This algorithm provides a sparse representation for the estimated matrices; the degree of sparseness increases with an increase in the values of the regularization coefficients (typically,  $\alpha_{\mathbf{A}} = \alpha_{\mathbf{B}} = 0.01 - 0.5$ ).

The above multiplicative update rules can be represented in compact matrix form

$$\boxed{\mathbf{A} \leftarrow \mathbf{A} \circledast [(\mathbf{YB} - \alpha_{\mathbf{A}} \mathbf{1}_{I \times J})]_+ \oslash (\mathbf{AB}^T \mathbf{B})}, \quad (21.168)$$

$$\boxed{\mathbf{B} \leftarrow \mathbf{B} \circledast [(\mathbf{Y}^T \mathbf{A} - \alpha_{\mathbf{B}} \mathbf{1}_{T \times J})]_+ \oslash (\mathbf{B} \mathbf{A}^T \mathbf{A})}, \quad (21.169)$$

where the symbols “ $\circledast$ ” and “ $\oslash$ ” denote the Hadamard element-wise product and division, respectively.

#### 1.21.4.4 The HALS algorithm and its extensions

This section focuses on a brief description of a simple local ALS method referred to as the HALS (Hierarchical Alternating Least Squares) algorithm. We call such ALS algorithm hierarchical, since we minimize sequentially a set of simple cost functions which are linked to each other hierarchically via the residual matrices  $\mathbf{Y}^{(j)}$ , which approximate rank-1 bilinear decomposition. Moreover, the HALS algorithm is usually used for multi-layer models in order to improve performance. We highlight the suitability of this method for large-scale NMF problems, and sparse nonnegative coding or representation [126, 137].

We can generalize the concept of ALS by using not only one or two cost functions but rather a set of cost functions to be minimized sequentially or simultaneously. For  $\mathbf{A} = [\mathbf{a}_1, \mathbf{a}_1, \dots, \mathbf{a}_J]$  and  $\mathbf{B} = \mathbf{X}^T = [\mathbf{b}_1, \mathbf{b}_2, \dots, \mathbf{b}_J]$ , we can express the squared Euclidean cost function as

$$D(\mathbf{a}_1, \mathbf{a}_1, \dots, \mathbf{a}_J, \mathbf{b}_1, \mathbf{b}_2, \dots, \mathbf{b}_J) = \frac{1}{2} \|\mathbf{Y} - \mathbf{AB}^T\|_F^2 = \frac{1}{2} \|\mathbf{Y} - \sum_{j=1}^J \mathbf{a}_j \mathbf{b}_j^T\|_F^2. \quad (21.170)$$

An underlying idea is to define the residuals as:

$$\mathbf{Y}^{(j)} = \mathbf{Y} - \sum_{p \neq j} \mathbf{a}_p \mathbf{b}_p^T = \mathbf{Y} - \mathbf{AB}^T + \mathbf{a}_j \mathbf{b}_j^T = \mathbf{E} + \mathbf{a}_j \mathbf{b}_j^T \quad (j = 1, 2, \dots, J), \quad (21.171)$$

and alternately minimize the set of cost functions with respect to the unknown variables  $\mathbf{a}_j, \mathbf{b}_j$ :

$$D_A^{(j)}(\mathbf{a}) = \frac{1}{2} \|\mathbf{Y}^{(j)} - \mathbf{a}\mathbf{b}_j^T\|_F^2, \quad \text{for a fixed } \mathbf{b}_j, \quad (21.172a)$$

$$D_B^{(j)}(\mathbf{b}) = \frac{1}{2} \|\mathbf{Y}^{(j)} - \mathbf{a}_j\mathbf{b}^T\|_F^2, \quad \text{for a fixed } \mathbf{a}_j, \quad (21.172b)$$

for  $j = 1, 2, \dots, J$  subject to  $\mathbf{a} \geq \mathbf{0}$  and  $\mathbf{b} \geq \mathbf{0}$ , respectively.

In other words, we perform alternatively the minimization of the set of cost functions

$$D_F^{(j)}(\mathbf{Y}^{(j)} \|\mathbf{a}_j\mathbf{b}_j^T) = \frac{1}{2} \|\mathbf{Y}^{(j)} - \mathbf{a}_j\mathbf{b}_j^T\|_F^2, \quad (21.173)$$

for  $j = 1, 2, \dots, J$  subject to  $\mathbf{a}_j \geq \mathbf{0}$  and  $\mathbf{b}_j \geq \mathbf{0}$ .

In order to estimate the stationary points we simply compute the gradients of the local cost functions (21.173) with respect to the unknown vectors  $\mathbf{a}_j$  and  $\mathbf{b}_j$  (assuming that the other vectors are fixed) as follows:

$$\nabla_{\mathbf{a}_j} D_F^{(j)}(\mathbf{Y}^{(j)} \|\mathbf{a}_j\mathbf{b}_j^T) = \frac{\partial D_F^{(j)}(\mathbf{Y}^{(j)} \|\mathbf{a}_j\mathbf{b}_j^T)}{\partial \mathbf{a}_j} = \mathbf{a}_j\mathbf{b}_j^T\mathbf{b}_j - \mathbf{Y}^{(j)}\mathbf{b}_j, \quad (21.174)$$

$$\nabla_{\mathbf{b}_j} D_F^{(j)}(\mathbf{Y}^{(j)} \|\mathbf{a}_j\mathbf{b}_j^T) = \frac{\partial D_F^{(j)}(\mathbf{Y}^{(j)} \|\mathbf{a}_j\mathbf{b}_j^T)}{\partial \mathbf{b}_j} = \mathbf{a}_j^T\mathbf{a}_j\mathbf{b}_j - \mathbf{Y}^{(j)T}\mathbf{a}_j. \quad (21.175)$$

$$\mathbf{a}_j \leftarrow \frac{1}{\mathbf{b}_j^T\mathbf{b}_j} [\mathbf{Y}^{(j)}\mathbf{b}_j]_+, \quad \mathbf{b}_j \leftarrow \frac{1}{\mathbf{a}_j^T\mathbf{a}_j} [\mathbf{Y}^{(j)T}\mathbf{a}_j]_+ \quad (j = 1, 2, \dots, J), \quad (21.176)$$

where  $[\mathbf{A}]_+ = \max\{\epsilon, \mathbf{A}\}$ . We refer to these update rules as the HALS algorithm which was first introduced for the NMF in [126]. The same or similar update rules for the NMF have been proposed, extended or rediscovered independently in other publications [116, 138–140]. However, our practical implementations of the HALS algorithm are quite different and allow various extensions to sparse and smooth NMF, and also for the  $N$ -order NTF [8]. It was proved in that for every constant  $\varepsilon > 0$  the limit points of the HALS algorithm initialized with positive matrices and applied to the optimization problem (21.173) are stationary points (see also [139]).

The nonlinear projections can be imposed individually for each source  $\mathbf{b}_j$  and/or vector  $\mathbf{a}_j$ , so the algorithm can be directly extended to a semi-NMF, in which some parameters are relaxed to be unconstrained (by removing the half-wave rectifying  $[\cdot]_+$  operator, if necessary). In practice it is necessary to normalize the column vectors  $\mathbf{a}_j$  and/or  $\mathbf{b}_j$  to unit length vectors (in  $\ell_p$ -norm sense ( $p = 1, 2, \dots, \infty$ )) at each iteration step. In the special case of the  $\ell_2$ -norm, the above algorithm can be further simplified by ignoring the denominators in (21.176) and by imposing a vector normalization after each iterative step, to give a simplified scalar form of the HALS algorithm:

$b_{tj} \leftarrow \left[ \sum_{i=1}^I a_{ij} y_{it}^{(j)} \right]_+, \quad a_{ij} \leftarrow \left[ \sum_{t=1}^T b_{tj} y_{it}^{(j)} \right]_+,$

(21.177)

with  $a_{ij} \leftarrow a_{ij}/\|\mathbf{a}_j\|_2$ , where  $y_{it}^{(j)} = [\mathbf{Y}^{(j)}]_{it} = y_{it} - \sum_{p \neq j} a_{ip}b_{tp}$ .

The above simple algorithm can be further extended or improved with respect to the convergence rate and performance by imposing additional constraints such as sparsity and smoothness. Firstly, observe that the residual matrix  $\mathbf{Y}^{(j)}$  can be rewritten as

$$\begin{aligned}\mathbf{Y}^{(j)} &= \mathbf{Y} - \sum_{p \neq j} \mathbf{a}_p \mathbf{b}_p^T = \mathbf{Y} - \mathbf{AB}^T + \mathbf{a}_j \mathbf{b}_j^T, \\ &= \mathbf{Y} - \mathbf{AB}^T + \mathbf{a}_{j-1} \mathbf{b}_{j-1}^T - \mathbf{a}_{j-1} \mathbf{b}_{j-1}^T + \mathbf{a}_j \mathbf{b}_j^T.\end{aligned}\quad (21.178)$$

It then follows that instead of computing explicitly the residual matrix  $\mathbf{Y}^{(j)}$  at each iteration step, we can just perform smart updates (see [8, 141]).

Different cost functions can be used for the estimation of the columns of matrix  $\mathbf{A}$  and/or  $\mathbf{B}$ , possibly with various additional regularization terms [141]. Furthermore, the columns of  $\mathbf{A}$  can be estimated simultaneously, and the columns of  $\mathbf{B}$  sequentially. In other words, by minimizing the set of cost functions in (21.173) with respect to  $\mathbf{b}_j$ , and simultaneously the cost functions (21.154) with normalization of the columns  $\mathbf{a}_j$  to unit  $\ell_2$ -norm, we obtain a very efficient NMF learning algorithm in which the individual columns of  $\mathbf{B} = [\mathbf{b}_1, \mathbf{b}_2, \dots, \mathbf{b}_J]$  are updated locally (column-by-column) and the matrix  $\mathbf{A}$  is updated globally using the global nonnegative ALS (all columns  $\mathbf{a}_j$  simultaneously):

$$\boxed{\mathbf{b}_j \leftarrow [\mathbf{Y}^{(j)T} \mathbf{a}_j]_+, \quad \mathbf{A} \leftarrow [\mathbf{YB}(\mathbf{B}^T \mathbf{B})^{-1}]_+}, \quad (21.179)$$

with the normalization (scaling) of the columns of  $\mathbf{A}$  to unit length in the sense of the  $\ell_2$ -norm after each iteration.

In order to impose sparseness and smoothness constraints for the vectors  $\mathbf{b}_j$  (source signals), we can minimize the following set of cost functions [34, 139]:

$$D_F^{(j)}(\mathbf{Y}^{(j)} \| \mathbf{a}_j \mathbf{b}_j^T) = \frac{1}{2} \|\mathbf{Y}^{(j)} - \mathbf{a}_j \mathbf{b}_j^T\|_F^2 + \alpha_{sp} \|\mathbf{b}_j\|_1 + \alpha_{sm} \|\varphi(\mathbf{Lb}_j)\|_1, \quad (21.180)$$

for  $j = 1, 2, \dots, J$  subject to  $\mathbf{a}_j \geq \mathbf{0}$  and  $\mathbf{b}_j \geq \mathbf{0}$ , where  $\alpha_{sp} > 0, \alpha_{sm} > 0$  are regularization parameters controlling the levels of sparsity and smoothness, respectively,  $\mathbf{L}$  is a suitably designed matrix (the Laplace operator) which measures the smoothness (by estimating the differences between neighboring samples of  $\mathbf{b}_j$ ) and  $\varphi : \mathbb{R} \rightarrow \mathbb{R}$  is an edge-preserving function applied component-wise [8].

### 1.21.4.5 Large-scale NMF

In many applications, especially for dimension reduction applications, the data matrix  $\mathbf{Y} \in \mathbb{R}^{I \times T}$  can be very large (with millions of entries), but it can be approximately factorized using a much smaller number of nonnegative components ( $J$ ), that is,  $J \ll I$  and  $J \ll T$ . Then the problem  $\mathbf{Y} \approx \mathbf{AB}^T$  becomes highly redundant and we do not need to use the information about all entries of  $\mathbf{Y}$  in order to estimate precisely the factor matrices  $\mathbf{A} \in \mathbb{R}^{I \times J}$  and  $\mathbf{B} \in \mathbb{R}^{T \times J}$ . In other words, to solve the large-scale NMF problem we do not need to know the whole data matrix, but only a small random part of it. Such an approach can outperform considerably the standard NMF methods, especially for extremely overdetermined systems.

There are several strategies to choose the columns and rows of the input data matrix [120, 123, 142, 143]. In Eqs. (21.168), (21.169), and (21.176), the major bottleneck is caused by the matrix multiplications with the large matrices  $\mathbf{Y}$  and  $\mathbf{Y}_i$ . If these large matrices can be replaced by much smaller matrices, the efficiency of the NMF\_MU and HALS algorithm can be improved. For this reason we consider the following cost function:

$$\begin{aligned} \min_{\tilde{\mathbf{A}}, \tilde{\mathbf{B}}; \mathbf{A}, \mathbf{B}} D(\tilde{\mathbf{A}}, \tilde{\mathbf{B}}; \mathbf{A}, \mathbf{B}) &= \|\mathbf{Y} - \tilde{\mathbf{A}}\tilde{\mathbf{B}}^T\|_F^2 + \|\tilde{\mathbf{A}}\tilde{\mathbf{B}}^T - \mathbf{AB}^T\|_F^2, \\ \text{s.t. } \mathbf{A} &\in \mathbb{R}_+^{I \times J}, \mathbf{B} \in \mathbb{R}_+^{T \times J}, \tilde{\mathbf{A}} \in \mathbb{R}^{I \times R}, \tilde{\mathbf{B}} \in \mathbb{R}^{T \times R}, \end{aligned} \quad (21.181)$$

where the data matrix is first approximated by any low-rank approximation  $\mathbf{Y} \approx \tilde{\mathbf{A}}\tilde{\mathbf{B}}^T$  [144]. Therefore, we can solve (21.181) instead of (21.154) with the same global minimum.

We call this procedure low-rank approximation based NMF (LRA-NMF) [144], which can be performed as follows:

- Step 1: Perform the low-rank approximation using  $\min\{\|\mathbf{Y} - \tilde{\mathbf{A}}\tilde{\mathbf{B}}^T\|_F^2\}$ , where  $\tilde{\mathbf{A}}$  and  $\tilde{\mathbf{B}}$  are of low-rank  $J$ , without imposing any nonnegativity constraints;
- Step 2: Perform nonnegative matrix factorization using  $\min\{\|\tilde{\mathbf{A}}\tilde{\mathbf{B}}^T - \mathbf{AB}^T\|_F^2\}$  with fixed and known  $\tilde{\mathbf{A}}, \tilde{\mathbf{B}}$ , where  $\mathbf{A}, \mathbf{B}$  are nonnegative and possibly with additional constraints such as sparsity, smoothness, etc.

The Step 1 of the LRA-NMF can be solved efficiently by using standard PCA or truncated SVD or any other efficient low-rank approximation algorithms such as CUR decomposition. In the Step 2, we assume that the optimal  $\tilde{\mathbf{A}}$  and  $\tilde{\mathbf{B}}$  have been obtained and then  $\min\{\|\tilde{\mathbf{A}}\tilde{\mathbf{B}}^T - \mathbf{AB}^T\|_F^2\}$  can be solved.

From (21.168)–(21.169) by simply substituting the low-rank approximation  $\mathbf{Y} \approx \tilde{\mathbf{A}}\tilde{\mathbf{B}}^T$ , it yields

$$\mathbf{A} \leftarrow \mathbf{A} \circledast \left[ (\tilde{\mathbf{A}}(\tilde{\mathbf{B}}^T \mathbf{B}) - \alpha_{\mathbf{A}} \mathbf{1}_{I \times J}) \right]_+ \oslash (\mathbf{A}\mathbf{B}^T \mathbf{B}), \quad (21.182)$$

$$\mathbf{B} \leftarrow \mathbf{B} \circledast \left[ (\tilde{\mathbf{B}}(\tilde{\mathbf{A}}^T \mathbf{A}) - \alpha_{\mathbf{B}} \mathbf{1}_{T \times J}) \right]_+ \oslash (\mathbf{B}\mathbf{A}^T \mathbf{A}). \quad (21.183)$$

The algorithm based on (21.182)–(21.183) is named as LRA-NMF\_MU. At a first glance there is not a big difference between it (21.168)–(21.169). However, we should note that the dimensionality of  $\tilde{\mathbf{A}}, \tilde{\mathbf{B}}$  is much smaller than that of  $\mathbf{Y}$ . As a matter of fact, LRA-NMF\_MU has much lower time complexity of  $\mathcal{O}(TJ^2)$  and space complexity of  $\mathcal{O}(TJ)$ . In other words, LRA-NMF\_MU is about  $I/J$  times faster than NMF\_MU. In addition, we do not need to load the whole matrix  $\mathbf{Y}$  in the memory during the iterations. Instead,  $\tilde{\mathbf{A}}, \tilde{\mathbf{B}}$  are employed explicitly during the NMF iterations.

Similarly to the HALS algorithm, let  $\mathbf{Y}_j = \tilde{\mathbf{A}}\tilde{\mathbf{B}} - \sum_{p \neq j} \mathbf{a}_p \mathbf{b}_p^T$  and the formulas in (21.176) become

$$\mathbf{b}_j \leftarrow \frac{1}{\mathbf{a}_j^T \mathbf{a}_j} \left[ \tilde{\mathbf{B}}(\tilde{\mathbf{A}}^T \mathbf{a}_j) - \mathbf{B}_j(\mathbf{A}_j^T \mathbf{a}_j) \right]_+, \quad (21.184)$$

$$\mathbf{a}_j \leftarrow \frac{1}{\mathbf{b}_j^T \mathbf{b}_j} \left[ \tilde{\mathbf{A}}(\tilde{\mathbf{B}}^T \mathbf{b}_j) - \mathbf{A}_j(\mathbf{B}_j^T \mathbf{b}_j) \right]_+, \quad (21.185)$$

where  $\mathbf{A}_j \in \mathbb{R}^{I \times (J-1)}$  and  $\mathbf{B}_j \in \mathbb{R}^{T \times (J-1)}$  are the sub-matrices of  $\mathbf{A}$  and  $\mathbf{B}$  obtained by removing their  $j$ th columns. The algorithm based on (21.184) is called LRANMF\_HALS. The time complexity of LRA-NMF\_HALS per iteration is  $\mathcal{O}(NR)$  and the space complexity is only  $\mathcal{O}(NR)$ .

Similar approach can be applied to nonnegative tensor factorization (NTF) (see Section 1.21.5).

### 1.21.4.6 Robust NMF algorithms

In many applications the observed data sets are corrupted by large noise (not necessary with a Gaussian distribution). In such cases we need to use a suitably chosen cost function or divergence.

#### 1.21.4.6.1 The alpha-beta divergences

For positive measures  $\mathbf{Y}$  and  $\hat{\mathbf{Y}}$  consider the following generalized dissimilarity measure, which we will refer to as the AB-divergence [130]:

$$D_{AB}^{(\alpha, \beta)}(\mathbf{Y} \| \hat{\mathbf{Y}}) = -\frac{1}{\alpha\beta} \sum_{it} \left( y_{it}^\alpha \hat{y}_{it}^\beta - \frac{\alpha}{\alpha + \beta} y_{it}^{\alpha+\beta} - \frac{\beta}{\alpha + \beta} \hat{y}_{it}^{\alpha+\beta} \right) \quad (21.186)$$

for  $\alpha, \beta, \alpha + \beta \neq 0$ ,

or equivalently

$$D_{AB}^{(\alpha, \lambda-\alpha)}(\mathbf{Y} \| \hat{\mathbf{Y}}) = \frac{1}{(\alpha - \lambda)\alpha} \sum_{it} \left( y_{it}^\alpha \hat{y}_{it}^{\lambda-\alpha} - \frac{\alpha}{\lambda} y_{it}^\lambda - \frac{\lambda - \alpha}{\lambda} \hat{y}_{it}^\lambda \right), \quad (21.187)$$

for  $\alpha \neq 0, \alpha \neq \lambda, \lambda = \alpha + \beta \neq 0$ ,

We shall now illustrate how a suitable choices of the  $(\alpha, \beta)$  parameters simplify the AB-divergence into some existing divergences, including the well-known Alpha- and Beta-divergences [8, 145, 146].

When  $\alpha + \beta = 1$  the AB-divergence reduces to the Alpha-divergence [130, 145, 147].

On the other hand, when  $\alpha = 1$ , it reduces to the Beta-divergence [19, 146, 148, 149].

The AB-divergence reduces to the standard Kullback–Leibler (KL) divergence ( $D_{KL}(\cdot, \cdot)$ ) for  $\alpha = 1$  and  $\beta = 0$

$$D_{AB}^{(1,0)}(\mathbf{Y} \| \hat{\mathbf{Y}}) = D_{KL}(\mathbf{Y} \| \hat{\mathbf{Y}}) = \sum_{it} \left( y_{it} \ln \frac{y_{it}}{\hat{y}_{it}} - y_{it} + \hat{y}_{it} \right), \quad (21.188)$$

and it reduces to the standard Itakura-Saito divergence ( $D_{IS}(\cdot, \cdot)$ ) for  $\alpha = 1$  and  $\beta = -1$  [19, 148]

$$D_{AB}^{(1,-1)}(\mathbf{Y} \| \hat{\mathbf{Y}}) = D_{IS}(\mathbf{Y} \| \hat{\mathbf{Y}}) = \sum_{it} \left( \ln \frac{\hat{y}_{it}}{y_{it}} + \frac{y_{it}}{\hat{y}_{it}} - 1 \right). \quad (21.189)$$

Using the  $1 - \alpha$  deformed logarithm defined as

$$\ln_{1-\alpha}(z) = \begin{cases} \frac{z^\alpha - 1}{\alpha}, & \alpha \neq 0, \\ \ln z, & \alpha = 0, \end{cases} \quad (21.190)$$

where  $z > 0$ , we observe that the AB-divergence is symmetric with respect to both arguments for  $\alpha = \beta \neq 0$  and it takes the form of a metric distance

$$D_{AB}^{(\alpha,\alpha)}(\mathbf{Y} \| \hat{\mathbf{Y}}) = D_E(\ln_{1-\alpha}(\mathbf{Y}) \| \ln_{1-\alpha}(\hat{\mathbf{Y}})) = \frac{1}{2} \sum_{it} (\ln_{1-\alpha}(y_{it}) - \ln_{1-\alpha}(\hat{y}_{it}))^2, \quad (21.191)$$

in the transform domain  $\phi(x) = \ln_{1-\alpha}(x)$ . As particular cases, it includes the scaled squared Euclidean distance (for  $\alpha = 1$ ) and the Hellinger distance (for  $\alpha = 0.5$ ).

#### 1.21.4.6.2 The derivation of robust NMF algorithms based on the AB-divergence

We can easily derive NMF algorithms by employing the AB-divergence with  $\mathbf{Y} = [y_{it}] \in \mathbb{R}_+^{I \times T}$ ,  $\hat{\mathbf{Y}} = [\hat{y}_{it}] = \mathbf{AB}^T \in \mathbb{R}_+^{I \times T}$ , where  $\hat{y}_{it} = [\mathbf{AB}^T]_{it} = \sum_j a_{ij} b_{tj}$ . In this case the gradient of the AB-divergence (21.187) can be expressed in a compact form (for any  $\alpha, \beta \in \mathbf{R}$ ) in terms of  $1 - \alpha$  deformed logarithm (see (21.190))

$$\frac{\partial D_{AB}^{(\alpha, \beta)}}{\partial b_{tj}} = - \sum_{i=1}^I \hat{y}_{it}^{\lambda-1} a_{ij} \ln_{1-\alpha} \left( \frac{y_{it}}{\hat{y}_{it}} \right), \quad (21.192)$$

$$\frac{\partial D_{AB}^{(\alpha, \beta)}}{\partial a_{ij}} = - \sum_{t=1}^T \hat{y}_{it}^{\lambda-1} b_{tj} \ln_{1-\alpha} \left( \frac{y_{it}}{\hat{y}_{it}} \right). \quad (21.193)$$

The multiplicative learning rules are gradient descent based in the natural parameter space  $\phi(x)$  of the proposed divergence:

$$a_{ij} \leftarrow \phi^{-1} \left( \phi(a_{ij}) - \eta_{ij} \frac{\partial D_{AB}^{(\alpha, \beta)}}{\partial \phi(a_{ij})} \right), \quad b_{tj} \leftarrow \phi^{-1} \left( \phi(b_{tj}) - \eta_{tj} \frac{\partial D_{AB}^{(\alpha, \beta)}}{\partial \phi(b_{tj})} \right). \quad (21.194)$$

These updates can be considered as a generalization of the exponentiated gradient (EG) algorithm [130, 150].

In general, such a nonlinear scaling (or transformation) provides a stable solution and the resulting gradients are much better behaved in the  $\phi$  space. We use the  $1 - \alpha$  deformed logarithm transformation  $\phi(z) = \ln_{1-\alpha}(z)$ , whose inverse transformation is the  $1 - \alpha$  deformed exponential

$$\phi^{-1}(z) = \exp_{1-\alpha}(z) = \begin{cases} \exp(z) & \text{for } \alpha = 0, \\ (1 + \alpha z)^{\frac{1}{\alpha}} & \text{for } \alpha \neq 0 \text{ and } 1 + \alpha z \geq 0, \\ 0 & \text{for } \alpha \neq 0 \text{ and } 1 + \alpha z < 0. \end{cases} \quad (21.195)$$

For positive measures  $z > 0$ , the direct transformation  $\phi(z)$  and the composition  $\phi^{-1}(\phi(z))$  are bijective functions which define a one to one correspondence, so we have  $\phi^{-1}(\phi(z)) = z$ .

By choosing suitable learning rates

$$\eta_{tj} = \frac{b_{tj}^{2\alpha-1}}{\sum_{i=1}^I a_{ij} \hat{y}_{it}^{\lambda-1}}, \quad \eta_{ij} = \frac{a_{ij}^{2\alpha-1}}{\sum_{t=1}^T b_{tj} \hat{y}_{it}^{\lambda-1}}. \quad (21.196)$$

a generalized multiplicative NMF algorithm (refereed to as the AB-multiplicative NMF algorithm) is obtained as [130]:

$$\begin{aligned} b_{tj} &\leftarrow b_{tj} \exp_{1-\alpha} \left( \sum_{i=1}^I \frac{a_{ij} \hat{y}_{it}^{\lambda-1}}{\sum_{i=1}^I a_{ij} \hat{y}_{it}^{\lambda-1}} \ln_{1-\alpha} \left( \frac{y_{it}}{\hat{y}_{it}} \right) \right), \\ a_{ij} &\leftarrow a_{ij} \exp_{1-\alpha} \left( \sum_{t=1}^T \frac{b_{tj} \hat{y}_{it}^{\lambda-1}}{\sum_{t=1}^T b_{tj} \hat{y}_{it}^{\lambda-1}} \ln_{1-\alpha} \left( \frac{y_{it}}{\hat{y}_{it}} \right) \right), \end{aligned} \quad (21.197)$$

In these equations, the deformed logarithm of order  $1 - \alpha$  of the quotients  $y_{it}/\hat{y}_{it}$  plays a key role in controlling the relative error terms whose weighted mean provides the multiplicative corrections. This deformation in the relative error is controlled by the parameter  $\alpha$ . The parameter  $\alpha > 1$  gives more relevance to large values of the quotient, while the case of  $\alpha < 1$  puts more emphasis on smaller values of the quotient. On the other hand, the parameter  $\lambda - 1$  (where  $\lambda = \alpha + \beta$ ) controls the influence of the values of the approximation ( $\hat{y}_{it}$ ) on the weighing of the deformed error terms. For  $\lambda = 1$ , this influence disappears.

It is interesting to note that the multiplicative term of the main updates

$$M_\alpha(\mathbf{z}, \mathbf{w}, S) = \exp_{1-\alpha} \left( \frac{1}{\sum_{i \in S} w_i} \sum_{i \in S} w_i \ln_{1-\alpha}(z_i) \right), \quad (21.198)$$

can be interpreted as a weighted generalized mean across the elements with indices in the set  $S$ .

Depending on the value of  $\alpha$  we obtain the following particular cases: the minimum of the vector  $\mathbf{z}$  (for  $\alpha \rightarrow -\infty$ ), its weighted harmonic mean ( $\alpha = -1$ ), the weighted geometric mean ( $\alpha = 0$ ), the arithmetic mean ( $\alpha = 1$ ), the weighted quadratic mean ( $\alpha = 2$ ) and the maximum of the vector ( $\alpha \rightarrow \infty$ ), i.e.,

$$M_\alpha(\mathbf{z}, \mathbf{w}, \{1, \dots, n\}) = \begin{cases} \min\{z_1, \dots, z_n\}, & \alpha \rightarrow -\infty, \\ (\sum_{i=1}^n w_i) \left( \sum_{i=1}^n \frac{w_i}{z_i} \right)^{-1}, & \alpha = -1, \\ \prod_{i=1}^n z^{\frac{w_i}{\sum_{i=1}^n w_i}}, & \alpha = 0, \\ \frac{1}{\sum_{i=1}^n w_i} \sum_{i=1}^n w_i z_i, & \alpha = 1, \\ \left( \frac{1}{\sum_{i=1}^n w_i} \sum_{i=1}^n w_i z_i^2 \right)^{1/2}, & \alpha = 2, \\ \max\{z_1, \dots, z_n\}, & \alpha \rightarrow \infty. \end{cases} \quad (21.199)$$

The generalized weighted means are monotonically increasing functions of  $\alpha$ , i.e., if  $\alpha_1 < \alpha_2$ , then

$$M_{\alpha_1}(\mathbf{z}, \mathbf{w}, S) < M_{\alpha_2}(\mathbf{z}, \mathbf{w}, S). \quad (21.200)$$

Thus, by increasing the values of  $\alpha$ , we put more emphasis on large relative errors in the update formulas (21.197).

In the special case of  $\alpha \neq 0$ , the above update rules can be simplified as:

$$\boxed{a_{ij} \leftarrow a_{ij} \left( \frac{\sum_{t=1}^T b_{tj} y_{it}^\alpha \hat{y}_{it}^{\beta-1}}{\sum_{t=1}^T b_{tj} \hat{y}_{it}^{\alpha+\beta-1}} \right)^{1/\alpha}, \quad b_{tj} \leftarrow b_{tj} \left( \frac{\sum_{i=1}^I a_{ij} y_{it}^\alpha \hat{y}_{it}^{\beta-1}}{\sum_{i=1}^I a_{ij} \hat{y}_{it}^{\alpha+\beta-1}} \right)^{1/\alpha}}, \quad (21.201)$$

where  $\hat{y}_{it} = [\mathbf{A}\mathbf{B}^T]_{it}$  and at every iteration the columns of  $\mathbf{A}$  are normalized to the unit length. The above multiplicative update rules can be written in a compact matrix form as

$$\mathbf{A} \leftarrow \mathbf{A} \circledast [(\mathbf{Z}\mathbf{B}) \oslash (\hat{\mathbf{Y}}^{[\alpha+\beta-1]} \mathbf{B})]^{[1/\alpha]}, \quad (21.202)$$

$$\mathbf{B} \leftarrow \mathbf{B} \circledast [(\mathbf{Z}^T \mathbf{A}) \oslash ((\hat{\mathbf{Y}}^{[\alpha+\beta-1]})^T \mathbf{A})]^{[1/\alpha]}, \quad (21.203)$$

where  $\hat{\mathbf{Y}} = \max\{\mathbf{A}\mathbf{X}, \varepsilon\}$  and  $\mathbf{Z} = \mathbf{Y}^{[\alpha]} \circledast \hat{\mathbf{Y}}^{[\beta-1]}$ .

In order to address the scaling indeterminacy between the columns of  $\mathbf{A}$  and the rows of  $\mathbf{X}$ , in practice, after each iteration, we can usually evaluate the  $l_1$ -norm of the columns of  $\mathbf{A}$  and normalize the elements of the matrices as  $a_{ij} \leftarrow a_{ij} / \sum_p a_{pj}$ . This normalization does not alter  $\hat{\mathbf{Y}} = \mathbf{AX}$ , thus, preserving the value of the AB-divergence.

The above multiplicative update rules are natural extensions of many existing algorithms for NMF, including the ISRA, EMML, Lee-Seung algorithms and Alpha- and Beta-multiplicative NMF algorithms [8, 130]. For example, by selecting  $\alpha + \beta = 1$ , we obtain the Alpha-NMF algorithm, for  $\alpha = 1$ , we have Beta-NMF algorithms, for  $\alpha = -\beta \neq 0$  we obtain a family of multiplicative NMF algorithms based on the extended Itakura-Saito distance [19, 148]. Furthermore, for  $\alpha = 1$  and  $\beta = 1$ , we obtain the ISRA algorithm and for  $\alpha = 1$  and  $\beta = 0$  we obtain the EMML (Expectation Maximization Maximum Likelihood) algorithm.

It is important to note that in low-rank approximations, we do not need access to all input data  $y_{it}$ . In other words, the above algorithms can be applied for low-rank approximations even if some data are missing or they are purposely omitted or ignored. For large-scale problems the learning rules can be written in a more efficient form by restricting the generalized mean only to those elements whose indices belong to the preselected subsets  $S_T \subset \{1, \dots, T\}$  and  $S_I \subset \{1, \dots, I\}$  of the whole set of indices [130].

Using a duality property ( $D_{AB}^{(\alpha, \beta)}(\mathbf{Y} \| \hat{\mathbf{Y}}) = D_{AB}^{(\beta, \alpha)}(\hat{\mathbf{Y}} \| \mathbf{Y})$ ) of the AB-divergence, we obtain now the dual update rules for  $\beta \neq 0$

$$\boxed{a_{ij} \leftarrow a_{ij} \left( \frac{\sum_{t \in S_T} b_{tj} y_{it}^{\alpha-1} \hat{y}_{it}^\beta}{\sum_{t \in S_T} b_{tj} y_{it}^{\alpha+\beta-1}} \right)^{1/\beta}, \quad b_{tj} \leftarrow b_{tj} \left( \frac{\sum_{i \in S_I} a_{ij} y_{it}^{\alpha-1} \hat{y}_{it}^\beta}{\sum_{i \in S_I} a_{ij} y_{it}^{\alpha+\beta-1}} \right)^{1/\beta}.} \quad (21.204)$$

#### 1.21.4.6.3 Why is the AB-divergence potentially robust?

To illustrate the role of the hyperparameters  $\alpha$  and  $\beta$  on the robustness of the AB-divergence with respect to errors and noises we will compare the behavior of the AB-divergence with the standard Kullback–Leibler divergence [130]. We will assume, without loss of generality, that the proposed factorization model  $\hat{\mathbf{Y}}$  (for given noisy (observed)  $\mathbf{Y}$ ) is a function of the vector of parameters  $\theta$  and that each of its elements  $\hat{y}_{it}(\theta) > 0$  is non-negative for a certain range of the parameters, say  $\Theta$ .

The estimator  $\hat{\theta}$  obtained for the Kullback-Leibler divergence between two discrete positive measures  $\mathbf{Y}$  and  $\hat{\mathbf{Y}}$ , is the solution of

$$\frac{\partial D_{KL}(\mathbf{Y} \| \hat{\mathbf{Y}})}{\partial \theta} = - \sum_{it} \frac{\partial \hat{y}_{it}}{\partial \theta} \ln_0 \left( \frac{y_{it}}{\hat{y}_{it}} \right) = \mathbf{0}, \quad (21.205)$$

while, for the Beta-divergence, the estimator solves

$$\frac{\partial D_B^{(\beta)}(\mathbf{Y} \| \hat{\mathbf{Y}})}{\partial \theta} = - \sum_{it} \frac{\partial \hat{y}_{it}}{\partial \theta} \hat{y}_{it}^\beta \ln_0 \left( \frac{y_{it}}{\hat{y}_{it}} \right) = \mathbf{0}. \quad (21.206)$$

The main difference between these equations is in the weighting factors  $\hat{y}_{it}^\beta$  for the Beta-divergence which are controlled by the parameter  $\beta$ . In the context of probability distributions, these weighting

factors may control the influence of the likelihood ratios  $y_{it}/\hat{y}_{it}$ . The parameter  $\beta$  determines a tradeoff between robustness to outliers (for  $\beta > 0$ ) and efficiency (for  $\beta$  near 0) (see e.g., [130]). In the special case of  $\beta = 1$  the Euclidean distance is obtained, which is known to be more robust and less efficient than the Kullback–Leibler divergence (for  $\beta = 0$ ).

On the other hand, for the Alpha-divergence, the estimating equation takes a different form

$$\frac{\partial D_A^{(\alpha)}(\mathbf{Y} \parallel \hat{\mathbf{Y}})}{\partial \theta} = - \sum_{it} \frac{\partial \hat{y}_{it}}{\partial \theta} \ln_{1-\alpha} \left( \frac{y_{it}}{\hat{y}_{it}} \right) = \mathbf{0}. \quad (21.207)$$

In this case, the influence of the values of individual ratios  $y_{it}/\hat{y}_{it}$  is controlled not by weighting factors but by the deformed logarithm of order  $1 - \alpha$ . This feature can be interpreted as a zoom or over-weight of the interesting details of the likelihood ratio. For  $\alpha > 1$  (a zoom-out), we emphasize the relative importance of larger values of the ratio  $y_{it}/\hat{y}_{it}$ , whereas for  $\alpha < 1$  (a zoom-in), we put more emphasis on smaller values of  $y_{it}/\hat{y}_{it}$ . The major consequence is the inclusive ( $\alpha \rightarrow \infty$ ) and exclusive ( $\alpha \leftarrow -\infty$ ) behavior of the Alpha-divergence discussed by [147].

The estimating equation for the AB divergence combines both effects:

$$\frac{\partial D_{AB}^{(\alpha, \beta)}(\mathbf{Y} \parallel \hat{\mathbf{Y}})}{\partial \theta} = - \sum_{it} \frac{\partial \hat{y}_{it}}{\partial \theta} \underbrace{\hat{y}_{it}^{\alpha+\beta-1}}_{\text{weights}} \underbrace{\ln_{1-\alpha}(y_{it}/\hat{y}_{it})}_{\alpha\text{-zoom}} = \mathbf{0}, \quad (21.208)$$

and therefore is much more flexible and powerful regarding robustness to error and noise. Depending on the value of  $\alpha$  we can zoom-in or zoom-out the interesting sets of the ratios  $y_{it}/\hat{y}_{it}$  and simultaneously weight these ratios by scaling factors  $\hat{y}_{it}^{\lambda-1}$  controlled by the parameter  $\lambda = \alpha + \beta$ . Therefore, the parameter  $\alpha$  can be used to control the influence of large or small ratios in the estimator, while the parameter  $\beta$  provides some control on the weighting of the ratios depending on the demand to provide better fit to larger or smaller values of the model [130].

#### 1.21.4.7 Convulsive NMF

The Convulsive NMF (CNMF) is a natural extension and generalization of the standard NMF. In the CNMF, we process a set of nonnegative matrices or patterns which are shifted (or time delayed) versions of the primary matrix  $\mathbf{X}$  [151]. In its simplest form the CNMF can be described as

$$\mathbf{Y} = \sum_{r=0}^{R-1} \mathbf{A}_r \mathbf{X} \mathbf{T}_r + \mathbf{E} = \sum_{r=0}^{R-1} \mathbf{A}_r \overset{r \rightarrow}{\mathbf{X}} + \mathbf{E}, \quad (21.209)$$

where  $\mathbf{Y} \in \mathbb{R}_+^{I \times T}$  is a given input data matrix,  $\mathbf{A}_r \in \mathbb{R}_+^{I \times J}$  is a set of unknown nonnegative basis matrices,  $\mathbf{X} = \overset{0 \rightarrow}{\mathbf{X}} \in \mathbb{R}_+^{J \times T}$  is a matrix representing primary sources or patterns, and  $\overset{r \rightarrow}{\mathbf{X}}$  is a shifted by  $r$  columns version of  $\mathbf{X}$ . In other words,  $\overset{r \rightarrow}{\mathbf{X}}$  means that the columns of  $\mathbf{X}$  are shifted to the right  $r$  spots (columns), while the entries in the columns shifted into the matrix from the outside are set to zero. We denote a shift matrix  $\mathbf{T}_r$  of size  $T \times T$  by a binary matrix with ones only on the  $r$ th superdiagonal for

$r > 0$ , or on the  $r$ th subdiagonal for  $r < 0$ , and zeroes elsewhere.  $\overset{r \rightarrow}{\mathbf{X}} = \mathbf{X}\mathbf{T}_r$  is an  $r$  column shifted version of  $\mathbf{X}$  to the right, with the columns shifted in from outside the matrix set to zero. Note that,  $\overset{0 \rightarrow}{\mathbf{X}} = \overset{\leftarrow 0}{\mathbf{X}} = \mathbf{X}$ .

The shift operator can be illustrated by the following simple example:

$$\mathbf{X} = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix}, \quad \overset{1 \rightarrow}{\mathbf{X}} = \begin{bmatrix} 0 & 1 & 2 \\ 0 & 4 & 5 \end{bmatrix}, \quad \overset{2 \rightarrow}{\mathbf{X}} = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 4 \end{bmatrix}, \quad \overset{\leftarrow 1}{\mathbf{X}} = \begin{bmatrix} 2 & 3 & 0 \\ 5 & 6 & 0 \end{bmatrix}.$$

The goal is to estimate the input sources represented by the nonnegative matrix  $\mathbf{X} \in \mathbb{R}_+^{J \times T}$  (typically,  $T \gg J$ ) and to identify the convoluting system, i.e., to estimate a set of nonnegative matrices  $\{\mathbf{A}_0, \mathbf{A}_1, \dots, \mathbf{A}_{R-1}\}$  ( $\mathbf{A}_r \in \mathbb{R}_+^{I \times J}$ ,  $r = 0, 1, \dots, R-1$ ) knowing only the input data matrix  $\mathbf{Y} \in \mathbb{R}^{I \times T}$ . Each operator  $\mathbf{T}_r$  ( $r = 0, 1, \dots, R-1$ ) performs a horizontal shift of the columns in  $\mathbf{X}$  by one spot.

In the simplest case scenario, update rules for  $\mathbf{A}_r$  and  $\mathbf{X}$  can be derived by minimizing a standard cost function:

$$D(\mathbf{Y} \|\widehat{\mathbf{Y}}) = \frac{1}{2} \|\mathbf{Y} - \widehat{\mathbf{Y}}\|_F^2 = \frac{1}{2} \|\mathbf{Y} - \sum_{r=0}^{R-1} \mathbf{A}_r \mathbf{X} \mathbf{T}_r\|_F^2. \quad (21.210)$$

Note that, the approximation of  $\mathbf{Y}$  can be expressed as a standard NMF problem with rank- $JR$  as

$$\mathbf{Y} = [\mathbf{A}_0 \ \mathbf{A}_1 \ \dots \ \mathbf{A}_{R-1}] \begin{bmatrix} \mathbf{X} \\ \overset{1 \rightarrow}{\mathbf{X}} \\ \vdots \\ \overset{(R-1) \rightarrow}{\mathbf{X}} \end{bmatrix} + \mathbf{E} = \overline{\mathbf{AB}}^T + \mathbf{E}, \quad (21.211)$$

where  $\overline{\mathbf{A}} = [\mathbf{A}_0, \mathbf{A}_1, \dots, \mathbf{A}_{R-1}] \in \mathbb{R}^{I \times RJ}$  and  $\overline{\mathbf{B}} = [\mathbf{X}, \overset{1 \rightarrow}{\mathbf{X}}, \dots, \overset{(R-1) \rightarrow}{\mathbf{X}}]^T \in \mathbb{R}^{RT \times J}$ .

From (21.209) and (21.210), we can apply any existing standard NMF algorithm. For example, we can employ a simple multiplicative update rule using the ISRA algorithm [8]:

$$\overline{\mathbf{A}} \leftarrow \overline{\mathbf{A}} \circledast (\mathbf{Y}\overline{\mathbf{B}}) \oslash (\widehat{\mathbf{Y}}\overline{\mathbf{B}}) = \overline{\mathbf{A}} \circledast [\mathbf{Y}\mathbf{T}_r^T \mathbf{X}^T]_{r=0}^{R-1} \oslash [\widehat{\mathbf{Y}}\mathbf{T}_r^T \mathbf{X}^T]_{r=0}^{R-1}, \quad (21.212)$$

which can be rewritten for the component matrices  $\mathbf{A}_r$ ,

$$\mathbf{A}_r \leftarrow \mathbf{A}_r \circledast (\mathbf{Y}\mathbf{T}_r^T \mathbf{X}^T) \oslash (\widehat{\mathbf{Y}}\mathbf{T}_r^T \mathbf{X}^T) \quad (r = 0, 1, \dots, R-1). \quad (21.213)$$

$$\mathbf{X} \leftarrow \mathbf{X} \circledast \left( \sum_{r=0}^{R-1} \mathbf{A}_r^T \mathbf{Y} \mathbf{T}_r^T \right) \oslash \left( \sum_{r=0}^{R-1} \mathbf{A}_r^T \widehat{\mathbf{Y}} \mathbf{T}_r^T \right). \quad (21.214)$$

The update rules (21.213)–(21.214) are particular cases of the multiplicative algorithm for CNMF2D proposed first in [152] and extended in [153].

For the more general scenarios, the CNMF searches for basis patterns which shift vertically [154] or horizontally [155] or in both directions [152] in the nonnegative data matrix. More advanced and efficient algorithms for generalized and flexible CNMF models can be found in [153, 156].

The CNMF has found a number of applications in music analysis, source detection, image processing [155, 157]. In the CNMF model, temporal continuity exhibited by many audio signals are usually expressed efficiently in the time-frequency domain, especially for signals whose frequencies vary with time.

## 1.21.5 Future directions: constrained multi-block tensor factorizations and multilinear blind source separation

In this section, we discuss an important problem: how to extend established and efficient algorithms for constrained matrix factorization techniques (especially, PCA, ICA and NMF) to tensor scenarios. In what follows, this approach is referred to as multiway Generalized Component Analysis (GCA) or multilinear blind source separation (MBSS).

The constrained matrix factorization techniques are widely applied to PCA, ICA, and NMF, dimensionality reduction, data compression and feature extraction. Although standard 2D BSS (constrained matrix factorizations) approaches, such as PCA, ICA, NMF, and their variants, are invaluable tools for BSS, feature extraction and selection, dimensionality reduction, noise reduction, and data mining, it should be noted that they have only two modes or two-way representations (typically, space and time), and their use is therefore limited. In many applications the data structures often contain higher-order ways (modes) such as subjects, groups, trials, classes, and conditions, together with the intrinsic dimensions of space, time, and frequency. For example, studies in neuroscience often involve multiple subjects (people or animals) and trials, leading to experimental data structures conveniently represented by multiway arrays or blocks of multiway data.

How to find informative and sparse/compact representations of experimental or measured multi-dimensional large tensor data is a fundamental and challenging problem in data mining and data analysis.

### 1.21.5.1 Basic tensor multilinear operations

Tensors are denoted by underlined capital boldface letters, e.g.,  $\underline{\mathbf{Y}} \in \mathbb{R}^{I_1 \times I_2 \times \dots \times I_N}$ . The order of a tensor is the number of modes, also known as ways or dimensions (e.g., space, time, frequency, subjects, trials, classes, groups, and conditions). In contrast, matrices (second-order tensors) are denoted by boldface capital letters, e.g.,  $\mathbf{Y}$ ; vectors (first-order tensors) are denoted by boldface lowercase letters, e.g., the columns of the matrix  $\mathbf{A}$  are denoted by  $\mathbf{a}_j$  and scalars are denoted by lowercase letters, e.g.,  $a_{ij}$ .

Throughout this section, standard notations and basic tensor operations proposed in the literature [5, 8] are used. Specifically, the mode- $n$  product

$$\underline{\mathbf{Y}} = \underline{\mathbf{G}} \times_n \mathbf{A} \quad (21.215)$$

of a tensor  $\underline{\mathbf{G}} \in \mathbb{R}^{J_1 \times J_2 \times \dots \times J_N}$  and a matrix  $\mathbf{A} \in \mathbb{R}^{I \times J_n}$  is a tensor  $\underline{\mathbf{Y}} \in \mathbb{R}^{J_1 \times \dots \times J_{n-1} \times I \times J_{n+1} \times \dots \times J_N}$ , with elements

$$y_{j_1, j_2, \dots, j_{n-1}, i, j_{n+1}, \dots, j_N} = \sum_{j_n=1}^{J_n} (g_{j_1, j_2, \dots, j_N})(a_{i, j_n}). \quad (21.216)$$

The mode- $n$  multiplication of a tensor  $\underline{\mathbf{Y}} \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$  by a vector  $\mathbf{a} \in \mathbb{R}^{I_n}$  is denoted by

$$\underline{\mathbf{Y}} \bar{\times}_n \mathbf{a} \quad (21.217)$$

and has dimension  $I_1 \times \cdots \times I_{n-1} \times I_{n+1} \times \cdots \times I_N$ , that is,

$$\underline{\mathbf{Z}} = \underline{\mathbf{Y}} \bar{\times}_n \mathbf{a} \in \mathbb{R}^{I_1 \times \cdots \times I_{n-1} \times I_{n+1} \times \cdots \times I_N}, \quad (21.218)$$

and element-wise, we have

$$z_{i_1, i_2, \dots, i_{n-1}, i_{n+1}, \dots, i_N} = \sum_{i_n=1}^{I_n} y_{i_1, i_2, \dots, i_N} a_{i_n}. \quad (21.219)$$

A bar over the operator  $\times$  indicates a contracted product. For example, using this notation we can write:  $\mathbf{Y}\mathbf{w} = \underline{\mathbf{Y}} \bar{\times}_2 \mathbf{w}$  and  $\mathbf{v}^T \mathbf{Y}\mathbf{w} = \underline{\mathbf{Y}} \bar{\times}_1 \mathbf{v} \bar{\times}_2 \mathbf{w}$ . Multiplying a third-order tensor by vectors in two modes results in a first-order tensor (a vector); multiplying it in all modes results in a scalar. We can exchange the order of multiplication by the using following rule:

$$\underline{\mathbf{Y}} \bar{\times}_m \mathbf{a} \bar{\times}_n \mathbf{b} = (\underline{\mathbf{Y}} \bar{\times}_m \mathbf{a}) \bar{\times}_n \mathbf{b} = (\underline{\mathbf{Y}} \bar{\times}_n \mathbf{b}) \bar{\times}_m \mathbf{a}, \quad (21.220)$$

For example, the mode- $n$  multiplication of a tensor  $\underline{\mathbf{G}} \in \mathbb{R}^{J \times R \times P}$  by vectors  $\mathbf{a} \in \mathbb{R}^J$ ,  $\mathbf{b} \in \mathbb{R}^R$  and  $\mathbf{c} \in \mathbb{R}^P$  can be expressed as

$$z = \underline{\mathbf{G}} \bar{\times}_1 \mathbf{a} \bar{\times}_2 \mathbf{b} \bar{\times}_3 \mathbf{c} = \sum_{j=1}^J \sum_{r=1}^R \sum_{p=1}^P g_{jrp} a_j b_r c_p.$$

More generally, for  $\underline{\mathbf{G}} \in \mathbb{R}^{J_1 \times J_2 \times \cdots \times J_N}$  and  $\mathbf{a}^{(n)} \in \mathbb{R}^{J_n}$ , the multiplication by all vectors in all modes ( $n = 1, 2, \dots, N$ ) gives a scalar:

$$y = \underline{\mathbf{G}} \bar{\times}_1 \mathbf{a}^{(1)} \bar{\times}_2 \mathbf{a}^{(2)} \cdots \bar{\times}_N \mathbf{a}^{(N)} = \underline{\mathbf{G}} \bar{\times} \{\mathbf{a}\} \in \mathbb{R}, \quad (21.221)$$

whereas the multiplication in every mode except mode- $n$  results in a vector  $\mathbf{x}$  of length  $J_n$ :

$$\begin{aligned} \mathbf{x} &= \underline{\mathbf{G}} \bar{\times}_1 \mathbf{a}^{(1)} \cdots \bar{\times}_{n-1} \mathbf{a}^{(n-1)} \bar{\times}_{n+1} \mathbf{a}^{(n+1)} \cdots \bar{\times}_N \mathbf{a}^{(N)} \\ &= \underline{\mathbf{G}}_{(n)}(\mathbf{a}^{(N)} \otimes \cdots \otimes \mathbf{a}^{(n+1)} \otimes \mathbf{a}^{(n-1)} \otimes \cdots \otimes \mathbf{a}^{(1)}) = \underline{\mathbf{G}} \bar{\times}_{-n} \{\mathbf{a}\} \in \mathbb{R}^{J_n}. \end{aligned} \quad (21.222)$$

Also note that multiplication in every mode except mode- $n$  and mode- $m$  results in a matrix of size  $J_n \times J_m$ .

The mode-1 product of two tensors:  $\underline{\mathbf{A}} \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$  and  $\underline{\mathbf{B}} \in \mathbb{R}^{J_1 \times J_2 \times \cdots \times J_M}$ , e.g., with a common first mode  $I_1 = J_1$  is defined as a tensor:

$$\underline{\mathbf{C}} = \underline{\mathbf{A}} \times_1 \underline{\mathbf{B}} \in \mathbb{R}^{I_2 \times \cdots \times I_N \times J_2 \times \cdots \times J_M}, \quad (21.223)$$

with entries  $c_{\mathbf{i}_{2:N}, \mathbf{j}_{2:M}} = \sum_{i=1}^{I_1} a_{i, \mathbf{i}_{2:N}} b_{i, \mathbf{j}_{2:M}}$ , (where we use the shorthand MATLAB notation  $\mathbf{i}_{p:q} = \{i_p, i_{p+1}, \dots, i_{q-1}, i_q\}$ ).

The outer product  $\underline{\mathbf{C}} = \underline{\mathbf{A}} \circ \underline{\mathbf{B}}$  of two tensors  $\underline{\mathbf{A}} \in \mathbb{R}^{I_1 \times \dots \times I_N}$  and  $\underline{\mathbf{B}} \in \mathbb{R}^{J_1 \times \dots \times J_M}$  is a tensor  $\underline{\mathbf{C}} \in \mathbb{R}^{I_1 \times \dots \times I_N \times J_1 \times \dots \times J_M}$  with entries  $c_{i_1, \dots, i_N, j_1, \dots, j_M} = a_{i_1, \dots, i_N} b_{j_1, \dots, j_M}$ . Specifically, the outer product of two nonzero vectors  $\mathbf{a} \in \mathbb{R}^I$ ,  $\mathbf{b} \in \mathbb{R}^J$  produces a rank-1 matrix  $\mathbf{X} = \mathbf{a} \circ \mathbf{b} = \mathbf{a}\mathbf{b}^T \in \mathbb{R}^{I \times J}$  and the outer product of three nonzero vectors:  $\mathbf{a} \in \mathbb{R}^I$ ,  $\mathbf{b} \in \mathbb{R}^J$  and  $\mathbf{c} \in \mathbb{R}^K$  produces a 3rd order rank-1 tensor:  $\underline{\mathbf{X}} = \mathbf{a} \circ \mathbf{b} \circ \mathbf{c} \in \mathbb{R}^{I \times J \times K}$ , whose entries are  $x_{ijk} = a_i b_j c_k$ . A tensor  $\underline{\mathbf{X}} \in \mathbb{R}^{I_1 \times I_2 \times \dots \times I_N}$  is said to be rank-1 if it can be expressed exactly by  $\underline{\mathbf{X}} = \mathbf{b}_1 \circ \mathbf{b}_2 \circ \dots \circ \mathbf{b}_N$  with entries  $x_{i_1, i_2, \dots, i_N} = b_{i_1} b_{i_2} \cdots b_{i_N}$ , where  $\mathbf{b}_n \in \mathbb{R}^{I_n}$  are nonzero vectors.

The symbol  $\otimes$  denotes the Kronecker product, i.e.,  $\mathbf{A} \otimes \mathbf{B} = [a_{ij} \mathbf{B}]$ , and the symbol  $\odot$  denotes the Khatri-Rao product or column-wise Kronecker product, i.e.,  $\mathbf{A} \odot \mathbf{B} = [\mathbf{a}_1 \otimes \mathbf{b}_1 \cdots \mathbf{a}_J \otimes \mathbf{b}_J]$ .

Subtensors are formed when a subset of indices is fixed. Particularly, a fiber is defined as a vector by fixing every index but one, while a tensor slice is a two-dimensional section (matrix) of a tensor, obtained by fixing all indices but two. Unfolding (matricization, flattening) of a tensor  $\underline{\mathbf{Y}} \in \mathbb{R}^{I_1 \times I_2 \times \dots \times I_N}$  in the  $n$ -mode is denoted as  $\underline{\mathbf{Y}}_{(n)} \in \mathbb{R}^{I_n \times (I_1 \cdots I_{n-1} I_{n+1} \cdots I_N)}$ , which consists of arranging all possible  $n$ -mode fibers as the columns of a matrix [5]. For simplicity, we define  $\check{I}_k = \Pi_{n \neq k} I_n$ ,  $\check{J}_k = \Pi_{n \neq k} J_n$ .  $\bigotimes_{n \neq k} \mathbf{A}^{(n)} = \mathbf{A}^{(N)} \otimes \dots \mathbf{A}^{(n+1)} \otimes \mathbf{A}^{(n-1)} \dots \otimes \mathbf{A}^{(1)}$  and  $\bigodot_{n \neq k} \mathbf{A}^{(n)} = \mathbf{A}^{(N)} \odot \dots \mathbf{A}^{(k+1)} \odot \mathbf{A}^{(k-1)} \dots \odot \mathbf{A}^{(1)}$ . An *n-mode fiber* is obtained by fixing all indices except the index for one dimension. For a third-order tensor  $\underline{\mathbf{Y}} \in \mathbb{R}^{I \times T \times K}$  its  $n$ -mode fibers are called *column fibers* ( $n = 1$ ), *row fibers* ( $n = 2$ ) and *tube fibers* ( $n = 3$ ).<sup>1</sup> In other words, the unfolding operation consists of arranging the fibers of an  $N$ -way array into a matrix in a specific order, e.g., in reverse lexicographical order [5]. Given an  $N$ th-order tensor  $\underline{\mathbf{Y}} \in \mathbb{R}^{I_1 \times I_2 \times \dots \times I_N}$  we define the *n-mode unfolding matrix* by  $\underline{\mathbf{Y}}_{(n)} \in \mathbb{R}^{I_n \times \prod_{m \neq n} I_m}$ , which is obtained by grouping all indices for dimensions  $m \neq n$ . For example, given a third-order tensor  $\underline{\mathbf{Y}} \in \mathbb{R}^{I \times T \times K}$  the corresponding 1-mode unfolding matrix is obtained by creating a new index, corresponding to the grouping of indices  $t$  and  $k$ , which is denoted by  $\underline{\mathbf{Y}}_{(1)}(i, (tk)) = y_{itk}$ .

We use calligraphic style letters to denote a subset of indices for a given dimension, for example, for 3D tensors with indices  $i = 1, 2, \dots, I$ ,  $t = 1, 2, \dots, T$  and  $k = 1, 2, \dots, K$ , we define the subsets containing  $P_1 \leq I$ ,  $P_2 \leq T$ ,  $P_3 \leq K$  indices as:  $\mathcal{I} = [i_1, i_2, \dots, i_{P_1}]$ ,  $\mathcal{T} = [t_1, t_2, \dots, t_{P_2}]$ , and  $\mathcal{K} = [k_1, k_2, \dots, k_{P_3}]$ . Then we define the *subtensor*  $\underline{\mathbf{W}} \in \mathbb{R}^{P_1 \times P_2 \times P_3}$  as the one determined by indices  $\mathcal{I}$ ,  $\mathcal{T}$  and  $\mathcal{K}$ , i.e.,  $\underline{\mathbf{W}} = \underline{\mathbf{Y}}(\mathcal{I}, \mathcal{T}, \mathcal{K})$  and its unfolding matrices will be denoted by  $\mathbf{W}_{(1)}$ ,  $\mathbf{W}_{(2)}$  and  $\mathbf{W}_{(3)}$ . We may also extract matrices containing the tensor fibers determined by these subsets of indices as follows:  $\mathbf{C}^{(1)} = \underline{\mathbf{Y}}_{(1)}(:, \mathcal{T} \times \mathcal{K}) \in \mathbb{R}^{I \times P_2 P_3}$ ,  $\mathbf{C}^{(2)} = \underline{\mathbf{Y}}_{(2)}(:, \mathcal{I} \times \mathcal{K}) \in \mathbb{R}^{T \times P_1 P_3}$  and  $\mathbf{C}^{(3)} = \underline{\mathbf{Y}}_{(3)}(:, \mathcal{I} \times \mathcal{J}) \in \mathbb{R}^{K \times P_1 P_2}$  for the column, row, and tube fibers respectively, where “ $:$ ” denotes all the indices in a dimension and  $\mathcal{J} \times \mathcal{K}$  denotes all indices produced as a combination of an index in  $\mathcal{J}$  and an index in  $\mathcal{K}$  [120]. Readers can refer to [5,8] for more details regarding the notations and tensor operations.

### 1.21.5.2 Basic tensor decompositions models

There are two basic models for tensor decompositions: Tucker and CP (CANDECOMP/PARAFAC) decomposition. The Tucker- $N$  decomposition or rank- $J_1, J_2, \dots, J_N$  Tucker model, the data is decomposed as the product of a core tensor with  $N$  mode factor (component) matrices [6], i.e., a given data

<sup>1</sup>For convenience, for third-order tensors we use simplified indices  $I = I_1$ ,  $T = I_2$  and  $K = I_3$ .

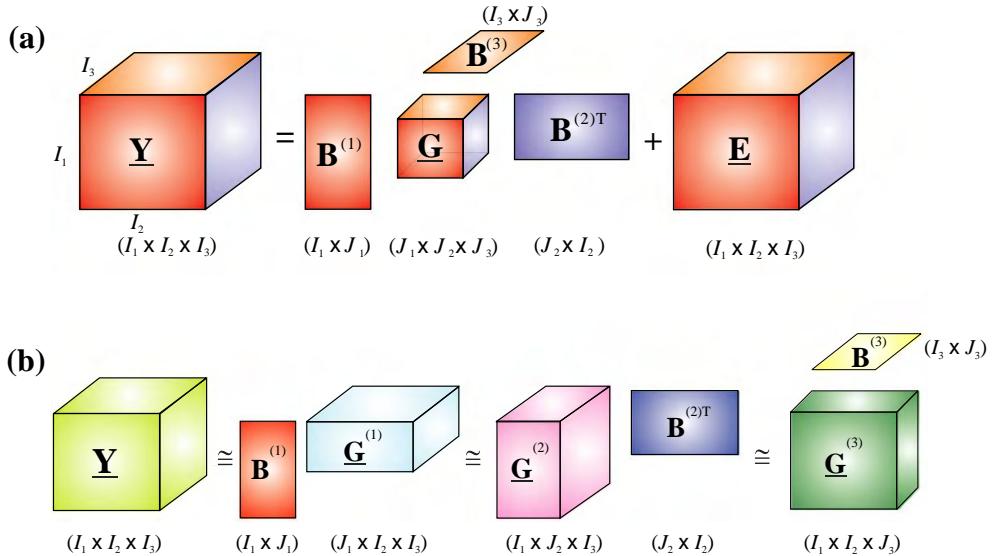

FIGURE 21.8

Illustration of a third-order tensor decomposition (a) using a constrained Tucker-3 model:  $\underline{\mathbf{Y}} = \underline{\mathbf{G}} \times_1 \mathbf{B}^{(1)} \times_2 \mathbf{B}^{(2)} \times_3 \mathbf{B}^{(3)} + \underline{\mathbf{E}} = [\underline{\mathbf{G}}; \mathbf{B}^{(1)}, \mathbf{B}^{(2)}, \mathbf{B}^{(3)}] + \underline{\mathbf{E}} = \sum_{j_1, j_2, j_3} g_{j_1 j_2 j_3} (\mathbf{b}_{j_1}^{(1)} \circ \mathbf{b}_{j_2}^{(2)} \circ \mathbf{b}_{j_3}^{(3)}) + \underline{\mathbf{E}}$ . The objective is to estimate the components  $\mathbf{b}_{j_n}^{(n)}$ , i.e., the columns of the component matrices  $\mathbf{B}^{(n)} = [\mathbf{b}_1^{(n)}, \mathbf{b}_2^{(n)}, \dots, \mathbf{b}_{J_n}^{(n)}] \in \mathbb{R}^{I_n \times J_n}$ , with desired diversities or statistical properties and a possibly sparse core tensor  $\underline{\mathbf{G}} \in \mathbb{R}^{I_1 \times J_2 \times J_3}$ , typically with  $J_n \ll I_n$ , ( $n = 1, 2, 3$ ). Note that some selected component matrices from the Tucker-3 model can be absorbed in the core tensor  $\underline{\mathbf{G}}$ , which leads to Tucker-1 models (b):  $\underline{\mathbf{Y}} = \underline{\mathbf{G}}^{(n)} \times_n \mathbf{B}^{(n)} + \underline{\mathbf{E}}_n$ . Instead of applying the standard Alternating Least Squares (ALS) algorithms to the Tucker-3 model, we can apply the unfolding of the data tensor according to Tucker-1 models and then perform constrained matrix factorizations for the unfolded matrices (multilinear BSS) by imposing desired constraints (nonnegativity, sparseness, independence, smoothness, or decorrelation, etc.). More generally, we wish to model complex interactions embedded in multidimensional data and/or predict missing entries.

tensor  $\underline{\mathbf{Y}} \in \mathbb{R}^{I_1 \times I_2 \times \dots \times I_N}$ , is decomposed as (see Figure 21.8a)

$$\begin{aligned} \underline{\mathbf{Y}} &= \underline{\mathbf{G}} \times_1 \mathbf{B}^{(1)} \times_2 \mathbf{B}^{(2)} \cdots \times_N \mathbf{B}^{(N)} + \underline{\mathbf{E}} = \widehat{\mathbf{Y}} + \underline{\mathbf{E}} \\ &= \sum_{j_1=1}^{J_1} \cdots \sum_{j_N=1}^{J_N} g_{j_1 j_2 \cdots j_N} (\mathbf{b}_{j_1}^{(1)} \circ \mathbf{b}_{j_2}^{(2)} \circ \cdots \circ \mathbf{b}_{j_N}^{(N)}) + \underline{\mathbf{E}}, \end{aligned} \quad (21.224)$$

where  $\underline{\mathbf{G}} \in \mathbb{R}^{J_1 \times J_2 \times \dots \times J_N}$  is the core tensor,  $\mathbf{B}^{(n)} = [\mathbf{b}_1^{(n)}, \mathbf{b}_2^{(n)}, \dots, \mathbf{b}_{J_n}^{(n)}] \in \mathbb{R}^{I_n \times J_n}$  is the mode- $n$  component matrix for  $n = 1, 2, \dots, N$ ,  $\circ$  denotes the outer product, and the tensor  $\underline{\mathbf{E}} \in \mathbb{R}^{I_1 \times I_2 \times \dots \times I_N}$  represents errors or noise. For simplicity, we also use a shorter notation for (21.224) as  $\widehat{\mathbf{Y}} = [\underline{\mathbf{G}}; \mathbf{B}^{(1)}, \mathbf{B}^{(2)}, \dots, \mathbf{B}^{(N)}]$ .

The Tucker-N model with orthogonal factor matrices  $\mathbf{B}^{(n)}$  is also known Multilinear SVD or Higher-order SVD (HOSVD) [9]. In fact, the original Tucker model made the assumptions of orthogonality of the factor matrices (analogous to SVD) and orthogonality of the core tensor [8, 138, 158, 159]. However, in many practical applications we ignore or relax such constraints to make model more flexible. For example, by imposing nonnegativity constraints the problem of estimating the component matrices and the core tensor is converted into a generalized NMF problem called the Nonnegative Tucker Decomposition (NTD). Several implementations of Tucker decomposition algorithms with nonnegativity constraints together with a number of other constraints are given in [8, 138, 158, 160]. The NTD imposes nonnegativity constraints for all component matrices and the core tensor, while a semi-NTD (analogous to semi-NMF) imposes nonnegativity constraints to only some component matrices and/or some elements of the core tensor [8].

Note that the Tucker- $N$  model (21.224) can be represented equivalently by a set of  $N$  different matrix factorizations with three factors:

$$\mathbf{Y}_{(n)} \approx \mathbf{B}^{(n)} \mathbf{G}_{(n)} \mathbf{Z}^{(n)} \quad (n = 1, 2, \dots, N), \quad (21.225)$$

where the matrix  $\mathbf{Z}^{(n)} = [\mathbf{B}^{(N)} \otimes \dots \otimes \mathbf{B}^{(n+1)} \otimes \mathbf{B}^{(n-1)} \dots \otimes \mathbf{B}^{(1)}]^T$  was the Kronecker structure. In many applications, we usually need to estimate only a pre-selected number of component matrices. Without loss of generality, let us assume for simplicity that we are interested in extractions only the first  $K$  component matrices, with  $K \leq N$ . In that case, we can use a simplified Tucker- $K$  model described as

$$\underline{\mathbf{Y}} = \check{\underline{\mathbf{G}}} \times_1 \mathbf{B}^{(1)} \times_2 \mathbf{B}^{(2)} \dots \times_K \mathbf{B}^{(K)} + \underline{\mathbf{E}}, \quad (21.226)$$

where the core tensor  $\check{\underline{\mathbf{G}}} \in \mathbb{R}^{J_1 \times \dots \times J_K \times I_{K+1} \dots \times I_N}$  is expressed as

$$\check{\underline{\mathbf{G}}} = \underline{\mathbf{G}} \times_{K+1} \mathbf{B}^{(K+1)} \times_{K+2} \mathbf{B}^{(K+2)} \dots \times_N \mathbf{B}^{(N)}. \quad (21.227)$$

Furthermore, the Tucker decomposition (21.224) can be represented by using simple Tucker-1 decompositions, with only one component matrix  $\mathbf{B}^{(n)}$  in each mode (see Figure 21.8b):

$$\underline{\mathbf{Y}} \approx \underline{\mathbf{G}}^{(\bar{n})} \times_n \mathbf{B}^{(n)} \quad \text{or in matrix form } \mathbf{Y}_{(n)} \approx \mathbf{B}^{(n)} \mathbf{G}_{(n)}^{(\bar{n})}, \quad (21.228)$$

where  $\underline{\mathbf{G}}^{(\bar{n})} = \underline{\mathbf{G}} \times_1 \mathbf{B}^{(1)} \dots \times_{n-1} \mathbf{B}^{(n-1)} \times_{n+1} \mathbf{B}^{(n+1)} \dots \times_N \mathbf{B}^{(N)}$  is a tensor,  $(n = 1, 2, \dots, N)$ . This means that Tucker decomposition problems can be converted to a set of matrix factorization problems, with suitable constraints imposed on the component matrices in order to achieve essential uniqueness.

In the special case, when the core tensor  $\underline{\mathbf{G}}$  is a hypercube, i.e.,  $J_1 = J_2 = \dots = J_N = J$ , and it has nonzero entries only on its diagonal, the Tucker model is reduced to the CP model (CANDECOMP/PARAFAC) decomposition, analyzed by two independent research groups [2, 4, 161]). In the CP model a data tensor is represented as a linear combination of outer products of columns (components) of the component matrices:

$$\begin{aligned} \underline{\mathbf{Y}} &= \underline{\mathbf{G}} \times_1 \mathbf{B}^{(1)} \times_2 \mathbf{B}^{(2)} \dots \times_N \mathbf{B}^{(N)} + \underline{\mathbf{E}} \\ &= \sum_{j=1}^J \lambda_j \mathbf{b}_j^{(1)} \circ \mathbf{b}_j^{(2)} \dots \circ \mathbf{b}_j^{(N)} + \underline{\mathbf{E}}, \end{aligned} \quad (21.229)$$

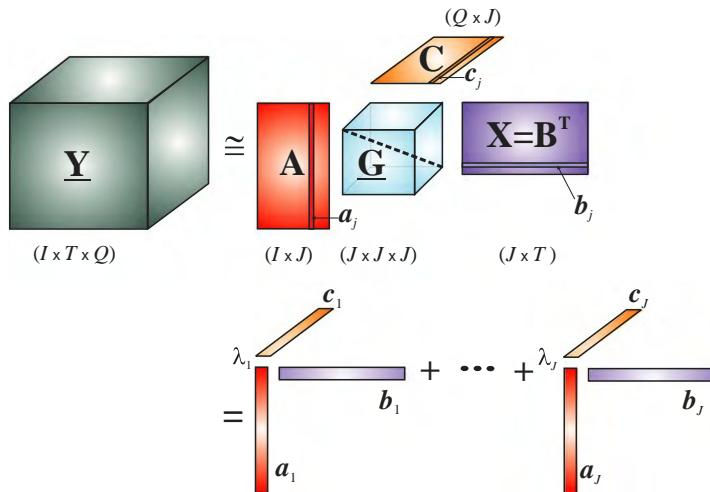

**FIGURE 21.9**

Illustration of a 3-way CP model performing tensor decomposition  $\underline{Y} \cong \underline{G} \times_1 \underline{A} \times_2 \underline{B} \times_3 \underline{C} = \sum_{j=1}^J \lambda_j (\underline{a}_j \circ \underline{b}_j \circ \underline{c}_j)$  with a diagonal core tensor  $\underline{G} = \underline{\Lambda} \in \mathbb{R}^{J \times J \times J}$ , with entries  $\lambda_{jjj} = \lambda_j$ .

where  $\underline{G} = \underline{\Lambda} \in \mathbb{R}^{J \times J \times \dots \times J}$  is a diagonal tensor with all entries zero except the diagonal entries  $\lambda_j$ . We usually assume that the vectors  $\underline{b}_j^{(n)}$  (for  $n = 1, 2, \dots, N$ ) are normalized to unit length. In other words, the CP model represents multiway data as a sum of rank-1 components [5, 162].

The CP model decomposes a given tensor into a sum of multilinear terms, in a way analogous to the bilinear matrix decomposition (see Figure 21.9). Unlike standard SVD, usually CP does not impose any constraints. Since model is unique under mild conditions. A model which imposes nonnegativity on factor matrices is called a Nonnegative Tensor Factorization (NTF) or Nonnegative PARAFAC. A nonnegative version of CP was first introduced by Carroll et al. [163]. Later, more efficient approaches were developed [164, 165], based on the modified NLS (Nonnegative Least Squares) by Paatero [166, 167] who extended his earlier 2-way positive matrix factorization (PMF) method to the three-way CP model, referring to the result as PMF3 (three-way positive matrix factorization). Although such constrained nonnegativity based model may not match perfectly the input data (i.e., it may have larger residual errors  $\mathbf{E}$  than the standard CP without any constraints), such decompositions are often more meaningful and have clearer physical interpretations [8, 34].

The advantage of the Tucker model over the CP model is that the Tucker model is more general since the number of components in each mode can be different, and the components are linked via a core tensor, and hence it allows us to model more complex hidden data structures. Both the CP and the Tucker decompositions attempt to obtain optimal low-rank ( $J$  or  $\{J_1, J_2, \dots, J_N\}$ , respectively) approximations to the original data. However, quite different from the matrix case, the optimal low-rank approximation may not exist at all or, if it exists, it may not be unique for high-order tensors [168, 169]. Particularly, an unconstrained Tucker decomposition is in general non-unique, as it has arbitrary rotational ambiguity.

Due to many degrees of freedom, the results of such decompositions are difficult to interpret because the components do not have a clear physical meaning. The CP model in contrast is essentially unique if the fundamental Kruskal uniqueness conditions are satisfied, which was addressed by Kruskal for third-order tensors and then extended to  $N$ th-order tensors by Sidiropoulos et al. [170, 171]. These are sufficient (but not necessary) conditions. Basically, algebraic properties, e.g., the ranks of the tensors and their component matrices, play a central role for such uniqueness analyze.

If we impose additional constraints to the CP model, such as nonnegativity, sparsity, or orthogonality, the conditions for uniqueness can be relaxed. Moreover, by imposing the nonnegativity or orthogonality constraints the CP model has an optimal solution, i.e., there is no risk for degenerate solutions [172]. Imposing nonnegativity constraints makes degenerate solutions impossible, since no factor can counteract the effect of another factor, and usually it improves the convergence of the learning algorithms since the search space is greatly reduced. For the Tucker and CP decompositions there exist many algorithms [5, 8]. Most of them are based on the ALS (Alternating Least Squares), HALS (Hierarchical ALS) [8, 34, 173, 174] and CUR tensor decompositions [120]. However, the ALS algorithms are often slow for noisy or ill-conditioned data and they may get stuck in local minima due to the non-convexity of the optimization problem, especially when nonnegativity or other constraints are imposed on the component matrices.

In contrast to most of the existing tensor decomposition methods, where only the best fit of a decomposed tensor to the original data tensor is pursued, in this section, the multilinear Blind Source Separation (MBSS) approach is briefly described and we show how to perform constrained tensor decompositions in which both the satisfactory fit and a wide variety of desired properties/constraints and diversities of estimated components can be pursued simultaneously.

### 1.21.5.3 Sparse CP decomposition using the generalized power method

Although the CP tensor decomposition is in general unique without any constraints, in some applications, especially for large-scale problems, we need components  $\mathbf{b}_j^{(n)}$  that are sparse in one specific mode or in all modes. Let us consider now the basic CP model. In order to estimate the first set of components we can consider the following optimization problem (see Section 1.21.2.6.3)

$$\min_{\mathbf{b}_j^{(n)}} \left\{ \left\| \underline{\mathbf{Y}} - \sum_{j=1}^J \lambda_j (\mathbf{b}_j^{(1)} \circ \mathbf{b}_j^{(2)} \cdots \circ \mathbf{b}_j^{(N)}) \right\|_F^2 \right\}.$$

Assuming that we want to extract the desired components sequentially one by one, we can first consider the constrained optimization problem

$$\begin{aligned} & \min_{\mathbf{b}_1^{(n)}} \{ \| \underline{\mathbf{Y}} - \lambda_1 (\mathbf{b}_1^{(1)} \circ \mathbf{b}_1^{(2)} \cdots \circ \mathbf{b}_1^{(N)}) \|_F^2 \}, \\ & \text{s.t. } \|\mathbf{b}_1^{(n)}\|_2 \leq 1, \|\mathbf{b}_1^{(n)}\|_1 \leq 1, P_1(\mathbf{b}_1^{(n)}) \forall C_1 \leq c_1, P_2(\mathbf{b}_1^{(n)}) \leq c_2 \quad \forall n. \end{aligned}$$

**Algorithm 5.** Power Method for Sparse CP Decomposition

**Require:** Data tensor  $\underline{\mathbf{Y}}^{(1)} = \underline{\mathbf{Y}}$ , sparsity coefficients  $\alpha_n \geq 0$ , ( $n = 1, \dots, N$ ) and initial vectors  $\mathbf{b}_j^{(n)}$ .

1: For  $j = 1, 2, \dots, J$  and  $n = 1, 2, \dots, N$ :

(a) Repeat until convergence of  $\mathbf{b}_j^{(n)}$ :

$$2: \quad \mathbf{b}_j^{(\bar{n})} = \underline{\mathbf{Y}}^{(j)} \tilde{\times}_1 \mathbf{b}_1^{(1)} \dots \tilde{\times}_{n-1} \mathbf{b}_1^{(n-1)} \tilde{\times}_{n+1} \mathbf{b}_1^{(n+1)} \dots \tilde{\times}_N \mathbf{b}_1^{(N)};$$

$$3: \quad \mathbf{b}_j^{(n)} = \frac{\mathcal{S}_1(\mathbf{b}_j^{(\bar{n})}, \alpha_n)}{\|\mathcal{S}_1(\mathbf{b}_j^{(\bar{n})}, \alpha_n)\|_2} \quad (\text{for } \alpha_n = 0 \text{ take } \mathbf{b}_j^{(n)} = \frac{\mathbf{b}_j^{(\bar{n})}}{\|\mathbf{b}_j^{(\bar{n})}\|_2});$$

$$4: (b) \quad \lambda_j = |\underline{\mathbf{Y}}^{(j)} \tilde{\times}_1 \mathbf{b}_j^{(1)} \tilde{\times}_2 \mathbf{b}_j^{(2)} \dots \tilde{\times}_N \mathbf{b}_j^{(N)}|;$$

$$5: (c) \quad \underline{\mathbf{Y}}^{(j+1)} = \underline{\mathbf{Y}}^{(j)} - \lambda_j (\mathbf{b}_j^{(1)} \circ \mathbf{b}_j^{(2)} \dots \circ \mathbf{b}_j^{(N)});$$

$$6: \text{return } \mathbf{B}^{(n)} = [\mathbf{b}_1^{(n)}, \mathbf{b}_2^{(n)}, \dots, \mathbf{b}_J^{(n)}], \quad \Lambda^* = \text{diag}\{\lambda_1, \lambda_2, \dots, \lambda_J\}.$$

The problem is equivalent to the following optimization problem

$$\max_{\mathbf{b}_1^{(n)}} \{ \underline{\mathbf{Y}} \tilde{\times}_1 \mathbf{b}_1^{(1)} \tilde{\times}_2 \mathbf{b}_1^{(2)} \dots \tilde{\times}_N \mathbf{b}_1^{(N)} \}, \quad (21.230)$$

$$\text{s.t. } \|\mathbf{b}_1^{(n)}\|_2 \leq 1, \quad \|\mathbf{b}_1^{(n)}\|_1 \leq 1, \quad P_1(\mathbf{b}_1^{(n)}) \leq c_1, \quad P_2(\mathbf{b}_1^{(n)}) \leq c_2 \quad \forall n.$$

If we impose sparsity constraints, we can formulate the following optimization problem

$$\max_{\mathbf{b}_1^{(n)}} \{ \underline{\mathbf{Y}} \tilde{\times}_1 \mathbf{b}_1^{(1)} \tilde{\times}_2 \mathbf{b}_1^{(2)} \dots \tilde{\times}_N \mathbf{b}_1^{(N)} - \sum_n \alpha_n \|\mathbf{b}_1^{(n)}\|_1 \}, \quad \text{s.t. } \|\mathbf{b}_1^{(n)}\|_2 \leq 1 \quad \forall n.$$

This optimization leads to the following simple update rules

$$\mathbf{b}_1^{(n)} = \frac{\mathcal{S}_1(\mathbf{b}_1^{(\bar{n})}, \alpha_n)}{\|\mathcal{S}_1(\mathbf{b}_1^{(\bar{n})}, \alpha_n)\|_2}, \quad (21.231)$$

where

$$\mathcal{S}_1(\mathbf{b}, \alpha) = \text{sign}(\mathbf{b})[|\mathbf{b}| - \alpha]_+, \quad (21.232)$$

and

$$\mathbf{b}_1^{(\bar{n})} = \underline{\mathbf{Y}} \tilde{\times}_1 \mathbf{b}_1^{(1)} \dots \tilde{\times}_{n-1} \mathbf{b}_1^{(n-1)} \tilde{\times}_{n+1} \mathbf{b}_1^{(n+1)} \dots \tilde{\times}_N \mathbf{b}_1^{(N)}. \quad (21.233)$$

This update formula simplifies in the absence of sparsity constraints (i.e.,  $\alpha_n = 0 \forall n$ ) as

$$\mathbf{b}_1^{(n)} = \frac{\mathbf{b}_1^{(\bar{n})}}{\|\mathbf{b}_1^{(\bar{n})}\|_2}. \quad (21.234)$$

In order to extract the next set of components, we need to apply deflation approach for  $j = 1, 2, \dots, J$

$$\lambda_j = |\underline{\mathbf{Y}}^{(j)} \tilde{\times}_1 \mathbf{b}_j^{(1)} \tilde{\times}_2 \mathbf{b}_j^{(2)} \dots \tilde{\times}_N \mathbf{b}_j^{(N)}|, \quad (21.235)$$

$$\underline{\mathbf{Y}}^{(j+1)} = \underline{\mathbf{Y}}^{(j)} - \lambda_j (\mathbf{b}_j^{(1)} \circ \mathbf{b}_j^{(2)} \dots \circ \mathbf{b}_j^{(N)}), \quad (21.236)$$

with  $\underline{\mathbf{Y}}^{(1)} = \underline{\mathbf{Y}}$  (see Algorithm 5).

### 1.21.5.4 Multilinear BSS via constrained unique Tucker decompositions

There are two possible approaches to represent constrained Tucker decompositions for the MBSS. In the first approach the columns of the component matrices  $\mathbf{B}^{(n)}$  represent the desired components or latent variables, and the core tensor  $\mathbf{G}$  represents some kind of a "mixing process". More precisely, the core tensor shows the links among the components from different modes, while the data tensor  $\underline{\mathbf{Y}}$  represents a collection of 1-D or 2-D mixing signals. In the second approach the core tensor represents the desired (but unknown hidden)  $N$ -dimensional signal (e.g., 3D MRI image or 4D video), and the component matrices represent specific transformations, e.g., time frequency transformations or wavelets dictionaries (mixing or filtering processes). In this case the data tensor  $\underline{\mathbf{Y}}$  represents observed  $N$ -dimensional signal, which may be distorted, transformed, compressed, or mixed, depending on the specific applications. In this section, we will only consider the first interpretation or approach.

We can implement multilinear BSS algorithms in several ways. First of all, to estimate desired components, we can minimize a global cost function with suitable penalty and regularization terms (see Eq. (21.224)):

$$D_F(\underline{\mathbf{Y}} \parallel \widehat{\underline{\mathbf{Y}}}) = \|\underline{\mathbf{Y}} - \underline{\mathbf{G}} \times_1 \mathbf{B}^{(1)} \times_2 \mathbf{B}^{(2)} \cdots \times_N \mathbf{B}^{(N)}\|_F^2 + \sum_n \alpha_n D_n(\mathbf{B}^{(n)}), \quad (21.237)$$

where  $\|\underline{\mathbf{Y}}\|_F = (\sum_{i_1=1}^{I_1} \cdots \sum_{i_N=1}^{I_N} y_{i_1 \cdots i_N}^2)^{\frac{1}{2}}$ ;  $\alpha_n \geq 0$  are penalty coefficients and  $D_n(\mathbf{B}^{(n)})$  are penalty terms, which are added to achieve desired characteristics of the components. For example, if we need to impose mutual independence constraints the penalty terms can take the following form:  $D_n(\mathbf{B}^{(n)}) = \sum_{j=1}^J \sum_{p \neq j} \mathbf{b}_j^{(n)T} f_n(\mathbf{b}_n^{(p)})$ , where  $f_n(u)$  are suitable nonlinear functions.

In principle, this way leads to penalized ALS algorithms which allow us to find the component matrices  $\mathbf{B}^{(n)}$  and the associated core tensor. However, the method involves heavy computations and it is very time consuming.

A simpler, practical, and much more efficient approach is to exploit unfolding in each mode of the data tensor  $\underline{\mathbf{Y}}$ , according to the Tucker- $N$  or Tucker-1 decompositions (21.228), to allow us to directly apply suitable constrained low-rank matrix factorizations algorithms (PCA/SVD, ICA, NMF, SCA).

Note that in practice, for large-scale problems, we do not need to perform explicitly the unfolding of the full data tensor. Instead, we may apply fast sampling of tubes (columns) of data tensors [120].

For the Tucker decomposition, let  $\underline{\mathbf{Y}} \approx \underline{\mathbf{G}}; \mathbf{B}^{(1)}, \mathbf{B}^{(2)}, \dots, \mathbf{B}^{(N)}$  and assume that only the factor matrices (whose columns represent the components)  $\mathbf{B}^{(n)}$ , ( $n = 1, 2, \dots, N$ ), are subject of interest. Then we have

$$\mathbf{Y}_n = \mathbf{Y}_{(n)}^T \cong \mathbf{A}_{\bar{n}} [\mathbf{B}^{(n)}]^T \quad (n = 1, 2, \dots, N), \quad (21.238)$$

where the basis matrices have a Kronecker structure:

$$\begin{aligned} \mathbf{A}_{\bar{n}} &= (\mathbf{B}^{(N)} \otimes \cdots \otimes \mathbf{B}^{(n+1)} \otimes \mathbf{B}^{(n-1)} \otimes \cdots \otimes \mathbf{B}^{(1)}) \mathbf{G}_{(n)}^T \\ &= \left( \bigotimes_{p=1, p \neq n}^N \mathbf{B}^{(p)} \right) \mathbf{G}_{(n)}^T. \end{aligned} \quad (21.239)$$

For the CP model, the basis (mixing) matrices  $\mathbf{A}_{\bar{n}}$  take much simpler forms (with Khatri-Rao structure):

$$\mathbf{A}_{\bar{n}} = (\mathbf{B}^{(N)} \odot \cdots \odot \mathbf{B}^{(n+1)} \odot \mathbf{B}^{(n-1)} \cdots \odot \mathbf{B}^{(1)}) \mathbf{\Lambda} = \left( \bigodot_{p=1, p \neq n}^N \mathbf{B}^{(p)} \right) \mathbf{\Lambda}, \quad (21.240)$$

where  $\mathbf{\Lambda}$  is a diagonal matrix whose diagonal elements consist of the diagonal entries  $\lambda_j$  of the core tensor  $\underline{\mathbf{G}} = \underline{\mathbf{\Lambda}}$  (see Figure 21.9).

Note that the above models correspond to group BSS/ICA models (21.7) with the following correspondences:  $\mathbf{Y}_n = \mathbf{Y}_{(n)}^T$ ,  $\mathbf{A}_n = \mathbf{A}_{\bar{n}}$ , and  $\mathbf{B}_n = \mathbf{B}^{(n)}$ , for all  $n$ , if we impose desired constraints on the component matrices  $\mathbf{B}^{(n)}$ . From (21.238), we can observe that the columns of the mode- $n$  matricization of  $\underline{\mathbf{Y}}$  are just the linear mixtures of the mode- $n$  component matrices  $\mathbf{B}^{(n)}$ , ( $n = 1, 2, \dots, N$ ). This suggests that we can use various available BSS algorithms to directly extract factor matrices with specific properties and diversities. For example, if apply SVD in each mode, we obtain HOSVD, and if apply ICA algorithms we have multilinear ICA [32, 175].

Once all desired component matrices  $\mathbf{B}^{(n)}$ ,  $n = 1, 2, \dots, N$  have been estimated, the core tensor can be computed using any suitable matrix factorization method which provides an essentially unique decomposition method. In the simplest scenario we can apply the following formula:

$$\widehat{\underline{\mathbf{G}}} = \underline{\mathbf{Y}} \times_1 \mathbf{B}^{(1)\dagger} \times_2 \mathbf{B}^{(2)\dagger} \cdots \times_N \mathbf{B}^{(N)\dagger}, \quad (21.241)$$

where  $\mathbf{B}^\dagger$  denotes the Moore–Penrose inverse of a matrix  $\mathbf{B}$ .

In general,  $\widehat{\underline{\mathbf{G}}} \neq \underline{\mathbf{G}}$  due to the unavoidable ambiguities of the BSS methods. However, the links between the extracted components remain unchanged, except for the ambiguities due to permutation and scaling. The approach described above is called multilinear BSS (MBSS), where multiple sets of components  $\mathbf{B}^{(1)}, \mathbf{B}^{(2)}, \dots, \mathbf{B}^{(N)}$  can be extracted separately from multiple modes of a tensor.

The MBSS approach has two major advantages [32]:

1. The extracted component matrices  $\mathbf{B}^{(n)}$  are essentially unique (neglecting scaling and permutation ambiguities) and have specific desired properties or feature information, under conditions that apply a suitable BSS/PMD algorithm which provide a unique decomposition in each mode.
2. The component matrices of interest can be extracted directly, i.e., independently of the knowledge of other component matrices, due to application of a standard BSS for each mode separately or independently. In other words, using the MBSS, tensor decompositions can be achieved without ALS iterations. Note that in the ALS-based algorithms tensors have to be unfolded to each mode frequently, which is the main bottleneck to achieve high efficiency, especially for large-scale data. In contrast, the MBSS approach allows us to dramatically reduce the computational complexity, since each component matrix can be estimated independently on other modes by employing efficient BSS algorithms, particularly in the case where only a few preselected component matrices are of interest [32].

It should be noted that the unfolding matrices  $\mathbf{Y}_{(n)}^T \in \mathbb{R}^{\check{I}_n \times I_n}$  and the bases matrices  $\tilde{\mathbf{A}}_n \in \mathbb{R}^{\check{I}_n \times J_n}$  are usually very large-scale (very tall) matrices with  $\check{I}_n \gg I_n$  and  $I_n \geq J_n$ . Thus the MBSS

problems (21.238) are usually highly over-determined constrained matrix factorization problems and we need to perform dimensionality reduction first. Moreover, we need to estimate the number of components in each mode  $J_n$ , which in general are unknown. We can solve both problems by applying low-rank approximations, especially PCA/SVD decompositions or CUR decompositions.

### 1.21.5.5 CUR tensor decomposition for dimensionality reduction and compression of large-scale data

Although the PCA/SVD method can be relatively fast, optimal in the least squares sense, and quite robust with respect to Gaussian noise, unfortunately, it does not preserve the properties of original raw tensor data and it is rather time consuming for very large-scale problems. For example, the data tensor can be nonnegative while the reduced unfolding matrices may have in general positive and negative entries. In many applications, for example in NTF and NTD decompositions, we need to preserve in the reduced unfolded matrices the basic characteristic of the original data tensor. To overcome the above problem, we adopted the CUR algorithm for tensor compression and dimensionality reduction [120].

The concept of CUR decomposition has been successfully generalized to tensors in [120, 124]. A practical and fast technique is called Fiber Sampling Tucker Decomposition (FSTD) [120]. Since real-life data have often good low multilinear rank approximations, FSTD provides such a low-rank Tucker decomposition that is directly expressed in terms of a relatively small number of fibers (vector columns) of the data tensor. By virtue of its construction from raw data elements, FSTD preserves the original characteristics and features of tensor data and can be used for efficient compressed representations of the original data tensor.

For a given tensor  $\underline{\mathbf{Y}} \in \mathbb{R}^{I_1 \times I_2 \times \dots \times I_N}$  for which an exact rank- $(R_1, R_2, \dots, R_N)$  Tucker representation exists, FSTD selects  $R$  indices in each mode, which determine an intersection sub-tensor  $\underline{\mathbf{W}} \in \mathbb{R}^{R \times R \times \dots \times R}$  so that the following exact Tucker representation is obtained:

$$\underline{\mathbf{Y}} = \underline{\mathbf{U}}; \mathbf{C}^{(1)}, \mathbf{C}^{(2)}, \dots, \mathbf{C}^{(N)}, \quad (21.242)$$

in which the core tensor is computed as  $\underline{\mathbf{U}} = \underline{\mathbf{G}} = \underline{\mathbf{W}}; \mathbf{W}_{(1)}^\dagger, \mathbf{W}_{(2)}^\dagger, \dots, \mathbf{W}_{(n)}^\dagger$ , and the matrices  $\mathbf{C}^{(n)} \in \mathbb{R}^{I_n \times I_{\bar{n}}}$  contain the mode- $n$  fibers defined by restricting the indices in modes  $m \neq n$  to belong to the selected subsets. This can also be written as a rank- $(R, R, \dots, R)$  Tucker representation:

$$\underline{\mathbf{Y}} = \underline{\mathbf{W}}; \mathbf{C}^{(1)} \mathbf{W}_{(1)}^\dagger, \mathbf{C}^{(2)} \mathbf{W}_{(2)}^\dagger, \dots, \mathbf{C}^{(N)} \mathbf{W}_{(N)}^\dagger. \quad (21.243)$$

Observe that for  $N = 2$  this model simplifies into the CUR matrix case,  $\mathbf{X} = \mathbf{CUR}$ , where  $\mathbf{C}^{(1)} = \mathbf{C}, \mathbf{C}^{(2)} = \mathbf{R}^T$  and the core matrix is  $\mathbf{U} = \mathbf{W}; \mathbf{W}_{(1)}^\dagger, \mathbf{W}_{(2)}^\dagger = \mathbf{W}^\dagger \mathbf{W} \mathbf{W}^\dagger = \mathbf{W}^\dagger$ .

An efficient strategy for the selection of suitable fibers, only requiring access to a partial (small) subset of entries of a data tensor through identifying the entries with maximum modulus within single fibers [120]. The indices are selected sequentially using a deflation approach making the FSTD algorithm suitable for very large scale tensors (including tensors with missing fibers or entries). There are several strategies for the selection of suitable columns and rows. The main idea is to select columns and rows that exhibit high “statistical leverage” and provide the best low-rank fit for the data matrix [120, 122, 123].

CUR decompositions are low-rank tensor decompositions that are explicitly expressed in terms of a relatively small number of actual fibers (vector columns) of the data tensor. Because they are constructed from actual raw data elements, CUR tensor decompositions preserve the ordinal characteristics and features of data and can be used as efficient compressed representations of the original data tensor.

Multilinear BSS and generalized component analysis algorithms, e.g., a combination of PCA, ICA, SCA, NMF, and MCA, are often considered as pure mathematical formulas, powerful, but rather mechanical procedures. There is a misconception that there is not very much left for the user to do after the machinery has been optimally implemented. However, the successful and efficient use of such tools strongly depends on *a priori* knowledge, common sense, and appropriate use of preprocessing and postprocessing tools. In other words, it is the preprocessing of data and postprocessing of models where expertise is truly needed in order to extract and identify physically significant and meaningful hidden components.

### 1.21.5.6 Common component analysis: feature extraction for multi-block tensor data

Dimensionality reduction, feature extraction and future selection are essential problems in the analysis of multi-dimensional data sets with large number of variables [12]. We will first illustrate the basic concepts of dimensionality reduction and feature extraction for a set of large-scale sample matrices. Let us consider that we have available a set of  $K$  matrices (2-D samples)  $\mathbf{Y}_k \in \mathbb{R}^{I_1 \times I_2}$ , ( $k = 1, 2, \dots, K$ ) that represent multi-subjects or multi-trials 2D data, which belong to  $C$  different classes or categories (e.g., multiple mental task/state data or different mental diseases). In order to perform dimensionality reduction and extract essential features for all the training samples, we apply simultaneous (approximative and constrained) matrix factorizations (see Figure 21.10a):

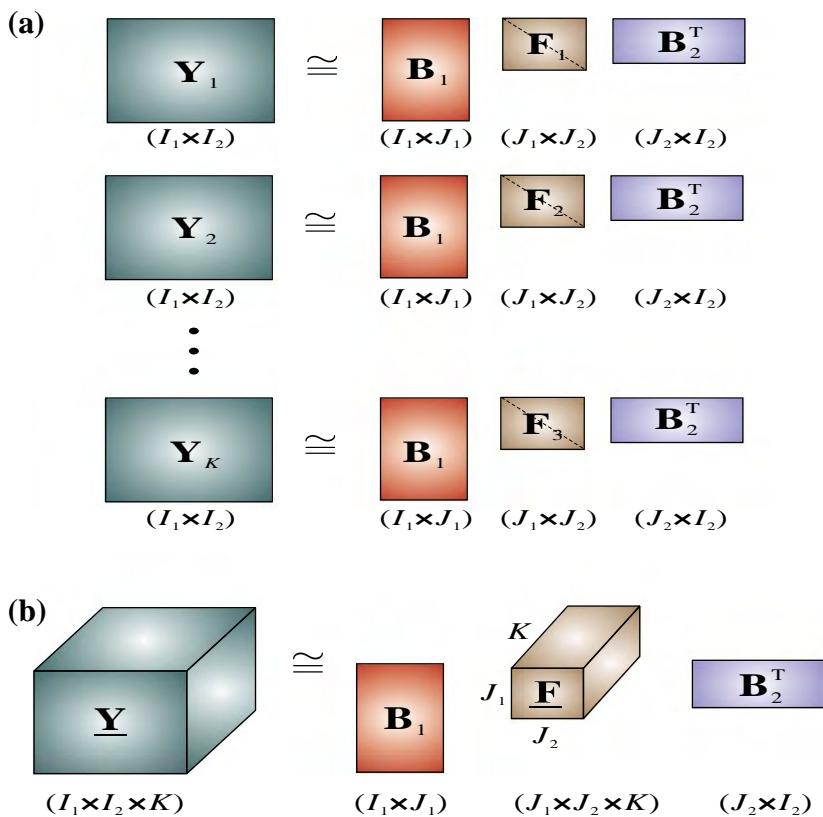

$$\mathbf{Y}_k = \mathbf{B}_1 \mathbf{F}_k \mathbf{B}_2^T + \mathbf{E}_k \quad (k = 1, 2, \dots, K), \quad (21.244)$$

where the two common factors (basis matrices)  $\mathbf{B}_1 \in \mathbb{R}^{I_1 \times J_1}$  and  $\mathbf{B}_2 \in \mathbb{R}^{I_2 \times J_2}$ ,  $J_n \leq I_n$ , code (explain) each sample  $\mathbf{Y}_k$  simultaneously along the horizontal and vertical dimensions and the extracted features are represented by matrices  $\mathbf{F}_k \in \mathbb{R}^{J_1 \times J_2}$ , typically, with  $J_1 \ll I_1$  and  $J_2 \ll I_2$ . In special cases  $\mathbf{F}_k$  are squared diagonal matrices. Then this problem can be considered as a generalization of Joint Approximative Diagonalization (JAD) [8,84].

The common method to solve such matrix factorizations problem is to minimize a set of cost functions  $\|\mathbf{Y}_k - \mathbf{B}_1 \mathbf{F}_k \mathbf{B}_2^T\|_F^2$ ,  $\forall k$ , sequentially or in parallel, with respect to all the factor matrices involved. Alternatively, we can solve the problem by concatenation or tensorization of all matrices  $\mathbf{Y}_k$  along the third dimension to form an  $I_1 \times I_2 \times K$  dimensional data tensor  $\underline{\mathbf{Y}} \in \mathbb{R}^{I_1 \times I_2 \times K}$  and perform the constrained Tucker decomposition (see Figure 21.10b).

In order to obtain meaningful components and a unique decomposition it is often convenient to impose additional constraints [8,12]. In the special case when the feature matrices  $\mathbf{F}_k$  are diagonal the Tucker-2 model is reduced to the special form of the CP model [8].

This approach can be naturally and quite straightforwardly extended to multi-dimensional data. Assume that we have available a multi-block of multi-dimensional tensors  $\underline{\mathbf{Y}}^{(k)} \in \mathbb{R}^{I_1 \times I_2 \times \dots \times I_N}$ , ( $k = 1, 2, \dots, K$ ), representing training data [12]. In such a case we can apply simultaneous

**FIGURE 21.10**

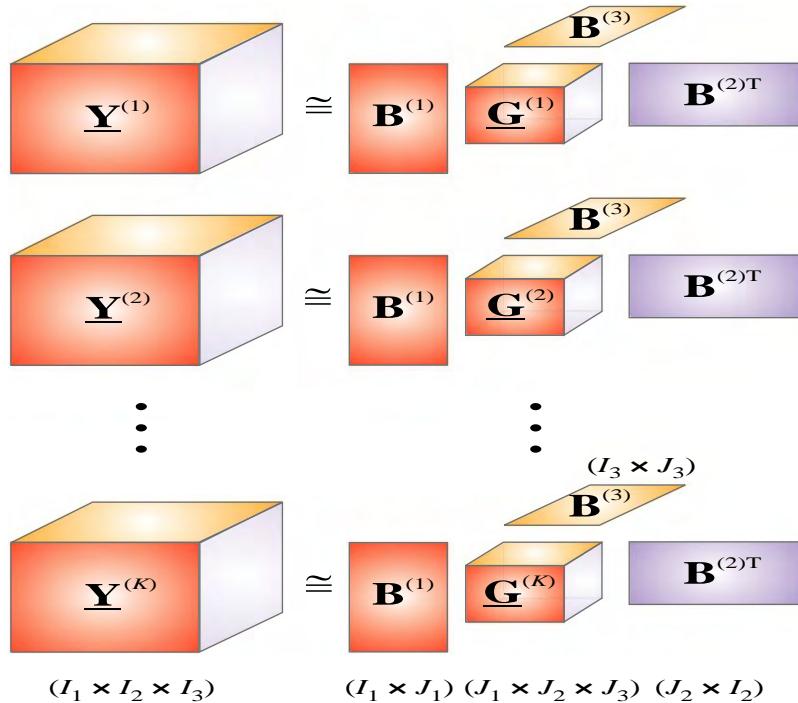

Common Component Analysis for a multi-block set of matrices. (a) Simultaneous matrix factorizations for dimensionality reduction and feature extraction. (b) This model is equivalent to a Tucker-2 decomposition of a third-order tensor as  $\underline{\mathbf{Y}} = \mathbf{F} \times_1 \mathbf{B}_1 \times_2 \mathbf{B}_2$ , where  $\mathbf{F} \in \mathbb{R}^{J_1 \times J_2 \times K}$  is a constrained core tensor (representing features). In the special case matrices  $\mathbf{F}_k$  are diagonal metrices.

approximative tensor decompositions (see Figure 21.11)

$$\underline{\mathbf{Y}}^{(k)} = \underline{\mathbf{G}}^{(k)} \times_1 \mathbf{B}^{(1)} \times_2 \mathbf{B}^{(2)} \cdots \times_N \mathbf{B}^{(N)} + \underline{\mathbf{E}}^{(k)}, \quad (21.245)$$

$(k = 1, 2, \dots, K)$ , where the compressed core tensors  $\underline{\mathbf{G}}^{(k)} \in \mathbb{R}^{J_1 \times J_2 \times \dots \times J_N}$  representing features are of lower dimensions than the original data tensors  $\underline{\mathbf{Y}}^{(k)}$ , and we assume that the factors (basis matrices)  $\mathbf{B}^{(n)} = [\mathbf{b}_1^{(n)}, \mathbf{b}_2^{(n)}, \dots, \mathbf{b}_{J_n}^{(n)}] \in \mathbb{R}^{I_n \times J_n}$ ,  $(n = 1, 2, \dots, N)$  are common factors for all data tensors.

To compute the factor matrices  $\mathbf{B}^{(n)}$  and the core tensors  $\underline{\mathbf{G}}^{(k)}$ , we concatenate all training (sample) tensors into one  $N + 1$  order training data tensor

**FIGURE 21.11**

Multiway Common Component Analysis for a multi-block set of tensors for dimensionality reduction and feature extraction from a set of third-order data tensors  $\underline{\mathbf{Y}}^{(k)} \in \mathbb{R}^{I_1 \times I_2 \times I_3}$ ,  $(k = 1, 2, \dots, K)$ . The objective is to estimate the common factor matrices  $\mathbf{B}^{(n)} \in \mathbb{R}^{I_n \times J_n}$  ( $n = 1, 2, 3$ ) and the core tensors  $\underline{\mathbf{G}}^{(k)} \in \mathbb{R}^{J_1 \times J_2 \dots \times J_N}$ , typically with  $J_n \ll I_n$ , representing features.

$\underline{\mathbf{Y}} = \text{cat}(\underline{\mathbf{Y}}^{(1)}, \underline{\mathbf{Y}}^{(2)}, \dots, \underline{\mathbf{Y}}^{(K)}, N + 1) \in \mathbb{R}^{I_1 \times I_2 \dots \times I_N \times I_{N+1}}$ , with  $N + 1 = K$  and perform the Tucker- $N$  decomposition [12]:

$$\underline{\mathbf{Y}} = \underline{\mathbf{G}} \times_1 \mathbf{B}^{(1)} \times_2 \mathbf{B}^{(2)} \dots \times_N \mathbf{B}^{(N)} + \underline{\mathbf{E}}, \quad (21.246)$$

where the sample tensors  $\underline{\mathbf{Y}}^{(k)}$  can be extracted back from the concatenated tensor by fixing the  $(N + 1)$ th index at a value  $k$ , i.e.,  $\underline{\mathbf{Y}}_{\cdot, \cdot, \dots, \cdot, k}^{(1, 2, \dots, N, N+1)} = \underline{\mathbf{Y}}^{(k)}$ , and the individual features (corresponding to different classes) are extracted from the core tensor  $\underline{\mathbf{G}} \in \mathbb{R}^{J_1 \times J_2 \dots \times J_N \times I_{N+1}}$  as  $\underline{\mathbf{G}}^{(k)} = \underline{\mathbf{G}}_{\cdot, \cdot, \dots, \cdot, k}^{(1, 2, \dots, N, N+1)}$ , with  $I_{N+1} = K$ . In other words, the features of a specific training data  $\underline{\mathbf{Y}}^{(k)}$  are represented by the  $k$ th row of the mode- $(N + 1)$  matricized version of the core tensor  $\underline{\mathbf{G}}$ . We can apply the procedure described above to various feature extraction classification problems [12].

### 1.21.5.7 Linked multilinear BSS/ICA for multi-block data

In many applications, we need to perform a so called group analysis or multi-block data analysis which seeks to identify hidden components, for example, stimuli driven brain patterns that are common in two or more subjects in a group. In many scenarios links or relationships need to be considered to analyze variability and consistency of the components across multi-block data sets. Furthermore, some components do not need to be necessarily independent, they can instead be sparse, smooth or non-negative (e.g., for spectral components). Moreover, it is often necessary to impose some additional constraints in order to estimate some components, which are identical or maximally correlated (across multi-block data sets) with regard to their spatial distributions, spectral, or temporal patterns. In the simplest scenario a multi-block dataset consists set of matrices  $\mathbf{Y}_1, \mathbf{Y}_2, \dots, \mathbf{Y}_K$  with  $K \geq 2$ . In general, each matrix may have different numbers of rows or different number of columns. Our objective is to simultaneously perform matrix decompositions (in the case when the number of columns of the data matrices is the same):

$$\mathbf{Y}_k = \mathbf{A}_k \mathbf{B}_C^T + \tilde{\mathbf{A}}_k \mathbf{B}_k^T + \mathbf{E}_k, \quad (21.247)$$

consisting of three terms. The first term  $\mathbf{A}_k \mathbf{B}_C^T$  represents joint structure via the common matrix  $\mathbf{B}_C \in \mathbb{R}^{I_k \times R}$ , the second term  $\tilde{\mathbf{A}}_k \mathbf{B}_k^T$  represents individual structure and the last term  $\mathbf{E}_k$  represents error.

Alternatively, for a set of data matrices  $\mathbf{Y}_k$  with common number of rows, but possibly different number of columns, we can consider the dual model (see Figure 21.12):

$$\mathbf{Y}_k = \mathbf{A}_k \mathbf{B}_k^T + \mathbf{E}_k = \mathbf{A}_C \mathbf{B}_{C,k}^T + \tilde{\mathbf{A}}_k \mathbf{B}_{I,k}^T + \mathbf{E}_k, \quad (21.248)$$

where  $\mathbf{A}_k = [\mathbf{A}_C, \tilde{\mathbf{A}}_k]$ .

In the special case, when  $\mathbf{A}_k = \mathbf{A}_C \in \mathbb{R}^{I_1 \times J_1}$  for  $k = 1, 2, \dots, K$  the problem simplifies to Common Component Analysis or Population Value Decomposition (PVD) [176]. In more general case, in order to estimate desired common factor matrices  $\mathbf{A}_C \in \mathbb{R}^{I_1 \times R}$  with  $R < J_k$ , we can formulate the following constrained optimization problem, with orthogonality constraints [177]:

$$\min \sum_{k=1}^K \|\mathbf{Y}_k - \mathbf{A}_C \mathbf{B}_{C,k}^T\|_F^2 \quad (21.249)$$

$$\text{s.t. } \mathbf{A}_C^T \mathbf{A}_C = \mathbf{I}, \quad \tilde{\mathbf{A}}_k^T \tilde{\mathbf{A}}_k = \mathbf{I}, \quad \mathbf{A}_C^T \tilde{\mathbf{A}}_k = \mathbf{0}, \quad \mathbf{Y}_k = \mathbf{A}_k \mathbf{B}_k^T \quad \forall k.$$

These 2-way models can be naturally extended to linked multilinear BSS and in the special case of linked multilinear ICA (assuming that mutual statistical independence constraints are used in all modes).

In the linked multilinear BSS the problem is formulated as approximative decompositions of a set of data tensors  $\underline{\mathbf{Y}}^{(k)} \in \mathbb{R}^{I_1 \times I_2 \cdots \times I_N}$ , ( $k = 1, 2, \dots, K$ ) (see Figure 21.13):

$$\underline{\mathbf{Y}}^{(k)} = \underline{\mathbf{G}}^{(k)} \times_1 \mathbf{B}^{(1,k)} \times_2 \mathbf{B}^{(2,k)} \cdots \times_N \mathbf{B}^{(N,k)} + \underline{\mathbf{E}}^{(k)}, \quad (21.250)$$

where each factor (component) matrix  $\mathbf{B}^{(n,k)} = [\mathbf{B}_C^{(n)}, \mathbf{B}_I^{(n,k)}] \in \mathbb{R}^{I_n \times J_n}$  is composed of two bases:  $\mathbf{B}_C^{(n)} \in \mathbb{R}^{I_n \times R_n}$  (with  $0 \leq R_n \leq J_n$ ), which are common bases for all available data or more generally

$$\begin{aligned}
 \mathbf{Y}_1 &\approx \mathbf{A}_1 \mathbf{B}_c^T + \tilde{\mathbf{A}}_1 \mathbf{B}_1^T \\
 (I_1 \times T) & \quad (I_1 \times R) \quad (R \times T) \quad (I_1 \times J_1) \quad (J_1 \times T) \\
 \mathbf{Y}_2 &\approx \mathbf{A}_2 \mathbf{B}_c^T + \tilde{\mathbf{A}}_2 \mathbf{B}_2^T \\
 (I_2 \times T) & \quad (I_2 \times R) \quad (R \times T) \quad (I_2 \times J_2) \quad (J_2 \times T) \\
 \vdots & \quad \vdots \\
 \mathbf{Y}_K &\approx \mathbf{A}_K \mathbf{B}_c^T + \tilde{\mathbf{A}}_K \mathbf{B}_K^T \\
 (I_K \times T) & \quad (I_K \times R) \quad (R \times T) \quad (I_K \times J_K) \quad (J_K \times T)
 \end{aligned}$$

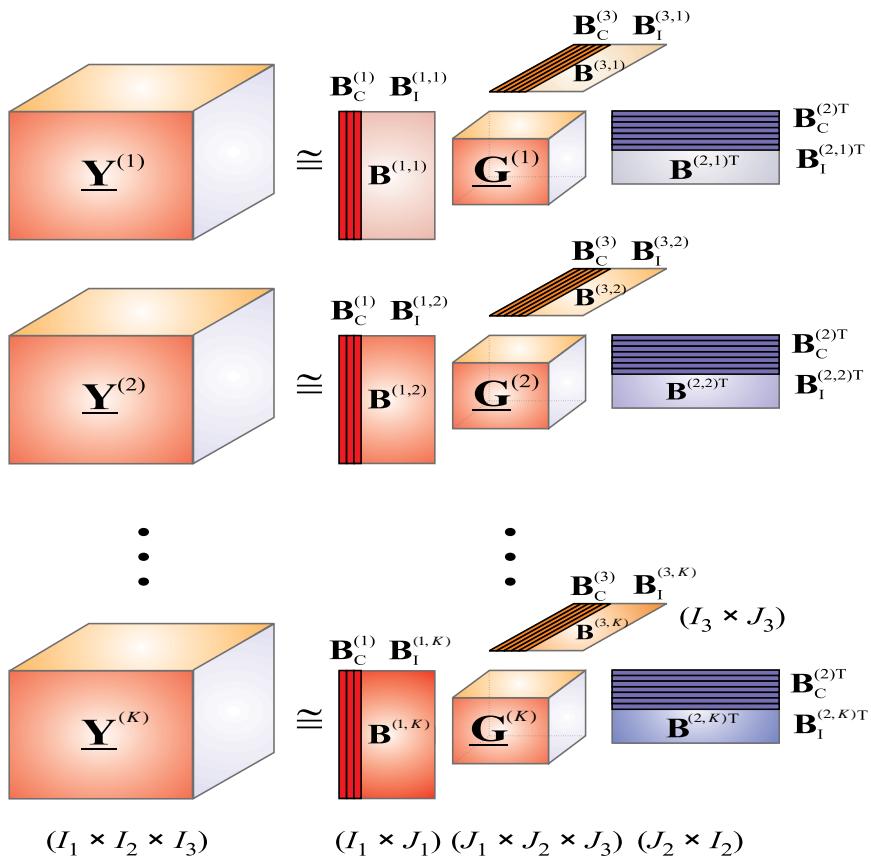

(a)

$$\begin{aligned}
 \mathbf{Y}_1 &\approx \underbrace{\mathbf{A}_C \widetilde{\mathbf{A}}_1}_{(I_1 \times J_1)} \mathbf{B}_1^T \\
 (I_1 \times T_1) & \quad (J_1 \times T_1) \\
 \mathbf{Y}_2 &\approx \underbrace{\mathbf{A}_C \widetilde{\mathbf{A}}_2}_{(I_1 \times J_2)} \mathbf{B}_2^T \\
 (I_1 \times T_2) & \quad (J_2 \times T_2) \\
 \vdots & \quad \vdots \\
 \mathbf{Y}_K &\approx \underbrace{\mathbf{A}_C \widetilde{\mathbf{A}}_K}_{(I_1 \times J_K)} \mathbf{B}_K^T \\
 (I_1 \times T_K) & \quad (J_K \times T_K)
 \end{aligned}$$

(b)

**FIGURE 21.12**

Simple models of linked multi-block matrix decomposition. (a) The objective is to find the constrained matrix  $\mathbf{B}_C \in \mathbb{R}^{R \times T}$  representing common components (e.g., independent, nonnegative, or sparse components) and individual components represented by matrices  $\mathbf{B}_k \in \mathbb{R}^{T \times J_k}$ . (b) Dual model, in which the objective is to find the common matrix  $\mathbf{A}_C \in \mathbb{R}^{I_1 \times R}$  and a set of individual matrices  $\widetilde{\mathbf{A}}_k \in \mathbb{R}^{I_1 \times (J_k - R)}$ . These models can be considered as generalization of low-rank matrix approximation methods, including, CCA/PLS, ICA, SCA and NMF.

**FIGURE 21.13**

A generalized model of multi-block tensor decompositions for linked multiway component analysis (especially, Linked Multilinear ICA). The objective is to find the core tensors  $\underline{\mathbf{G}}^{(k)} \in \mathbb{R}^{J_1 \times J_2 \times J_3}$  and constrained factor matrices  $\mathbf{B}^{(n,k)} = [\mathbf{B}_C^{(n)}, \mathbf{B}_I^{(n,k)}] \in \mathbb{R}^{I_n \times J_n}$ , ( $n = 1, 2, 3$ ), which are partially linked or locally maximally correlated, i.e., they have the same common (or highly correlated) components  $b_{j_n}^{(n,k)}$  for some selected indexes  $j_n$ ,  $n$ ,  $k$ .

represent similar or maximally correlated components, and  $\mathbf{B}_I^{(n,k)} \in \mathbb{R}^{I_n \times (J_n - R_n)}$ , which are generally different and mutually independent, for example, they correspond to stimuli/tasks independent individual characteristics. Based on such a decomposition model, our objective is to estimate the common factors  $\mathbf{B}_C^{(n)}$ , the independent factors  $\mathbf{B}_I^{(n,k)}$  and the interactions between them via the core tensors  $\underline{\mathbf{G}}^{(k)}$  for  $k = 1, 2, \dots, K$  and  $n = 1, 2, \dots, N$ .

If  $\mathbf{B}^{(n,k)} = \mathbf{B}_C^{(n)} \in \mathbb{R}^{I_n \times J_n}$  for all modes  $n$ , then we can concatenate all data tensors along this mode, perform tensor decomposition by applying any standard BSS algorithm for unfolding matrices to

compute the desired components in each mode (e.g., to estimate independent components, we apply any standard ICA algorithm) [12, 14]. In the more general case, when the number of common components  $R_n$  are unknown, we can perform the unfolding of each data tensor  $\underline{\mathbf{Y}}^{(k)}$  in each mode, and then apply suitable constrained matrix factorizations (e.g., by applying standard algorithms for ICA, NMF, SCA, PCA/SVD) for the reduced unfolding matrices:

$$\mathbf{Y}_{(n)}^{(k)} \cong \mathbf{B}^{(n,k)} \mathbf{G}_{(n)}^{(k)} \mathbf{Z}^{(n,k)} = \mathbf{B}_{n,k} \mathbf{A}_{n,k}^T, \quad (21.251)$$

for  $n = 1, 2, \dots, N$  and  $k = 1, 2, \dots, K$ , where the matrices  $\mathbf{B}^{(n,k)}$  represent individual components  $\mathbf{b}_j^{(n,k)}$  (some of them being linked), while the matrices  $\mathbf{A}_{n,k}^T = \mathbf{G}_{(n)}^{(k)} \mathbf{Z}^{(n,k)}$  represent basis (mixing) vectors or linked mixing processes, and  $\mathbf{Z}^{(n,k)} = [\mathbf{B}^{(N,k)} \otimes \dots \otimes \mathbf{B}^{(n+1,k)} \otimes \mathbf{B}^{(n-1,k)} \dots \otimes \mathbf{B}^{(1,k)}]^T$ .

In order to identify the common components  $\mathbf{b}_j^{(n)}$ , in the next stage we need to perform the statistical analysis and to rank and compare the individual components  $\mathbf{b}_j^{(n,k)}$  extracted in each mode  $n$ , for all blocks  $K$ , by performing clustering and ordering the components to identify common or similar (highly correlated) components (see e.g., [8, 14, 178]). In the last step, we compute the core tensors which describe the functional links between common components.

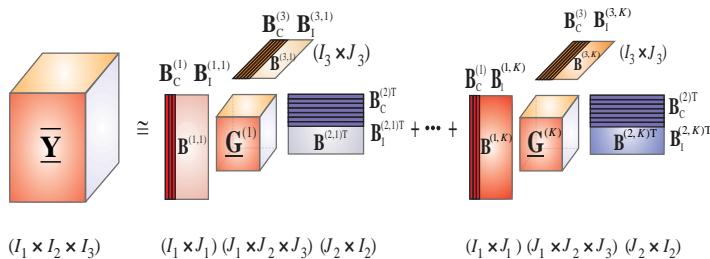

Alternative approach in the case when  $R_n < J_n$ , is to unfold each data tensor  $\underline{\mathbf{Y}}^{(k)}$  in each mode, and to perform a set of linked and constrained matrix factorizations:  $\mathbf{Y}_{(n)}^{(k)} \cong \mathbf{B}_C^{(n)} \mathbf{A}_C^{(n,k)T} + \mathbf{B}_I^{(n,k)} \mathbf{A}_I^{(n,k)T}$  through solving constrained optimization problems:

$$\begin{aligned} \min \sum_{k=1}^K & \| \mathbf{Y}_{(n)}^{(k)} - \mathbf{B}_C^{(n)} \mathbf{A}_C^{(n,k)T} + \mathbf{B}_I^{(n,k)} \mathbf{A}_I^{(n,k)T} \|_F^2 \\ & + f_n(\mathbf{B}_C^{(n)}), \quad \text{s.t. } \mathbf{B}_C^{(n)T} \mathbf{B}_I^{(n,k)} = \mathbf{0} \quad \forall k, n, \end{aligned} \quad (21.252)$$

where  $f_n$  denotes the penalty terms which impose additional constraints on common components  $\mathbf{B}_C^{(n)}$ , in order to extract unique and desired components. In the special case of orthogonality constraints, the problem can be transformed to a generalized eigenvalue problem and solved by the power method [177]. The key point is to assume that common factor sub-matrices  $\mathbf{B}_C^{(n)}$  are present in all multiple data blocks and hence reflect structurally complex (hidden) latent and intrinsic links between them. In practice, the number of common components  $C_n$  in each mode is unknown and should be estimated (see [177] for detail).

Note that our linked multilinear BSS is different from the linked ICA [38] and group NMF/ICA, since we do not limit components diversity by constraining them to be only statistically independent or only nonnegative components and our model is based on constrained Tucker models instead of the rather quite restrictive trilinear CP model.

We conclude that the proposed linked multilinear BSS model provides a framework that is quite flexible and general and it may substantially supplement many of the currently available techniques for group ICA and feature extraction for multi-block data. Moreover, the tensors decompositions models can be extended to a multiway Canonical Correlation Analysis (MCCA), and higher order Partial Least Squares, in which we impose maximal correlations among normalized factor matrices (or subsets of components) and/or core tensors [77].

**FIGURE 21.14**

A Block Term Decomposition (BTD) model of tensors decomposition for linked multiway component analysis (e.g., Linked Multilinear ICA).

For the linked multilinear BSS, we can also exploit the constrained Block Tensor Decomposition (BTD) models [179–181] for an averaging data tensor across subjects (see Figure 21.14):

$$\bar{\mathbf{Y}} = \sum_{k=1}^K (\underline{\mathbf{G}}^{(k)} \times_1 \mathbf{B}^{(1,k)} \times_2 \mathbf{B}^{(2,k)} \cdots \times_N \mathbf{B}^{(N,k)}) + \bar{\mathbf{E}}, \quad (21.253)$$

where  $\bar{\mathbf{Y}} = \sum_{k=1}^K \mathbf{Y}^{(k)}$ . Such model may provide us with additional information.

For group and linked multilinear BSS and ICA applied to the analysis of EEG/MEG data, we usually seek stimuli driven ERPs (event related responses) and/or task related common components (or common basis) reflecting both intra subject and inter subject features as basis, which are independent by involving individual on going brain activities. In other words, we seek event/task-related components  $\mathbf{B}_C^{(n)}$ , that are similar in each mode or maximally correlated across subjects, and event/task independent individual bases  $\mathbf{B}_I^{(s,n)}$ , which are independent or even as far apart as possible (anti-correlated).

How to select common components will depend on the validity of the underlying assumptions and *a priori* knowledge. For instance, identical spatial distributions can well be assumed for homogeneous subject groups, but may be unacceptable in studies that include patients with different ages, mental diseases, or abnormalities. Temporal components may be the same for stimulus- or task-evoked responses that are related to a specific mental task or paradigm, but these will vary for the spontaneous fluctuations that occur in resting state experiments. In some experiments, responses may be assumed similar or identical within, but different across subgroups [37].

### 1.21.5.8 Multiway sparse CCA/PLS using the generalized power method

The concept of standard (matrix) CCA and PLS can be extended to multiway (higher-order) models by using the normalized and standardized tensors  $\underline{\mathbf{X}} \in \mathbb{R}^{I_1 \times I_2 \cdots \times I_N}$  and  $\underline{\mathbf{Y}} \in \mathbb{R}^{K_1 \times K_2 \cdots \times K_M}$ , with  $I_1 = K_1 = I$ , instead of the matrices  $\mathbf{X} \in \mathbb{R}^{I \times N}$  and  $\mathbf{Y} \in \mathbb{R}^{I \times M}$  (see Section 1.21.2.6.6). We assume without any loss of generality that the tubes in mode-1 are standardized to have mean zero and standard deviation one. In such a case we can apply (after additional constraints) unified approach to multiway CCA and PLS.

The key factor is to find projection vectors  $\mathbf{w}_x^{(n)} \in \mathbb{R}^{I_n}$  and  $\mathbf{w}_y^{(m)} \in \mathbb{R}^{K_m}$  such that the canonical vectors, defined as

$$\mathbf{t}_1 = \underline{\mathbf{X}} \bar{\times}_2 \mathbf{w}_x^{(1)} \bar{\times}_3 \mathbf{w}_x^{(2)} \cdots \bar{\times}_N \mathbf{w}_x^{(N-1)} \in \mathbb{R}^{I_1}, \quad (21.254)$$

$$\mathbf{u}_1 = \underline{\mathbf{Y}} \bar{\times}_2 \mathbf{w}_y^{(1)} \bar{\times}_3 \mathbf{w}_y^{(2)} \cdots \bar{\times}_M \mathbf{w}_y^{(M-1)} \in \mathbb{R}^{I_1}, \quad (21.255)$$

are maximally correlated, that is

$$\begin{aligned} \max\{\mathbf{u}_1^T \mathbf{t}_1\} &= \\ \max\{(\underline{\mathbf{X}} \bar{\times}_2 \mathbf{w}_x^{(1)} \bar{\times}_3 \mathbf{w}_x^{(2)} \cdots \bar{\times}_N \mathbf{w}_x^{(N-1)})^T (\underline{\mathbf{Y}} \bar{\times}_2 \mathbf{w}_y^{(1)} \bar{\times}_3 \mathbf{w}_y^{(2)} \cdots \bar{\times}_M \mathbf{w}_y^{(M-1)})\}, \end{aligned} \quad (21.256)$$

subject to suitable constraints, typically  $\|\mathbf{w}_x^{(n)}\|_2 \leq 1$  and  $\|\mathbf{w}_y^{(m)}\|_2 \leq 1$ .

It can be shown that a such optimization problem is equivalent to the following maximization problem

$$\max_{\mathbf{w}_1^{(p)}} \{\underline{\mathbf{Z}} \bar{\times}_1 \mathbf{w}_1^{(1)} \bar{\times}_2 \mathbf{w}_1^{(2)} \cdots \bar{\times}_P \mathbf{w}_1^{(P)}\}, \quad \text{s.t. } \|\mathbf{w}_1\|_2 \leq 1, \quad (21.257)$$

where  $\mathbf{w}_1^{(p)} = \mathbf{w}_x^{(p)}$  for  $p = 1, 2, \dots, N-1$  and  $\mathbf{w}_1^{(p)} = \mathbf{w}_y^{(p-N+1)}$  for  $p = N, N+1, \dots, P$ , and the generalized covariance of two tensors is defined as

$$\underline{\mathbf{Z}} = \underline{\mathbf{X}} \times_1 \underline{\mathbf{Y}} = COV_{(1,1)}(\underline{\mathbf{X}} \underline{\mathbf{Y}}) \in \mathbb{R}^{I_2 \times I_3 \cdots \times I_N \times K_2 \times K_3 \cdots \times K_M}, \quad (21.258)$$

with entries

$$z_{i_2, \dots, i_N, k_2, \dots, k_M} = \sum_{i=1}^I x_{i, i_2, \dots, i_N} y_{i, k_2, \dots, k_M}. \quad (21.259)$$

Note that the tensor  $\underline{\mathbf{Z}}$  has order  $P = N + M - 2$ . In the special case when the tensor  $\underline{\mathbf{Y}}$  is reduced to the matrix  $\mathbf{Y}$ , we have

$$\underline{\mathbf{Z}} = \underline{\mathbf{X}} \times_1 \mathbf{Y} \quad (21.260)$$

or both data are matrices and we can use the standards notation  $\mathbf{Z} = \mathbf{X}^T \mathbf{Y}$ .

If we need to impose sparsity constraints we can use the following cost function

$$\max_{\mathbf{w}_1^{(p)}} \{(\underline{\mathbf{Z}} \bar{\times}_1 \mathbf{w}_1^{(1)} \bar{\times}_2 \mathbf{w}_1^{(2)} \cdots \bar{\times}_P \mathbf{w}_1^{(P)})^2 - \sum_p \alpha_p \|\mathbf{w}_1^{(p)}\|_1\}, \quad \text{s.t. } \|\mathbf{w}_1^{(p)}\|_2 \leq 1. \quad (21.261)$$

This optimization of the cost function (21.261) leads to the following simple update rule

$$\mathbf{w}_1^{(p)} = \frac{\mathcal{S}_1(\mathbf{w}_1^{(\bar{p})}, \alpha_p)}{\|\mathcal{S}_1(\mathbf{w}_1^{(\bar{p})}, \alpha_p)\|_2}, \quad (21.262)$$

where

$$\mathbf{w}_1^{(\bar{p})} = \underline{\mathbf{Z}} \bar{\times}_1 \mathbf{w}_1^{(1)} \cdots \bar{\times}_{p-1} \mathbf{w}_1^{(p-1)} \bar{\times}_{p+1} \mathbf{w}_1^{(p+1)} \cdots \bar{\times}_P \mathbf{w}_1^{(P)}. \quad (21.263)$$

In the special case when  $\alpha_n = 0$  the above updated formula simplifies to (without sparsity constraints)

$$\mathbf{w}_1^{(p)} = \frac{\mathbf{w}_1^{(\bar{p})}}{\|\mathbf{w}_1^{(\bar{p})}\|_2}. \quad (21.264)$$

Our objective in a Multiway CCA is to estimate the set of factor matrices or weights  $\mathbf{W}^{(p)} = [\mathbf{w}_1^{(p)}, \mathbf{w}_2^{(p)}, \dots, \mathbf{w}_J^{(p)}] \in \mathbb{R}^{Q_p \times J}$  for  $p = 1, 2, \dots, P$ , that maximize the following cost function (which can be considered as a generalization of the variance used in the standard sparse PCA and CCA).

$$\begin{aligned} \max_{\{\mathbf{w}_j^{(p)}\}} & \left\{ (\underline{\mathbf{Z}}^{(j)} \tilde{\times}_1 \mathbf{w}_j^{(1)} \tilde{\times}_2 \mathbf{w}_j^{(2)} \cdots \tilde{\times}_P \mathbf{w}_j^{(P)})^2 - \sum_p \alpha_p \|\mathbf{w}_j^{(p)}\|_1 \right\}, \\ \text{s.t. } & \|\mathbf{w}_j^{(p)}\|_2 \leq 1 \quad (j = 1, 2, \dots, J), \end{aligned} \quad (21.265)$$

where the tensor  $\underline{\mathbf{Z}}^{(j)}$  is estimated iteratively using a simple deflation approach

$$\lambda_j = |\underline{\mathbf{Z}}^{(j)} \tilde{\times}_1 \mathbf{w}_j^{(1)} \tilde{\times}_2 \mathbf{w}_j^{(2)} \cdots \tilde{\times}_P \mathbf{w}_j^{(P)}|, \quad (21.266)$$

$$\underline{\mathbf{Z}}^{(j+1)} = \underline{\mathbf{Z}}^{(j)} - \lambda_j (\mathbf{w}_j^{(1)} \circ \mathbf{w}_j^{(2)} \cdots \circ \mathbf{w}_j^{(P)}), \quad (21.267)$$

with  $\underline{\mathbf{Z}}^{(1)} = \underline{\mathbf{Z}}$ .

The above set of optimization problems leads to the following update rule (see Algorithm 6) which is very similar to the sparse sequential factorization for the CP model (see Section 1.21.5.3):

$$\mathbf{w}_j^{(p)} = \frac{\mathcal{S}_1(\mathbf{w}_j^{(\bar{p})}, \alpha_p)}{\|\mathcal{S}_1(\mathbf{w}_j^{(\bar{p})}, \alpha_p)\|_2} \quad (j = 1, 2, \dots, J),$$

where

$$\mathbf{w}_j^{(\bar{p})} = \underline{\mathbf{Z}}^{(j)} \tilde{\times}_1 \mathbf{w}_j^{(1)} \cdots \tilde{\times}_{p-1} \mathbf{w}_j^{(p-1)} \tilde{\times}_{p+1} \mathbf{w}_j^{(p+1)} \cdots \tilde{\times}_P \mathbf{w}_j^{(P)}$$

and

$$\mathcal{S}_1(\mathbf{w}, \alpha) = \text{sign}(\mathbf{w})[|\mathbf{w}| - \alpha 1]_+. \quad (21.268)$$

In multiway PLS our objective is to perform simultaneous constrained Tucker-1 decompositions, with common or maximally correlated factor matrices (see Figure 21.15):

$$\boxed{\underline{\mathbf{X}} = \mathbf{G}_{\mathbf{X}} \times_1 \mathbf{T}^{(1)} + \mathbf{E}_{\mathbf{X}},} \quad (21.269)$$

$$\boxed{\underline{\mathbf{Y}} = \mathbf{G}_{\mathbf{Y}} \times_1 \mathbf{U}^{(1)} + \mathbf{E}_{\mathbf{Y}},} \quad (21.270)$$

where the additional constraints imposed are that:  $\mathbf{T}^{(1)} = [\mathbf{t}_1, \mathbf{t}_2, \dots, \mathbf{t}_J]$  and  $\mathbf{U}^{(1)} = [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_J]$  should be maximally correlated, while the other factor matrices should be essentially different (e.g., orthogonal, or mutually independent).

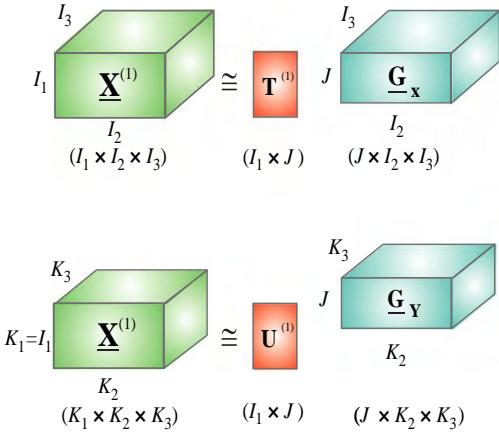

**FIGURE 21.15**

Illustration of a generalized Multiway PLS model for third-order tensors (see Eqs. 21.269, 21.270). The objective is to perform approximative decompositions of the independent tensor  $\underline{\mathbf{X}} \cong \mathbf{G}_{\mathbf{X}} \times_1 \mathbf{T}^{(1)} \in \mathbb{R}^{I_1 \times I_2 \times I_3}$  and dependent tensor  $\underline{\mathbf{Y}} \cong \mathbf{G}_{\mathbf{Y}} \times_1 \mathbf{U}^{(1)} \in \mathbb{R}^{K_1 \times K_2 \times K_3}$ , with  $I_1 = K_1 = I$ , by imposing additional constraints, specifically that the two factor matrices  $\mathbf{T}^{(1)} = [\mathbf{t}_1, \mathbf{t}_2, \dots, \mathbf{t}_J]$  and  $\mathbf{U}^{(1)} = [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_J]$  are maximally correlated in the sense that the covariances between all components are maximized, i.e.,  $\max\{\mathbf{u}_j^T \mathbf{t}_j\}, \forall j$ .

**Algorithm 6.** Power Method for Sparse Multiway CCA

**Require:** Data tensors  $\underline{\mathbf{X}}^{(1)} = \underline{\mathbf{X}}$ ,  $\underline{\mathbf{Y}}^{(1)} = \underline{\mathbf{Y}}$ , sparsity coefficients  $\alpha_p \geq 0$ , and initial vectors  $\mathbf{w}_j^{(p)}$  for  $(p = 1, 2, \dots, P)$ .

- 1: Compute  $\underline{\mathbf{Z}}^{(1)} = \underline{\mathbf{X}} \times_1 \underline{\mathbf{Y}} = COV_{(1,1)}(\underline{\mathbf{X}} \underline{\mathbf{Y}}) \in \mathbb{R}^{I_2 \times I_3 \dots \times I_N \times K_2 \times K_3 \dots \times K_M};$
- 2: For  $p = 1, 2, \dots, P$  and  $j = 1, 2, \dots, J$ 
  - (a) Repeat until convergence of  $\mathbf{w}_j^{(p)}$ ;
  - 3:  $\mathbf{w}_j^{(\bar{p})} = \underline{\mathbf{Z}}^{(j)} \bar{\times}_1 \mathbf{w}_j^{(1)} \dots \bar{\times}_{p-1} \mathbf{w}_j^{(p-1)} \bar{\times}_{p+1} \mathbf{w}_j^{(p+1)} \dots \bar{\times}_P \mathbf{w}_j^{(P)};$
  - 4:  $\mathbf{w}_j^{(p)} = \frac{\mathcal{S}_1(\mathbf{w}_j^{(\bar{p})}, \alpha_p)}{\|\mathcal{S}_1(\mathbf{w}_j^{(\bar{p})}, \alpha_p)\|_2}$  (for  $\alpha_p = 0$  take  $\mathbf{w}_j^{(p)} = \frac{\mathbf{w}_j^{(\bar{p})}}{\|\mathbf{w}_j^{(\bar{p})}\|_2}$ );
  - 5: (b) Perform optional Gram-Schmidt orthogonalization;
  - 6: (c)  $\lambda_j = |\underline{\mathbf{Z}}^{(j)} \bar{\times}_1 \mathbf{w}_j^{(1)} \bar{\times}_2 \mathbf{w}_j^{(2)} \dots \bar{\times}_P \mathbf{w}_j^{(P)}|;$
  - 7: (d)  $\underline{\mathbf{Z}}^{(j+1)} = \underline{\mathbf{Z}}^{(j)} - \lambda_j (\mathbf{w}_j^{(1)} \circ \mathbf{w}_j^{(2)} \dots \circ \mathbf{w}_j^{(P)});$
  - 8: **return**  $\mathbf{W}^{(p)} = [\mathbf{w}_1^{(p)}, \mathbf{w}_2^{(p)}, \dots, \mathbf{w}_J^{(p)}] \in \mathbb{R}^{Q_p \times J}$ ,  $\Lambda^* = \text{diag}(\lambda_1, \dots, \lambda_J);$
  - 9: **return**  $\mathbf{t}_j = \underline{\mathbf{X}} \bar{\times}_2 \mathbf{w}_j^{(1)} \bar{\times}_3 \mathbf{w}_j^{(2)} \dots \bar{\times}_N \mathbf{w}_j^{(N-1)}$ ,  
 $\mathbf{u}_j = \underline{\mathbf{Y}} \bar{\times}_2 \mathbf{w}_j^{(N)} \bar{\times}_3 \mathbf{w}_j^{(N+1)} \dots \bar{\times}_K \mathbf{w}_j^{(P)}$ ; ( $j = 1, 2, \dots, J$ ).

Such models allow for different types of structures on  $\mathbf{X}$  and  $\mathbf{Y}$  and provides a general framework for solving multiway regression problems that explore complex relationships between multi-dimensional dependent and independent variables. For example, tensor decompositions can be applied to emerging neuroimaging genetics studies to investigate the links between biological parameters measured with brain imaging and genetic variability.

### 1.21.6 Summary

In this chapter, we have discussed several important latent variables models, especially PCA, ICA, NMF, CCA and PLS and their extensions. We have tried to unify different approaches and methods by applying constrained matrix factorizations or penalized matrix decompositions. Imposing various constraints on the factors, components, or latent variables allows us to extract the components with desired properties. This approach has been extended to the important case of multi-dimensional data by using constrained tensor decompositions. Moreover, the concept of blind source separation has been extended to multilinear or multiway BSS using tensor factorizations.

## 1.22.1 Introduction

Large amounts of data are being generated every second from a wide variety of sources including online news, social media, images from personal digital cameras, images from telescopy, financial data, biological data, such as DNA sequences, just to name a few.

Of course, all that raw data are useless without efficient tools for extracting and analyzing useful information contained within. One of the most standard and useful tasks in machine learning and data analysis is that of labeling, assigning each data point a certain tag, label or a numerical value according to some prespecified criterion. These labeled data, in the form of training sets, can be used to develop algorithms for making automatic inference about the future unseen data, for tasks, such as image classification, predicting disease susceptibility on the basis of genetic information, automatically tagging new topics, and many others.

However, in many situations obtaining high-quality labeled information can be costly and time-consuming as it may require human input (e.g., labeling speech, images, or news stories) or experimentation (testing for disease). Thus, there is a growing need to develop effective and computationally efficient machine learning algorithms utilizing data, which combines a small number of labeled instances with abundant unlabeled data. In addition, understanding the contribution of unlabeled data to learning from examples is closely related to the fundamental problem of understanding human and animal cognitive process, many of them, arguably, unsupervised or weakly supervised. Semi-supervised or partially supervised learning refers to a class of machine learning techniques which combine labeled and unlabeled data to build classifiers.

Two basic questions of semi-supervised learning is whether unlabeled data are helpful for inference, and if yes, how they can be used to improve the inference quality. These two questions have been studied intensively in the last decade. It should be made clear from the outset that effective use of unlabeled data requires certain assumptions. Certainly, it is not possible to have prediction purely on the basis of unlabeled data alone. Thus the role of unlabeled data is to restrict the space of potential inference rules, so that choosing a correct (or nearly correct) predictor requires less labeled data. To make this possible the structure of unlabeled data has to be aligned with the structure provided by the labels. The nature of this alignment can be encoded through several mathematical formulations leading to different algorithms and theoretical analyses.

The three most common assumptions of semi-supervised learning are the cluster assumption, manifold assumption, and what can be called a “compatibility” assumption. For simplicity, we will discuss these in the context of classification, although other setting may also be applicable.

The cluster assumption suggests that the unlabeled data has clusters, with each cluster corresponding to just a single class. Thus, identifying the clusters from unlabeled data dramatically reduces the space of possible classification rules. In the simplest noiseless case, one labeled instance per cluster is enough for classification.

The manifold assumption is a bit harder to formulate informally. Basically, it states that the data lie on or close to low-dimensional submanifolds in a high-dimensional space and that the conditional class likelihood varies smoothly along the manifold.

Finally, the compatibility assumption relies on data having a different set of attributes, such as web pages having both text and link information. The assumption is that the classification obtained separately using these attributes need to be consistent when compared on the unlabeled part of the data set.

Some of the earliest theoretical work on semi-supervised learning is based on the cluster assumption. For example, the papers [1–3] address the relative significance of labeled and unlabeled data under a special type of clustering assumption, when the classes are sampled from different mixture components. It turns out that in that setting the labeled data is exponentially more informative than the unlabeled points. An important early work on semi-supervised learning is based on the Vapnik’s idea of transductive inference [4]. Transductive inference is not completely equivalent to semi-supervised learning as the goal of transduction is to classify the unlabeled points without necessarily building a global classifier (known as the out-of-sample extension problem). Vapnik’s approach consisted in finding a classifier that maximized margin over *unlabeled data* and can be interpreted as a form of cluster assumption. Another important early algorithm was co-training [5], which introduced the idea of semi-supervised learning based on the “compatibility” assumption. A more recent class of algorithms has been based on graph Laplacian, where unlabeled data is utilized to construct a graph representing the underlying space. The Laplacian of that graph is then used for restricting the space of potential classifiers.

In a standard semi-supervised learning (SSL) problem, one is given two sample sets, the labeled set  $X_L$  together with its label set  $Y_L$ , and the unlabeled set  $X_U$ .  $X_L$  consists of  $l$  sample points  $X_L = \{x_1, \dots, x_l\}$ , with the corresponding labels as  $Y_L = \{y_1, \dots, y_l\}$ , and  $X_U$  consists of  $u$  sample points  $X_U = \{x_{l+1}, \dots, x_{l+u}\}$ . The label for  $X_U$  is  $Y_U = \{y_{l+1}, \dots, y_{l+u}\}$ , which is unknown. It is also convenient to denote  $X = X_L \cup X_U$ , and similarly  $Y = Y_L \cup Y_U$ , where all  $x_i \in \mathcal{X}$  and  $y_i \in \mathcal{Y}$ . Let  $n = l + u$ . The  $\mathcal{X}$  can be a regular subset of  $\mathbb{R}^d$ , a smooth manifold in  $\mathbb{R}^d$ , or sequences in language problems. Similarly,  $\mathcal{Y}$  can be binary class labels  $\{\pm 1\}$ , real-valued numbers, or complex structured output. The data in SSL is also called partially observed data.

In inductive inference, the goal is to find a function  $\hat{f}(x)$  on the whole data domain  $\mathcal{X}$  such that for a new data point  $x \in \mathcal{X}$ , its label  $y = \hat{f}(x)$  can be obtained by function evaluation. Instead of requiring  $\hat{f}(x)$  to be a good estimate on the whole domain, in transductive inference,  $\hat{f}(x)$  is only required to be defined on the unlabeled sample points, i.e., samples in  $X_U$ .

To define the setting for some of these problems more formally, let  $P(x, y)$  be a joint distribution on  $\mathcal{X} \times \mathcal{Y}$ , where  $\mathcal{X}$  is the domain for the attributes and  $\mathcal{Y}$  is the domain for the labels. We will assume that the data is sampled i.i.d. from the probability distribution  $P$ , a typical assumption in the machine learning literature. Let the marginal distribution on  $\mathcal{X}$  be  $P(x)$ . Then goal of inference is to reconstruct the conditional probability distribution  $P(y|x)$ . Abundant unlabeled data mean that  $P(x)$  can be assumed

to be given, or at least can be accurately estimated. Thus we need to connect the conditional distribution  $P(x|y)$  to the marginal  $P(x)$ . Thus the three assumptions can be represented as follows:

- *Cluster assumption*: Marginal distribution of the data  $P(x)$  has multiple clusters, and example points of the same cluster are likely to be of the same class. It is possible for one class to have multiple clusters. The cluster assumption is closely related to the low density separation assumption which states that the decision boundary should pass through a region of low density.
- *Manifold assumption*: The marginal distribution of the data  $P(x)$  is supported on a low-dimensional manifold embedded in a high-dimensional ambient space. The conditional distribution  $P(y|x)$  is smooth, as a function of  $x$ , with respect to this low-dimensional manifold.
- *Compatibility assumption*: In multi-view learning, disagreement between views happens with zero probability. Specifically, in the case of two views, for a data point  $x = (x_1, x_2)$ ,  $P(f_1(x_1) \neq f_2(x_2)) = 0$ , where  $f_1(\cdot)$  and  $f_2(\cdot)$  are classifiers in each view. This is one of the important assumptions of co-training [5].

The chapter is organized as follows. A variety of algorithms have been introduced for SSL since 1990s; several of them are reviewed in Section 1.22.2 according to a rough historical order.

One of the earliest SSL algorithms is transductive SVM (TSVM), which is also closely related to low density separation based algorithms. These methods try to find classifiers that lie in the low density regions which are more likely to be the decision boundary. Starting from the cluster assumption and manifold assumption, graph-based SSL methods are another active area. Some of these methods are based on mature function approximation theories, and also show promising results in practice.

Another early SSL algorithm is co-training, which explores the idea of using two different “views” of data to improve learning. Following the co-training framework, multi-view and co-regularization methods further explore the information gain from using more than one view.

SSL for structured outputs, a popular recent topic of research, is briefly discussed in Section 1.22.3. Applications include various natural language processing problems. The need for SSL algorithms is obvious: the difficulty of obtaining high-quality labels is even higher in structured learning, since the output is more complex than a single scalar value.

One key difficulty for a wider application of SSL in practice is the computational cost for most SSL algorithms. Several works on large scale SSL are reviewed in Section 1.22.4. In particular, one technique using graph Laplacian eigenvectors is discussed in detail.

The fundamental question for SSL: whether unlabeled data are helpful, and if so, how to use them is still an interesting question. Several related studies are discussed in Section 1.22.5, and several open issues of SSL are also briefly discussed in Section 1.22.6. For other reviews on SSL, see [6–8].

## 1.22.2 Semi-supervised learning algorithms

A variety of algorithms have been introduced for SSL since 1990s. Several of them are reviewed in this section.

### 1.22.2.1 TSVM and low density separation

Transductive support vector machines (TSVMs) generalize support vector machines to SSL setting with unlabeled data. Similar to SVMs, TSVMs also learn a large margin hyperplane classifier using labeled

training data. However, TSVMs simultaneously force this hyperplane to be far away from both the labeled and the unlabeled data.

The linear TSVMs solve the following optimization problem:

$$\begin{aligned} \min_{w, \xi, y_i, l+1 \leq i \leq n} \quad & \frac{1}{2} \|w\|^2 + C \sum_{i=1}^l \xi_i + C^* \sum_{i=l+1}^n \xi_i, \\ \text{s.t.} \quad & y_i (w^T x_i) \geq 1 - \xi_i, \quad \xi_i \geq 0, \quad 1 \leq i \leq l, \\ & y_i (w^T x_i) \geq 1 - \xi_i, \quad \xi_i \geq 0, \quad l+1 \leq i \leq n, \end{aligned} \quad (22.1)$$

where  $w$  is the coefficient of the hyperplane,  $C$  and  $C^*$  are the regularization penalty coefficients. The problem is similar to a regular SVM problem, while the difference lies in that the labels of unlabeled points are treated as optimization variables. Then a large margin constraint is added to both labeled and unlabeled data, hoping to find a classifier with the maximum classification margin for both labeled and unlabeled examples. Nonlinear classifiers can be obtained by choosing a reproducing Hilbert space as the solution space.

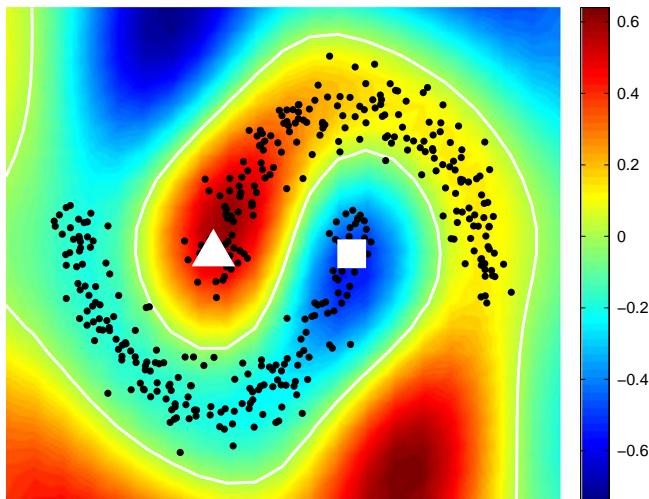

An approximation solution by local search is proposed by Joachims [9]. The algorithm begins with a labeling of the unlabeled data based on the classification of an inductive classifier. Then it improves the solution by switching the labels of the unlabeled data so that the objective function decreases. Notice that TSVMs are transductive, meaning that the algorithm only produces the prediction on unlabeled data, instead of a function over the whole domain. Several other algorithms are introduced to generalize to inductive learning, e.g., Laplacian SVM [10]. Since the optimization problem of TSVMs is non-convex, many approximation methods are introduced. The SVM-light [9] is the first widely used TSVMs implementation. A fast linear SVM (SVMlin) [11] is proposed for large scale application.  $\nabla$ TSVM using gradient descent is proposed in [12]. The concave-convex procedure (CCCP) is used in [13] to solve TSVMs problem. CCCP iteratively optimizes non-convex cost functions that can be expressed as the sum of a convex function and a concave function. The optimization is carried out iteratively by solving a sequence of convex problems obtained by linearly approximating the concave function in the vicinity of the solution of the previous convex problem. See [14] for a review of different optimization techniques.

TSVMs are shown to perform well in text classification tasks [9]. Particularly in small labeled data set cases, it generally outperforms supervised method such as SVMs. However, one drawback of TSVMs is that it is a non-convex optimization problem, which poses a serious hurdle. Chapelle et al. [15] use the branch and bound search method on small data sets to find the global optimal solution. The authors show that the globally optimal solution of the TSVMs problem is actually far better than what most practical methods are able to achieve.

An algorithm combining TSVMs and graph-based distance is proposed in [12]. This graph-based distance has a close relation to the geodesic on smooth manifolds. Many graph-based methods explicitly or implicitly involve the low density separation idea, which will be discussed in detail later.

One way of understanding the TSVM algorithm is closely related to the low density separation assumption, which states that the class separation boundaries should lie among the low density regions, or samples of different classes are separated by large margin. TSVMs try to find a decision boundary that lies in low density regions.

A typical classification result of low density separation algorithms is shown in Figure 22.1 [16, Chapter 2]. The triangle and square are the only labeled points in a binary classification problem and all

**FIGURE 22.1**

Low density separation on two-moon data.

other black dots are unlabeled data. The true decision boundary are the low density regions between the two “moons.” Although the data are distributed in such a way that most supervised classifiers will fail, several low density separation based SSL algorithms, e.g., TSVMs, can take advantage of the unlabeled data and recover the decision boundary.

### 1.22.2.2 Co-training and multi-view

One of the most influential SSL algorithms, so-called co-training, was introduced [5]. The framework of co-training is representative for various types of multi-view learning approaches.

In co-training, the data consist of a small labeled data set and a large unlabeled set, which is the typical setting of SSL. However, in addition, each data sample has two distinct views. One typical example studied in [5] is that the description of a web page can be partitioned into the words occurring on that page, and the words occurring in hyperlinks that point to that page. Another example would be two different feature representations of an image, e.g., SIFT [17] and GIST [18]. Notice that the two views of the first example are more likely created by different people, suggesting higher degree of independence, while for the latter example the two views are created from the same data, in the hope of capturing their different aspects.

Formally, let the instance space be  $\mathcal{X} = \mathcal{X}^{(1)} \times \mathcal{X}^{(2)}$ , where  $\mathcal{X}^{(1)}$  and  $\mathcal{X}^{(2)}$  correspond to the two different “views” of an example. Typically, a data point  $x$  is represented by two different feature vectors,  $x^{(1)}$  and  $x^{(2)}$ , such that  $x^{(1)} \in \mathcal{R}^{d_1}$  and  $x^{(2)} \in \mathcal{R}^{d_2}$ . In this case, instance space  $\mathcal{X}$  is simply  $\mathcal{R}^{d_1+d_2}$ . In co-training, each view is assumed to be sufficient for correct classification in itself. Let  $\mathcal{D}$  be a distribution over the instance space  $\mathcal{X}$ , and let  $\mathcal{C}^{(1)}$  and  $\mathcal{C}^{(2)}$  be the concept classes defined over  $\mathcal{X}^{(1)}$  and  $\mathcal{X}^{(2)}$ , respectively.

The co-training framework proceeds as given below:

- a set  $X_L$  of labeled examples, with the corresponding label  $Y_L$ ;
- a set  $X_U$  of unlabeled examples.

Create a pool  $X_{U'}$  of examples by choosing  $u$  examples at random from  $X_U$ , then loop for  $k$  iterations:

1. Use  $(X_L, Y_L)$  to train a classifier  $h_1$  that considers only the  $x_1$  portion of  $x$ .
2. Use  $(X_L, Y_L)$  to train a classifier  $h_2$  that considers only the  $x_2$  portion of  $x$ .
3. Allow  $h_1$  to label  $p$  positive and  $n$  negative examples from  $X_{U'}$ .
4. Allow  $h_2$  to label  $p$  positive and  $n$  negative examples from  $X_{U'}$ .
5. Add these self-labeled examples to  $X_L$ .
6. Randomly choose  $2p + 2n$  examples from  $X_U$  to replenish  $X_{U'}$ .

In steps 3–5, the  $p$  positive and  $n$  negative examples are the ones with the most confident predictions. There are different variations on how to select candidates from predictions and how to add them to  $X_L$ . For example, “agreement” is a natural criteria to select candidates from two classifiers; only a small fraction of the examples with the most confident predictions are allowed to be added to  $X_L$ , hoping to reduce noise; active learning can also be added to step 5 to further improves the candidate quality. As will be discussed later, many multi-view SSL algorithms follow this co-training framework.

Two important assumptions of co-training are: (i) the *compatibility assumption* and (ii) the *independence assumption*.

The compatibility assumption provides an interesting take on SSL, saying that a target function  $f = (f^{(1)}, f^{(2)}) \in \mathcal{C}^{(1)} \times \mathcal{C}^{(2)}$  is “compatible” with  $\mathcal{D}$  if it satisfies the condition that  $\mathcal{D}$  assigns probability zero to the set of examples  $(x^{(1)}, x^{(2)})$  such that  $f^{(1)}(x^{(1)}) \neq f^{(2)}(x^{(2)})$ . It was pointed out in [5] that  $\mathcal{C}^{(1)}$  and  $\mathcal{C}^{(2)}$  can be large concept classes with high complexity, but for a given  $\mathcal{D}$  the set of compatible target concept classes might be much smaller, which in turn reduces the requirement of labeled samples for learning.

Following a PAC-style argument, combining these two assumptions leads to learnability guarantees.

Many different theoretical aspects and applications of multi-view learning are studied, see, e.g., [19, 20]. One key step in multi-view learning is how to deal with view disagreement, as a result of either the intrinsic error or noise. A multi-view learning approach that uses a conditional entropy criterion to detect view disagreement is proposed in [21]. Once detected, samples with view disagreement are filtered and standard multi-view learning methods can be easily applied to the remaining samples.

### 1.22.2.3 Co-regularization

Following the co-training framework, regularized regression in reproducing kernel Hilbert spaces (RKHSs) is studied in multi-view learning in [22]. This method is called co-regularization. As the name suggests, regularization on different views at the same time plays a key role in the method.

Consider the two views case, let data set  $X$  have two views  $\mathcal{X} = \mathcal{X}^{(1)} \times \mathcal{X}^{(2)}$ . In general, cases with more than two views follow a similar analysis. The classifier spaces for different views are two RKHSs

$\mathcal{H}^{(1)}$  and  $\mathcal{H}^{(2)}$ . Then the co-regularization problem is defined as follows:

$$\begin{aligned} (f^{(1)*}, f^{(2)*}) = & \arg \min_{f^{(1)} \in \mathcal{H}^{(1)}, f^{(2)} \in \mathcal{H}^{(2)}} \gamma_1 \|f^{(1)}\|_{\mathcal{H}^{(1)}}^2 + \gamma_2 \|f^{(2)}\|_{\mathcal{H}^{(2)}}^2 \\ & + \sum_{x_i^{(1)} \in X_L} [y_i - f^{(1)}(x_i^{(1)})]^2 + \mu \sum_{x_i^{(2)} \in X_L} [y_i - f^{(2)}(x_i^{(2)})]^2 \\ & + \gamma_c \sum_{x_i \in X_U} [f^{(1)}(x_i^{(1)}) - f^{(2)}(x_i^{(2)})]^2. \end{aligned} \quad (22.2)$$

The solutions can be found by solving a linear system of equations. See Ref. [22] for details. The solutions are turned into binary classifiers through the sign function. The first two RKHS norms measure the complexity of the solutions in each RKHS. The next two terms are the data fitting error in different spaces. The last term is the “co-regularization” term, or called co-regularizer. It forces the estimators in two spaces  $\mathcal{H}^{(1)}$  and  $\mathcal{H}^{(2)}$  to be close in an  $L^2$  sense, i.e., small square distance.

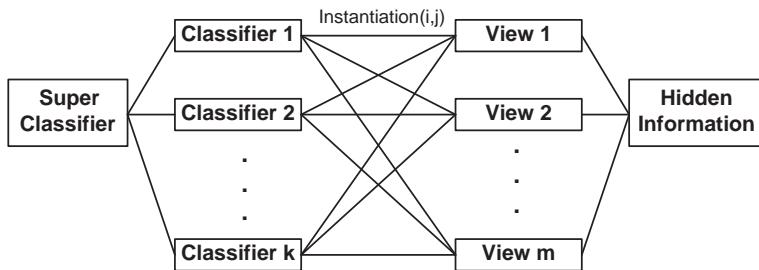

The theoretical properties of the co-regularization problem is studied in detail in [23]. It is shown that the solution space is also an RKHS, called “co-regularization RKHS.” With this result, the kernels can be found explicitly, since the reproducing kernels and the associated RKHS uniquely determine each other. For regularization problems in an RKHS, solutions can be found easily by the Representer Theorem, with the help of an explicit kernel function. Generalization bound based on Rademacher complexity is also given in [23].

Instead of studying each view separately first, then combining the results, co-regularization focuses on a single joint function space, which is generated from two individual function spaces. This provides a new understanding of the multi-view learning problem. The compatibility assumption of co-training can be studied more naturally and potentially easily in this single joint space. For instance, the agreement on unlabeled data by co-regularization is shown to reduce the function space complexity. By taking advantage of the single space view, the method and proof in [23] are elegant and insightful.

The co-regularizer studied in [23] can potentially transform any supervised learning algorithm to an SSL algorithm in a multi-view setting. This can be implemented by simply adding a co-regularizer term to the combined supervised learning problems in each view.

*The ensemble:* Compared to ensemble methods such as AdaBoost which studies how to combine different classifiers on the same data, multi-view learning studies how to combine different views of the same data. Therefore, there exists a natural many-to-many mapping from the entity of classifier to the entity of data. The mapping provides a flexible framework to integrate data and analysis methods, which is illustrated in Figure 22.2. An instantiation means the application of the  $i$ th family classifiers to the  $j$ th view of a data set. There are two “one-to-many” relations in this ensemble. For each specific family of classifiers, multi-view learning can be used to improve learning performance. This step can reduce the classifier space complexity using unlabeled data. The other “one-to-many” relation is that the “Super classifier” chooses a strategy to combined different classifiers on different views. These two steps can be designed and controlled carefully to produce powerful classifiers.

Co-training and multi-view methods provide a flexible and yet powerful framework in practice to combine different information sources and different classifiers. Notice that the specific classifiers do

**FIGURE 22.2**

The ensemble and multi-view.

not need to be from the same family. It is possible to combine artificial neural network in one view and SVM in another view. This can potentially explore the advantage of different classifier families on different views. However, the combination should be carefully controlled to avoid overfitting.

The ensemble of classifiers and data with multi-view has shown impressive performance in practice, e.g., see, Netflix competition grand prize winning algorithm and KDD Cup 2011 Track 1 winning algorithm “A Linear Ensemble of Individual and Blended Models for Music Rating Prediction,” which is a linear ensemble of more than 200 classifiers from different families.

#### 1.22.2.4 EM and self-train

Expectation-Maximization (EM) [24] is a general approach for iterative computation of maximum likelihood or maximum a posteriori estimation when the data is incomplete or have missing values.

First recall the definition of maximum likelihood estimation problem. Consider a probability density function  $p(x|\theta)$  which is governed by the set of parameter  $\theta$ . Assume the i.i.d. data samples  $X = \{x_1, x_2, \dots, x_n\}$  are drawn from  $p(x|\theta)$ . Therefore, the density for the sample set is

$$p(X|\theta) = \prod_{i=1}^n p(x_i|\theta) = \mathcal{L}(\theta|X). \quad (22.3)$$

The function  $\mathcal{L}(\theta|X)$  is called the likelihood function given the data  $X$ . It is a function of  $\theta$  for fixed data  $X$ . In a maximum likelihood problem, the goal is to find a  $\theta$  that maximizes  $\mathcal{L}$ :

$$\theta^* = \arg \max_{\theta} \mathcal{L}(\theta|X). \quad (22.4)$$

For certain family of probability density functions, it is possible to find  $\theta^*$  explicitly, e.g., a single Gaussian distribution. However, for many problems, it is difficult or even impossible to find an analytical expression for  $\theta^*$ . The EM algorithm is such a general method of finding the maximum likelihood estimate of the parameter  $\theta$ .

Let the complete data be  $Z = (X, Y)$ , where  $Y$  is either the missing data, or some hidden variables. Assume a joint density function:

$$p(z|\theta) = p(x, y|\theta) = p(y|x, \theta)p(x|\theta). \quad (22.5)$$

For example,  $y$  can be the cluster label in a clustering problem. The likelihood function for  $Z$  is  $\mathcal{L}(\theta|Z) = p(X, Y|\theta)$ . Due to the missing values, which are random variables,  $\mathcal{L}(\theta|Z)$  is in fact random.

The EM algorithm first finds the expected value of the log-likelihood  $\log p(X, Y|\theta)$  with respect to the unknown data  $Y$ , given the data  $X$  and the current parameter estimate  $\theta^{(t-1)}$ .

$$Q(\theta, \theta^{(t-1)}) = E[\log p(X, Y|\theta)|X, \theta^{(t-1)}]. \quad (22.6)$$

The computation of the expectation is called the *E-step*. The first argument  $\theta$  is the parameter to be optimized in the maximization of the likelihood function. The second argument  $\theta^{(t-1)}$  is the parameter from previous estimate. This means the expectation is taken with respect to the distribution determined by the data  $X$  and the density function with parameter  $\theta^{(t-1)}$ .

The second step is called the *M-step*, which is to maximize the expectation from the *E-step*:

$$\theta^{(t)} = \arg \max_{\theta} Q(\theta, \theta^{(t-1)}). \quad (22.7)$$

These two steps are repeated as necessary. Each iteration is guaranteed to increase the log-likelihood and the algorithm is guaranteed to converge to a local maximum of the likelihood function.

This is a general framework of EM algorithm. For different problems with different families of probability density functions, the specific steps are different.

The setting of SSL is similar to the general EM setting: a subset of  $Y$  is observed but the values on unlabeled data are missing. Therefore, EM can be applied naturally to SSL. In EM SSL, generative models and certain assumptions are usually used to take advantage of the unlabeled data. For example, one of the earliest successful applications of EM to SSL is text classification [25], which estimates the maximum a posteriori using EM on mixture of multinomials.

In a generative model, it is assumed that data are generated by a parametric model, such as a Gaussian mixture or other exponential families, with unknown parameters. Maximum likelihood estimation using the EM algorithm can be used to find these parameters given the data. For a supervised maximum likelihood estimation problem, the goal is to maximize  $p(X, Y|\theta)$ , where  $X$  and  $Y$  are the data, and  $\theta$  is the parameter for the chosen model. In an SSL setting, the data are  $X_L$ ,  $Y_L$ , and  $X_U$ , therefore, the goal is the maximize  $p(X_L, Y_L, X_U|\theta)$ . The key step is to fill in the missing  $Y_U$ . EM algorithms for SSL include the following two typical steps:

- *E-step*:  $Y_U^{(t+1)} = E[Y_U|X_L, Y_L, X_U, \theta^{(t)}]$ ;
- *M-step*:  $\theta^{(t+1)} = \arg \max_{\theta} p(X_L, Y_L, X_U, Y_U^{(t+1)}|\theta)$ .

The *E-step* is to label the unlabeled data using a model learnt from labeled data and previous estimates. Then the *M-step* is to estimate the parameters by treating all the data as labeled ones as in supervised learning, where the labels of unlabeled data are the predictions from the model in *E-step*. These two steps are similar to *K*-means method, which has a different cost function.

The first question to ask, when using a generative approach, is whether the model is correct. When the chosen model provides a good description of the data, generative approach can be powerful. However, when the true data generating process is very different from the chosen generative model, unlabeled data cannot improvement and, in fact, can even hurt performance.

Another issue for EM in generative model is that, typically it is a non-convex problem with local maxima. Different heuristics such as active learning and random restart can be used to improve the solution.

### 1.22.2.4.1 EM for mixture model

EM algorithm together with mixture models is used frequently in many aspects of machine learning, including supervised, unsupervised and semi-supervised learning. Mixture model assumes that data are sampled from a mixture of more than one distributions with densities  $p_i$ , which are parameterized by  $\theta_i$ :

$$p(x|\Theta) = \sum_{i=1}^m \alpha_i p_i(x|\theta_i), \quad (22.8)$$

where  $\Theta = (\alpha_1, \dots, \alpha_m, \theta_1, \dots, \theta_m)$ , and  $\forall i, \alpha_i > 0, \sum_{i=1}^m \alpha_i = 1$ . This means the data are generated in two steps: first, choose probability density  $p_i$  with probability  $\alpha_i$ ; second, sample from  $p_i$ . The log-likelihood for sample  $X$  then become

$$\log(\mathcal{L}(\Theta|X)) = \log \prod_{i=1}^n p(x_i|\Theta) = \sum_{i=1}^n \log \left( \sum_{j=1}^m \alpha_j p_j(x_i|\theta_j) \right). \quad (22.9)$$

The form of a log of sum is difficult to optimize. The EM algorithm solves this problem by assuming hidden variables  $Y = \{y_i, i = 1, \dots, n\}$ . These hidden variables are the labels of components. For instance,  $y_i \in \{1, \dots, m\}$  and  $y_i = k$  means  $x_i$  is generated by the  $k$ th component with probability density  $p_k$ . If  $Y$  is given, which is the case in supervised learning, the likelihood function for both  $X$  and  $Y$  is

$$\log(\mathcal{L}(\Theta|X, Y)) = \log(p(X, Y|\Theta)) = \sum_{i=1}^n \log(\alpha_{y_i} p_{y_i}(x_i|\theta_{y_i})). \quad (22.10)$$

This likelihood function is of the form of a sum of log functions, which is much easier to optimize.

In clustering,  $Y$  is not observed, given a guess of  $\Theta^t$ , it is not difficult to find the distribution of the unobserved  $Y$ , which is

$$p(y_i|x_i, \Theta^t) = \frac{\alpha_{y_i}^t p_{y_i}(x_i|\theta_{y_i}^t)}{p(x_i|\Theta^t)} = \frac{\alpha_{y_i}^t p_{y_i}(x_i|\theta_{y_i}^t)}{\sum_{j=1}^m \alpha_j^t p_j(x_i|\theta_j^t)}. \quad (22.11)$$

Then

$$p(Y|X, \Theta^t) = \prod_{i=1}^n p(y_i|x_i, \Theta^t). \quad (22.12)$$

Given these explicit results, EM algorithm can proceed without difficulty. The estimated  $\alpha_i$  after  $M$ -step is

$$\alpha_k = \frac{1}{n} \sum_{i=1}^n p(k|x_i, \Theta^t). \quad (22.13)$$

This means, given a guess  $\Theta^t$ , the best estimate for  $\alpha$  is the sum of the probability of all samples belonging to that component. Similarly,  $\theta_i$  can also be obtained. Then we have another better guess  $\Theta^{(t+1)}$ . The EM algorithm repeats as necessary. See, e.g., Ref. [26] for more details on mixture of Gaussians and EM in Hidden Markov Model.

In SSL,  $Y$  is partially observed. Then the likelihood function is

$$\log (\mathcal{L}(\Theta|X_L, X_U, Y_L)) = \log (p(X_L, X_U, Y_L|\Theta)), \quad (22.14)$$

which includes two parts, a likelihood function on unlabeled data with hidden variables and a regular likelihood function on observed data.

#### 1.22.2.4.2 Value of unlabeled data

The value of unlabeled data in parametric models is first studied in [1–3], where  $l$  labeled and  $u$  unlabeled samples were used together for learning. Let  $R(l, u)$  denote the optimal probability of error for  $l$  labeled and  $u$  unlabeled samples, the main results under mild condition in [1,2] are

$$R(0, u) = R(0, \infty) = \frac{1}{2}, \quad (22.15)$$

meaning that the unlabeled sample does not help without labeled points, and

$$R(l, \infty) = R^* + \exp(-\alpha l + o(l)), \quad (22.16)$$

where  $R^*$  is the optimal Bayes error, and  $\alpha$  depends on the weights of the mixture and each mixture density function. This means the labeled sample set reduces the probability of error exponentially fast to the Bayes risk. In a sequel, the value of unlabeled sample set is studied. The main result is that

$$R(l, u) = R^* + O(u^{-1}) + \exp(-\alpha l + o(l)). \quad (22.17)$$

This shows that the unlabeled set reduces the probability of error at the rate of  $u^{-1}$ , a much slower rate compared to labeled data.

A binary classification problem under the Gaussian mixture model is studied in [3]. Given finite labeled and unlabeled data, the goal is to estimate the Gaussian parameters and the mixture weights. The misclassification probability is shown to deviate from the minimal Bayes error rate by  $O(d^{3/5}u^{-1/5}) + O(e^{-cl})$ , where  $d$  is the dimensionality of the Gaussian and  $c$  is a positive constant.

#### 1.22.2.4.3 Self-training

In SSL, the two steps of EM algorithm can also be seen as labeling unlabeled examples first, then use the estimated value to train the classifier again. The process is repeated until certain criteria is met. This type of algorithm is also called self-training. Other relevant names include “bootstrap learning” and “automated labeling.” One of the earliest works on self-training is the application to the word sense disambiguation problem [27]. Instead of using all the estimates from the  $E$ -step in the  $M$ -step in this work, a subset of the result with higher “confidence” is selected and added to the labeled set. Similarly, active learning can also be used in this step to select different subsets to augment the labeled set. Co-training and multi-view methods also explore the idea of augmentation of a small labeled set in SSL, but from a different problem setting.

#### 1.22.2.5 Graph-based SSL

Graph-based SSL is among the most popular SSL methods. As the name suggests, graph plays an important role in this family of algorithms. The data in these problems appear in the form of a weighted

graph. This can be further categorized into two cases. First, the data itself is a weighted graph (directed or undirected), such as various social networks. Second, data are in the form of i.i.d. samples from certain domains other than graphs, then the data samples are converted into the weighted graph forms.

There are diverse algorithms for graph-based SSL methods, with plenty of variations and intuitions, such as, random walk on graphs [28–30], graph cut [31], electronic networks [32], harmonic functions [33,34], Green’s functions [35,36], regularization and reproducing kernels [10], etc. Among these algorithms, some are transductive, meaning the predictions are only on the unlabeled data. In this case, another step is needed for prediction on out-of-sample unseen examples: either add the unseen examples to the unlabeled data set and solve the problem again, or use another step to approximate the prediction, see, e.g., [37]. Others are inductive, meaning the algorithm output an estimator on the whole domain, e.g., [10]. See [8] for more reviews.

Some graph-based SSL algorithms are proposed as a discrete approximation to the corresponding continuous problem, while others are proposed for discrete graphs directly. This leads to an issue in the infinite sample analysis. Due to different problem settings and assumptions, certain graph-based SSL algorithms might not have a meaningful limit in the limit of infinite samples, either labeled or unlabeled. For instance, if the graph is the Internet graph or other social networks, then strictly speaking, even the “limit of infinite sample” is not well defined.

In this section, the focus is a family of graph Laplacian-based SSL methods whose limits are well defined under certain mild conditions. This family includes a large number of different algorithms, most of which fall under the same framework from a functional analysis view. The typical setting of these methods is as follows. The data samples  $x_i$  are from a smooth unknown probability density  $p(x)$  supported on a certain smooth subset  $\Omega$  of  $\mathcal{R}^d$ . This includes the cases when the domain is a low-dimensional smooth submanifold. Notice that most algorithms in this family can still be applied to finite graph data or samples from domains other than  $\mathcal{R}^d$ , such as unit hypercube  $\{0, 1\}^d$  or sequences in natural languages given finite data. However, the limit analysis and interpretation with infinite samples for algorithms on these data will be different, when the limits do exist.

For i.i.d. samples from a subset of  $\mathcal{R}^d$ , the graph construction proceeds as follows. Any sample point  $x_i \in X = X_L \cup X_U$  is mapped into a vertex of a weighted graph  $G(V, E)$ , and the edge weight  $w_{ij}$  is a similarity weight for each pair of example  $x_i$  and  $x_j$  defined by certain weight function on the edge, e.g., Gaussian weight  $w_{ij} = e^{-\|x_i - x_j\|^2/t}$  with parameter  $t$ . In directed graph, the weight is asymmetric. Graph  $G$  with vertex set  $V = X$  and weighted edge set  $E$  acts as a portal to the complex data source. An example is that, the local neighborhood graph constructed from uniform samples on a unit sphere acts as the approximate unit sphere.

### 1.22.2.5.1 Graph Laplacian regularization

Given sample sets  $X_L$ ,  $X_U$ , and  $Y_L$ , one popular family of graph-based SSL method is called the graph Laplacian regularization, which solves a regularized least squares problem as the following:

$$\min_{f \in \mathcal{R}^n} \sum_{i=1}^l (f(x_i) - y_i)^2 + \frac{\mu}{n^2} \sum_{i,j=1}^n w_{ij} (f(x_i) - f(x_j))^2, \quad (22.18)$$

where  $n = l + u$  is the total number of examples,  $w_{ij}$  is a “similarity” value for example  $x_i$  and  $x_j$ , and  $\mu$  is a weight balancing the fidelity to the observations on the labeled data and the second penalty

term. Notice that  $f$  is a vector in  $\mathcal{R}^n$ , and  $f(x_i) = f_i$ . This notation is convenient for the limit analysis, emphasizing that vector  $f$  is a projection of a continuous function on the sample set. Several different algorithms belong to this family of algorithm, see, e.g., [8].

For an inverse problem, there are possibly infinite functions that have zero cost. The second penalty term provides a preference to certain functions. Consider the following typical weight function:

$$w_{ij} = \exp\left(-\frac{\|x_i - x_j\|^2}{t}\right), \quad (22.19)$$

where the closer  $x_i$  and  $x_j$  are, the larger  $w_{ij}$  is. For data points that are far apart, the weight is close to zero. This means the function value differences in the penalty term of the optimization problem (22.18) only contribute to the summation for all data pairs that are near each other. The minimization drives the solution to have small difference for nearby data points, implying that the solution is smooth *locally*. On the other hand, there is little or no penalty for points that are far apart.

The quadratic term can be rewritten as the following matrix form using the graph Laplacian  $L$ :

$$f^T L f = \frac{1}{2} \sum_{i,j=1}^n w_{ij} (f(x_i) - f(x_j))^2. \quad (22.20)$$

The graph Laplacian matrix  $L$  is defined as follows. Given a graph  $G(V, E)$  with weight matrix  $W$ , and its diagonal degree matrix  $D$  defined as  $D(i, i) = \sum_j W(i, j)$ , where  $W(i, j)$  is the element at the  $i$ th row and  $j$ th column in matrix  $W$ , the commonly used graph Laplacian is defined as the following:

$$L = D - W. \quad (22.21)$$

$L$  is also called the *unnormalized graph Laplacian*, or the *combinatorial Laplacian* for 0/1 weights. There are other version of graph Laplacians, see, e.g., [38, 39].

Then the graph Laplacian regularization problem (22.18) can be rewritten as

$$\min_{f \in \mathcal{R}^n} \sum_{i=1}^l (f(x_i) - y_i)^2 + \frac{\mu}{n^2} f^T L f, \quad (22.22)$$

where the coefficient  $\frac{1}{2}$  is ignored. The solution using pseudoinverse can be found to be

$$\hat{f} = \left(S + \frac{\mu}{n^2} L\right)^+ S Y. \quad (22.23)$$

$Y$  is a column vector with  $Y(i) = y_i$  for  $x_i \in X_L$  and  $Y(i) = 0$  for  $x_i \in X_U$ ,  $S = \text{Diag}(1, \dots, 1, 0, \dots, 0)$  with the first  $l$  diagonal entries as 1 and the rest 0.

Several variations of the problem (22.22) have been proposed. An interpolation problem, instead of a “soft” regularization problem is introduced in [34]. The same regularization using a symmetric normalized version of graph Laplacian is proposed in [40]. Regularization based on the spectrum of the Laplacian is proposed in [33]. Tikhonov regularization interpretation and generalization error are discussed in [41]. The quadratic form  $f^T L f$  and its variations are frequently used in many other machine learning areas. See [8] for more variations.

When data is from the Euclidean space  $\mathcal{R}^d$ , and for a fixed function  $f \in C^2(\mathcal{R}^d)$ , the following limit of the quadratic form was studied in [42] as the number of data examples increases to infinity and

the weight function adjusts accordingly

$$f^T L f \xrightarrow{p} c \int \|\nabla f\|^2 p^2(x) dx, \quad (22.24)$$

where  $c$  is a constant depending on the weight function in the definition of graph Laplacian,  $p(x)$  is the probability density of the random sample, and  $\|\nabla f\|^2$  is the gradient square.

Notice that the limit analysis is based on the assumption that, the graph  $G$  is built on the data sample  $X$  from some distribution in  $\mathcal{R}^d$ . If graph  $G$  does not have this interpretation, e.g., some non-Euclidean space with other distance measure, the limit might not even exist, and the interpretation can be very different even the limit does exist.

The graph-based SSL problem in (22.22) then can be seen as an empirical version of the continuous problem

$$\min_f \sum_{i=1}^l (f(x_i) - y_i)^2 + \mu \int \|\nabla f\|^2 p^2(x) dx. \quad (22.25)$$

Notice that the uniform convergence of solutions on certain smooth function space is needed to show a rigorous equivalence.

Various explanations have been introduced to help the understanding of the graph Laplacian regularization. For example, random walk on graphs is one of the most popular ones [34, 40]. On the other hand, random walk is also used to argue why the method fails in the limit of infinite unlabeled data points in high dimensions [43]. The seemly contradictory views might be better understood from another context: there are pairwise equivalences between random walk (or diffusion), Laplace equation, and energy minimization problems. The Laplace equation governs a diffusion process, which is a random walk in finite sample case; the minimizer of the potential energy  $\int \|\nabla f\|^2 dx$  is the solution of a Laplace equation, which is a harmonic function. See, e.g., [44] for an application in the background of a boundary value problem. This view connects many different variants of the graph Laplacian-based SSL methods.

An alternative view to the graph Laplacian regularization is the reproducing kernel Hilbert space (RKHS) view. Since the graph Laplacian has a zero-valued eigenvalue, it has a null space spanned by the associated eigenvector. For instance, for the unnormalized graph Laplacian  $L = D - W$ , the null space is spanned by the constant eigenvector. The regularizer  $f^T L f$  in fact is an RKHS norm in the subspace that is orthogonal to the null space of  $L$ , see, e.g., [45, Chapter 6] or [35]. The reproducing kernel matrix is the pseudoinverse of  $L$ . This means, by the Representer Theorem, the solution of the graph Laplacian regularization is in the form of a summation of the rows of the kernel matrix.

These functional aspect views provide more insights to the graph Laplacian regularization problem, going beyond the random walk intuition. The idea is further explored in detail next.

### 1.22.2.5.2 Iterated graph Laplacian regularization

The setting of a small labeled set with a large unlabeled set is unique to SSL. This involves two factors in the large sample analysis of SSL: the limit analysis of both the labeled and unlabeled samples. Considering that the unlabeled data are generated much faster than the high-quality labeling process, the limit analysis of algorithms in the setting of a limited labeled set together with infinite unlabeled samples is attractive in practice.

In this SSL setting, the more unlabeled data become available to an SSL algorithm, the better prediction it should produce, according to the philosophy of SSL. However, this may not be the case

for certain SSL algorithms. For example, consider the SSL problem in Eq. (22.22), when the labeled set is fixed, the more unlabeled data involve in the optimization problem, the worse the classification results become, as shown in [43]. The graph Laplacian regularization only works in one-dimensional spaces with infinite unlabeled data. On domains with dimensions higher than 1, the solution will overfit labeled data perfectly. The solution is essentially a signed indicator function of labeled data for binary classifications. This shows there is no generalization in the limit. In practice, the overfitting causes two serious problems: first, the solution shifts to the positive or negative side, which depends greatly on the few labeled data examples; second, the solution is extremely close to zero. These two aspects make the graph Laplacian regularization method numerically unstable.

The reason for this problem is analyzed from a functional analysis point of view in [36]. The reason of the overfitting is that the solution space is too rich. With infinite unlabeled data, the graph Laplacian regularizer becomes the gradient square norm as

$$\int \|\nabla f(x)\|^2 dx, \quad (22.26)$$

where the probability density term  $p^2(x)$  is not important and ignored when it is bounded from below. This norm in fact is one of the Sobolev norms, see, e.g., [46].

The solution to the overfitting problem is solved in [36] by essentially shrinking the solution space. This can be implemented through a higher order Sobolev norm. The norm used in [36] is called the iterated graph Laplacian semi-norm, defined as the following:

$$f^T L^m f, \quad (22.27)$$

where  $m$  is a positive integer for computational purpose, though  $m$  can also be real numbers. The motivation is that the iterated Laplacian  $\Delta^m$  operator is a natural object associated with Sobolev spaces, and in particular, Sobolev spaces on smooth Riemannian submanifolds, see, e.g., [47, Chapter 5]. When  $m = 1$ , it becomes the regular Laplacian, which in  $\mathcal{R}^d$  is defined as

$$\Delta = \sum_{i=1}^d \frac{\partial^2}{\partial x_i^2}. \quad (22.28)$$

By connecting the power of the graph Laplacian matrix and the iterated Laplacian operator, the following iterated graph Laplacian regularization generally provides better solutions than the regular graph Laplacian regularization, as shown empirically in [36]:

$$\min_{f \in \mathcal{R}^n} \sum_{i=1}^l (f(x_i) - y_i)^2 + \mu_n f^T L^m f, \quad (22.29)$$

where  $\mu_n$  depends on  $n$  and the weight function.

The spectral transform of the graph Laplacian in finite sample cases has been discussed and tested in [10, 33, 35]; the limit is analyzed in [36]. Sobolev embedding theorem [46] provides the condition of the spectral transform for the graph Laplacian to give a smooth solution.

The spectral transform requirement is also closely related to RKHS view. In the finite sample case, the norm  $f^T L f$  corresponds to an RKHS, while in the limit of infinite unlabeled data, the Sobolev

normed space may not be an RKHS, depending on the dimensionality of the underlying data domain. Specifically,  $2m > d$  needs to hold in order to make sure the Sobolev space is an RKHS.  $d$  should be replaced with the intrinsic dimensionality when the data domain is a low-dimensional manifold. In non-RKHS cases, the Green's function is a useful tool to study the problem.

*Finite sample case:* In finite data cases, we always have an RKHS since any finite-dimensional Hilbert space is an RKHS, see, e.g., [45]. This means the discrete Green's function is the same as reproducing kernel in the subspace orthogonal to its null. Let the kernel matrix be  $K$  and the discrete Green's function matrix be  $G$ , then for semi-norm  $f^T L f$ , the reproducing kernel in the subspace orthogonal to its null is the pseudoinverse of matrix  $L$ , i.e.,  $K = L^+$  [45, Chapter 6]. Notice that the exact kernel for the semi-norm includes another kernel in its null space. The discrete Green's function should satisfy  $GL = I$  and  $LG = I$ , which implies that  $G = L^+$ . This is also true for symmetric semi-definite matrix  $L^m$ . We can write both discrete Green's function and reproducing kernel for  $L^m$  by eigenfunction expansion as

$$G_m(x, y) = K_m(x, y) = (L^m)^+(x, y) = \sum_{k=2}^n \frac{1}{(\lambda_k)^m} \phi_k(x) \phi_k(y), \quad (22.30)$$

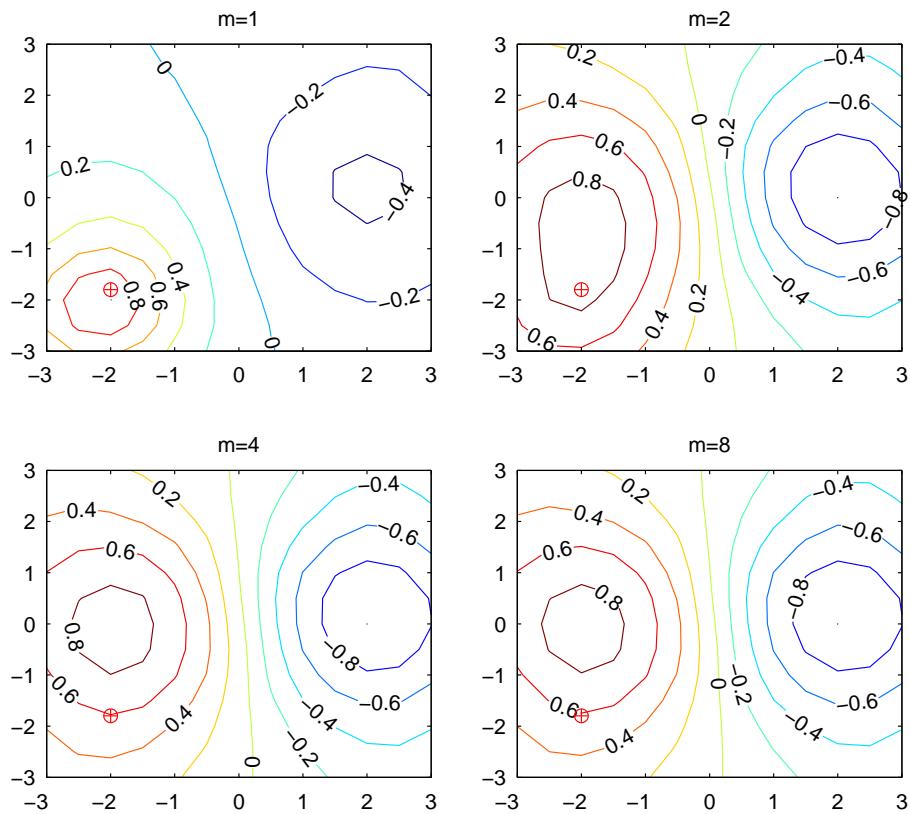

where  $\lambda_k$  and  $\phi_k(x)$  are the  $k$ th eigenvalue and eigenvector of  $L$ .  $\phi_k(x)$  means the  $x$  element of vector  $\phi_k$ . We can see that for a positive integer  $m$ , compared to  $\lambda_n$ , the smaller  $\lambda_k$  is, the larger  $1/\lambda_k^m$  will be relatively. This means  $G_m(x, y)$  will become smoother and smoother as  $m$  increases, since for graph Laplacians, the smaller  $\lambda_k$  is, the smoother the associated eigenvector is, and  $\lambda_k$  are in increasing order.

In order to have an intuitive understanding of the effect of  $m$ , we generate an artificial data set and plot the kernel functions in Figure 22.3. The data set includes a mixture of two Gaussians of unit variance on  $\mathcal{R}^2$  centered at  $(\pm 1.5, 0)$ , and an additional uniform over  $[-3, 3] \times [-3, 3]$  to avoid empty regions. In Figure 22.3, we show the discrete Green's function corresponding to  $L^m$  for two Gaussians with unit variance in  $\mathcal{R}^2$  at  $(-2, -1.8)$ . When  $m$  increases, the Green's function or reproducing kernel “grows” from “spikes” to smooth functions. From the contour plot, even the location of the kernel is not near the means of the Gaussians, when  $m$  increases, the kernel function recovers the true boundary of the two Gaussians. In fact, as long as the centers of kernel functions are in relatively high density regions of the Gaussians, a proper  $m$  value will produce a kernel function which changes little within those regions. This is exactly the basis for several graph Laplacian-based SSL algorithms.

Compared to the thin plate splines [48], the iterated Laplacian regularization can be viewed as a generalization of the thin plate splines from regular domains to unknown submanifolds, from a coordinate dependent Sobolev semi-norm defined by partial derivatives to a coordinate free iterated Laplacian semi-norm using Laplacians, from data independent reproducing kernels to data dependent kernels. One key difference is the null space between the two methods. The null space of  $f^T L^m f$  is spanned only by the first eigenvector, while in thin plate splines the null space is spanned by polynomials of high degrees, whose dimension increases fast as  $d$  and  $m$  increase.

### 1.22.2.5.3 Finite-dimensional approximation

As regularization is a solution for an ill-posed inverse problem, the finite-dimensional approximation is also an effective solution to an infinite-dimensional problem. Consider the graph Laplacian regularization problem (22.22), the solution lives in the span of all the eigenvectors of the graph Laplacian  $L$ . Instead of using all the eigenvectors, a subset of these eigenvectors are chosen and used in [33].

**FIGURE 22.3**

The Green's functions at  $(-2, -1.8)$  for a mixture of two Gaussians.

For a graph Laplacian  $L$ , whose limit is the Laplace operator in  $\mathcal{R}^d$  or Laplacian-Beltrami operator on a submanifold [49], the eigenfunctions form an  $L^2$  basis of square integrable functions. Let  $\phi_i$  and  $\lambda_i$  be the  $i$ th eigenfunction and eigenvalue of the Laplace operator  $\Delta$ , i.e.,  $\Delta\phi_i = \lambda_i\phi_i$ , then any  $L^2$  function  $f$  can be written as

$$f = \sum_{i=1}^{\infty} \alpha_i \phi_i, \quad \text{s.t. } \sum_{i=1}^{\infty} \alpha_i^2 < \infty. \quad (22.31)$$

Assume the eigenvalue and eigenfunctions are ordered in increasing-eigenvalue order. Then the finite-dimensional approximation problem is

$$\min_{\alpha_1, \dots, \alpha_k} \sum_{i=1}^l \left( y_i - \sum_{j=1}^k \alpha_j \phi_j(x_i) \right)^2, \quad (22.32)$$

where  $k$  is a fixed number that can be chosen by validation. This problem is also called Laplacian eigenmaps SSL, since these eigenvectors define the Laplacian eigenmaps [50]. The least squares solution can easily be written down explicitly. Notice that the squares error is only computed on the labeled data set, while the function basis  $\phi_i$  are computed on all the data points. This is a key step for SSL. Function basis can be computed without any label information. These basis are only supported on data samples, which has both pros and cons. One advantage is that they reduce the function class complexity, e.g., on intrinsic spaces; one disadvantage is that they are not defined for out-of-sample data. In finite sample case, the graph Laplacian eigenvectors are used instead of the continuous Laplacian eigenfunctions.

Another important advantage of using these eigenvectors is that they have an intrinsic smoothness ordering, measured by the eigenvalue. By multiplying  $\phi_i(x)$  to both side of  $\Delta\phi_i(x) = \lambda_i\phi_i(x)$ , and integrating both sides, the following relation can be found:

$$\int \phi_i(x)\Delta\phi_i(x)dx = \lambda_i \int \phi_i^2(x)dx = \lambda_i, \quad (22.33)$$

since the eigenfunctions are orthonormal. With proper boundary conditions for the Laplace operator  $\Delta$ , the left-hand side is

$$\int \phi_i(x)\Delta\phi_i(x)dx = \int \|\nabla\phi_i(x)\|^2 dx. \quad (22.34)$$

This means the smaller the eigenvalue is, the smoother the corresponding eigenfunction is, in the sense of gradient squares norm (one type of Sobolev norm). For instance, for the graph Laplacian  $\lambda_1 = 0$ , thus the gradient squares integral should be 0. This is consistent with fact that the first eigenvector of the graph Laplacian is constant. This nice property provides a key step for the asymptotic error analysis of the method, and also provide a flexible guidance for choosing eigenvectors in practice.

The optimal number of eigenfunctions and optimal integrated mean squares errors for the regression problem (22.32) is studied in [51]. In the limit of infinite unlabeled data, the error analysis shows that, when the true regression functions are differentiable, the optimal number of eigenvectors and the optimal integrated mean square error (IMSE) given  $l$  labeled and infinite unlabeled points are

$$k^* \sim \tilde{O}(l^{\frac{d}{d+2}}), \quad (22.35)$$

$$\text{IMSE}^* \sim \tilde{O}(l^{-\frac{2}{d+2}}), \quad (22.36)$$

where  $d$  is the intrinsic dimensionality of the domain, and the notation  $\tilde{O}$  includes a log factor. The results are further generalized to  $m$ -times differentiable functions.

Analysis in [51] also shows that Laplacian Eigenmaps SSL achieves the same error rate using the same optimal dimensions compared to least squares estimates using tensor product spline spaces with equidistant knots [52, Chapter 15.3], and the same rate as local polynomial regression [53].

Notice that the result is in a distribution-free setting. This means in cases when the cluster assumption does not hold, or there is no relationships between the marginal distribution of data  $X$  and its label  $Y$ , unlabeled data still can help learning asymptotically. This is achieved by reducing the function class complexity, which in turn improves learning rate.

#### 1.22.2.5.4 Manifold regularization

Graph Laplacian regularization in problem (22.22) is transductive. It cannot make prediction on out-of-sample data. Manifold regularization [10] is introduced to generalize the graph Laplacian regularization

to inductive inference. The framework introduced a novel regularizer combining the inductive ability and the geometry of the data domain. Manifold regularization includes a family of learning algorithms. Variants generalizing SVM and regularized least square are proposed in [10]. The regularized least square version of the inductive SSL problem is as follows:

$$\min_{f \in \mathcal{H}_K} \sum_{i=1}^l (f(x_i) - y_i)^2 + \mu_n \|f\|_K + \gamma_n \|f\|_I, \quad (22.37)$$

where  $\|f\|_K$  is a norm of  $f$  in a chosen reproducing kernel Hilbert space  $\mathcal{H}_K$ ,  $\|f\|_I$  is a norm depending on the intrinsic geometry of the data, e.g.,  $\|f\|_I = f^T L f$ , and  $\mu_n$  and  $\gamma_n$  are parameters to balance each term in the objective function.

A Representer Theorem to problem (22.37) when  $\|f\|_I = f^T L f$  is given as

$$\hat{f}(x) = \sum_{i=1}^{l+u} \alpha_i K(x_i, x). \quad (22.38)$$

The ambient space norm  $\|f\|_K$  provides the inductive ability of this algorithm, while the graph Laplacian regularizer term provides data dependent regularization. For example, RBF Kernels or polynomial kernels can be used as discussed in [10].

Manifold regularization connects spectral graph theory, manifold learning, and RKSH together in one regularization framework. One of the important advantages of the manifold regularization is the induction ability, which most other graph Laplacian regularization methods do not enjoy. The other feature is the regularization framework, i.e., an intrinsic norm plus an extrinsic norm. The combined regularization provides much flexibility from induction in the ambient space to the data dependent domain. More importantly, the problem can be easily solved with the help of the Representer Theorem.

Iterated Laplacian and Sobolev norms can also be used in the manifold regularization framework by simply replacing  $\|f\|_I$  with  $f^T L^m f$ , as suggested in [10, 36]. More Sobolev norms examples can be found in, e.g., [45]. Manifold regularization is further studied in the setting of co-regularization in [23], where different norms are treated to be in different views.

#### 1.22.2.5.5 Measure-based regularization

A density based regularization method is proposed in [42] with the following regularizer:

$$\int \langle \nabla f(x), \nabla f(x) \rangle p(x) dx = \int \|\nabla f(x)\|^2 p(x) dx, \quad (22.39)$$

where  $\nabla f(x)$  is the gradient vector and  $p(x)$  is the probability density of samples. The goal is to use a gradient based regularizer that penalizes variations of the function more in high density regions and less in low density regions. However, the kernel associated with this norm is not straightforward to obtain. As an alternative solution, the gradients of functions in the span of a chosen basis and the density  $p(x)$  are estimated directly. The experiments on real world data sets in [42] are not successful.

There are several difficulties in this method. First, density estimation is difficult in high dimensions. Although unlabeled data points are abundant in SSL, the computation is expensive. Second, the gradient estimated in [42] is in ambient spaces. If data live on or near a smooth submanifold, this gradient can be irrelevant to learning, which is first discussed in [10].

With the help of limit analysis of graph Laplacians and the graph Laplacian regularizer [49, 54, 55] and the two-step normalized graph Laplacian, next we show a simple method that solves both of the above problems.

*Two-step graph Laplacian:* Besides the commonly used graph Laplacians  $L = D - W$  and its variants, there is another family of more general “two-step” graph Laplacians, which is introduced by Coifman and Lafon [54] and further studied by Hein et al. [49]. In this definition, one first normalizes the weight matrix  $W$  as follows:

$$W_\alpha = D^{-\alpha} W D^{-\alpha}, \quad \alpha \in \mathcal{R}. \quad (22.40)$$

Then the element in the matrix, or the normalized weight function is

$$W_\alpha(x_i, x_j) = W_\alpha(i, j) = \frac{W(i, j)}{[D(i, i)D(j, j)]^\alpha}. \quad (22.41)$$

Given this new normalized weight matrix  $W_\alpha$ , one can define empirical Laplacians accordingly. For example,  $L^\alpha = D^\alpha - W^\alpha$ , where we use the superscript  $\alpha$  to emphasize the normalization parameter for the weight matrix. This should not be confused with the power of a matrix. Notice that when  $\alpha = 0$ , these two-step graph Laplacians become the usual ones. In particular, when  $\alpha = \frac{1}{2}$ , with proper scaling the following limit exists [55]:

$$f^T L^\alpha f \xrightarrow{p} \int \|\nabla f(x)\|^2 p(x) dx. \quad (22.42)$$

The gradient here is automatically computed on the data manifold when the data are sampled from a smooth manifold. The density term is implicitly encoded in the two-step normalized graph Laplacian. The reproducing kernel can also be found as the pseudoinverse of  $L^\alpha$ .

The measure associated with the two-step graph Laplacian with different  $\alpha$  brings another issue in using the graph Laplacian. For instance, for the commonly used unnormalized graph Laplacian ( $\alpha = 0$ ), the limit is as follows [42]:

$$f^T L f \xrightarrow{p} \int \|\nabla f(x)\|^2 p^2(x) dx. \quad (22.43)$$

The discrepancy between the measure for the regularizer and the probability of the sample needs more investigations.

### 1.22.2.5.6 Discussions

Graph-based SSL is closely related to two other areas: wavelet on graphs and kriging. Multiresolution analysis and wavelet have been a successful tool for low-dimensional data analysis such as time series and images. With the rising of graph data and high-dimensional data, the multiscale concept can be particularly powerful. One reason is that the concept of location and scale are more abstract and also more important in high-dimensional analysis. This include cases where data are not from a Euclidean space, e.g., social networks. However, the methods and theories for wavelet for graph and high-dimensional data are far behind their counterparts in low-dimensional data analysis. Several recent works in this area are reviewed next, including the discussions of their applications in SSL.

The basis of multiresolution analysis is a hierarchy structure of function spaces. One natural choice is the Sobolev spaces associated with iterated Laplacian. There are a family of generalized function

spaces associated with iterated Laplacian which are closely related to Sobolev spaces, see, e.g., [47, Chapters 4 and 5]. Iterated Laplacian is used in [36] to solve an illness problem of graph Laplacian regularization in a limit setting.

A novel method is introduced in [56] for constructing wavelet transforms of functions defined on the vertices of an arbitrary finite weighted graph. The approach is based on defining scaling using the graph analog of the Fourier domain, with the help of the graph Laplacian.

Diffusion wavelet [57] is another technique which is closely related to graph Laplacian. The method is built on a diffusion operator  $T$ . Functions at different scale corresponds to the diffusion process at different time. The main assumption is reduction of the numerical ranks as we take powers of the operator  $T$ .

Compared to graph spectral wavelet [56], the basis in diffusion wavelet are orthogonal. The orthogonalization step in the construction of wavelets destroys the compact support of the basis. Thus these basis are functions defined over the whole data domain. This might be preferable in SSL since global basis can be used to fit labeled data and make prediction on unlabeled data at the same time. On the other hand, wavelets in [56] are not orthogonal, but have compact support.

Haar-like wavelet is proposed in [58] for tree and graph data. One advantage of the method is that the wavelet coefficients decay exponentially fast, which encourages sparse representation of functions.

Another interesting view to several graph-based SSL algorithms is through kriging, which is a geostatistical technique to interpolate the value of a random field at an unobserved location from observations of its value at nearby locations. This idea resembles transductive SSL problems. In [59], several popular graph Laplacian regularization solutions are shown to be equivalent to kriging predictors with a fixed covariance matrix, which is determined by the data sample density and the geometry of the data domain. Kriging view brings more attention to the correlation among data samples, which is closely related to reproducing kernels and function space view.

Kriging provides an alternative way of interpreting graph Laplacian regularization in finite sample case, and also brings more insight under the Gaussian process framework. These results are consistent with the function analysis view presented earlier.

The kriging view shows that many different graph Laplacian regularization problems use a covariance matrix that is a given function of the graph adjacency matrix  $W$ . This might be a reasonable choice if the vertices of a graph are i.i.d. samples from certain subset of  $\mathcal{R}^d$ , e.g., the surface of a sphere. However, for other types of graphs that do not correspond to i.i.d. samples, e.g., social network graphs, the graph structure itself might not be enough to capture the correlations. One key step toward this covariance matrix design is discussed in [59]. Instead of only using the adjacency matrix  $W$  from data samples, response values are also used in the matrix design. Specifically, the covariance matrix consists of two component: one is stationary based on the vertex similarity, which comes from  $W$ , while the second part depends on vertex and need not to be stationary.

### 1.22.3 Semi-supervised learning for structured outputs

Complex output structures arise in speech recognition, various forms of object recognition tasks, and also in a wide range of natural language tasks such as Part of Speech (POS) tagging and parsing, just to name a few. Different supervised algorithms have been proposed to take advantage of the internal structure through Markovian or graphical model assumptions. Compared to SSL in vector or

scaled-valued function learning tasks, there is less progress in SSL with structured data. For structured data, the labeling process is even more expensive, which makes SSL more attractive in these tasks.

When each sample point  $x_i \in X$  and each label  $y_i \in Y$  are not vectors or scalars, but are sequences, e.g.,  $x_i$  is a sentence, and  $y_i$  is the Part of Speech (POS) tag, or even more complicated objects such as trees, the learning problem is called structured learning. The task is to learn a mapping  $f : \mathcal{X} \rightarrow \mathcal{Y}$ . For each  $x$ , let  $\mathcal{Y}(x)$  be the possible output set, which is finite in most practical problems.

A standard framework of learning structured models is by developing functions  $h : \mathcal{X} \rightarrow \mathcal{Y}$  as

$$h(x) = \arg \max_{y \in \mathcal{Y}(x)} F(x, y), \quad (22.44)$$

where  $F$  is a scoring function for each pair. For computational tractability and feasibility,  $F$  can be broken into scores that are defined on individual positions of the output sequence. This is also done to take advantage of the Markovian dependence that is generally assumed over the output sequences.

The unique feature for structured learning problem is how to model the structure/dependency among elements of data instance (both  $x$  and  $y$ ). With proper models for these dependencies, many SSL algorithms can be applied to the structured output problems. For instance, by defining a graph-based kernel for structured learning problems, kernel-based SSL methods can be applied directly to structured learning. See, e.g., [60, 61]. Manifold regularization for structured learning is discussed by Altun et al. [62]. Brefeld and Scheffer [63] studied a multiple-view regularizer for structured SVM in SSL. More references on structured SSL can be found in [64–71].

## 1.22.4 Large scale semi-supervised learning

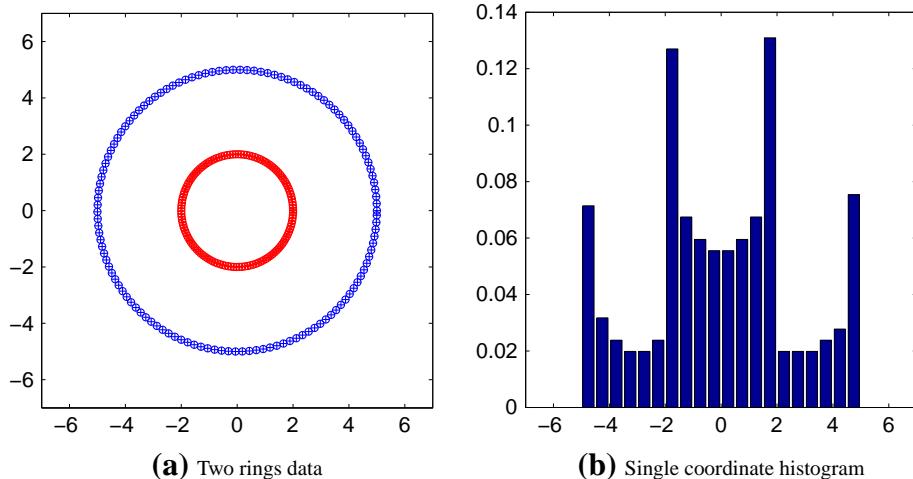

Large scale learning is particularly important for SSL, since the aim of SSL is to use the huge amount of unlabeled data to improve learning. Toward this goal, various new SSL methods and approximations of the existing methods have been proposed for scalable SSL.

From an optimization point of view, especially convex optimization, there are well-studied techniques for large scale computing. For example, Newton method is used in linear semi-supervised SVM in [11, 72]. Sparse grid is used in regularization in SSL [73]. However, the size of the grid increases exponentially fast with dimensions.

One attractive solution for large scale computing is online method. For instance, stochastic gradient descent is used to train TSVM in [74]. This type of algorithms allows training through linear scans of the whole data set. A graph-regularized transductive learning method that is based on minimizing a Kullback-Leibler divergence based loss is introduced in [75], and the algorithm can solve problems with as much as 120 million samples.

For many graph Laplacian-based SSL methods, the unique structure of the graph Laplacian matrix is explored in multi-grid method in [76]. The algorithm run-time and storage are linear in the number of graph edges. For sparse graphs, this is of the order of vertices, or data samples. Multiscale solvers for several (un)weighted graphs can be found in [77], with the software implementation.

There are methods based on the graph Laplacian on a smaller backbone graph, which is chosen in different ways from the whole data set. For example, random sampling is used in [78]. The problem with the approaches based on backbone graphs is that the spectrum of the graph Laplacian can change dramatically with different backbone construction methods, thus the solution is not stable.

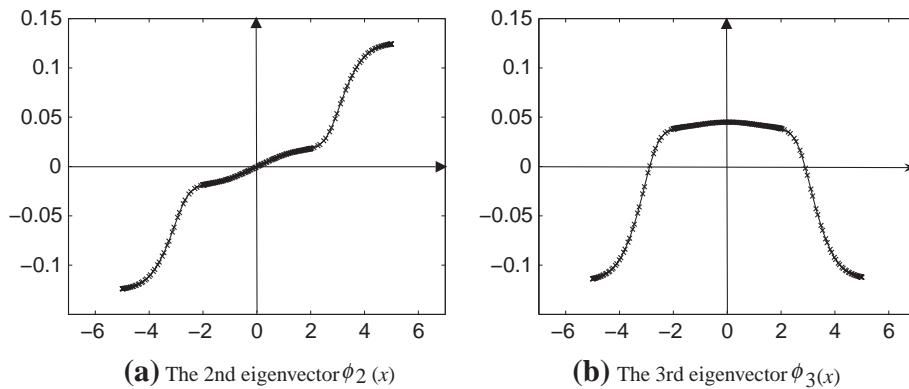

**FIGURE 22.4**

Two-ring data and its marginal distribution histogram.

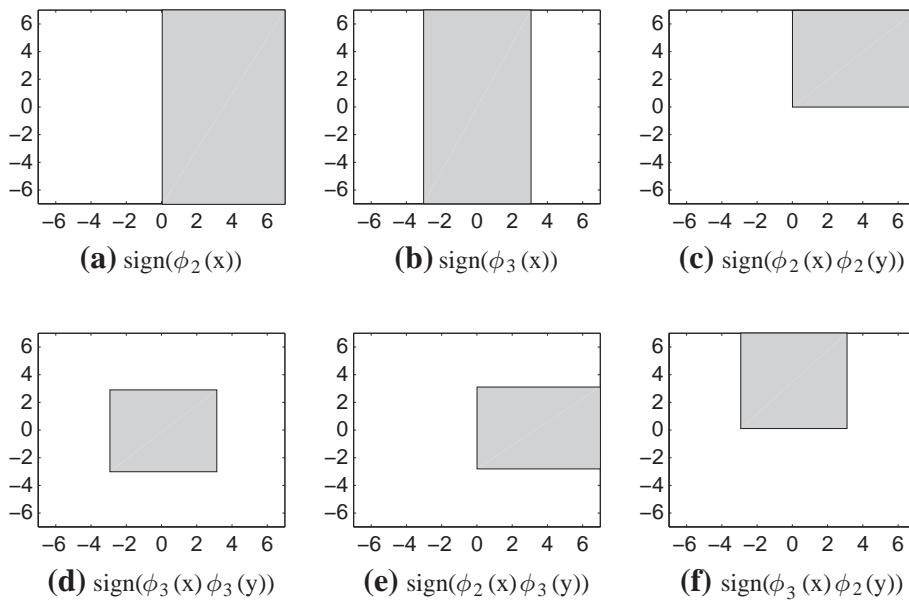

Most of above methods try to attack various approximations to the finite sample problems. On the contrary, starting from a well-studied infinite sample limit, Fergus et al. [79] proposed an attractive scalable SSL algorithm that can learn on much larger data sets. The eigenvectors of the graph Laplacian on data samples can be used as function basis to estimate functions on graphs. In the limit, the Laplacian eigenfunctions are natural square integrable function basis on smooth manifolds. With abundant unlabeled data, the graph Laplacian is close to its limit. Thus [79] starts from the limit, Laplacian on a smooth manifold, and under certain assumptions, takes advantage of a nice property of Laplacian: for product form densities, the Laplacian eigenfunctions on the marginal distribution of a single coordinate is also an eigenfunction of the Laplacian on the whole domain with the same eigenvalue. Then all these single-dimensional eigenvectors can be easily computed using various histogram and interpolation methods on a one-dimensional space.

As an example, a two-ring toy data set is plotted in Figure 22.4. The right panel is the marginal histogram. Since the data set is symmetric, marginal distributions of both dimensions are the same. Notice that this data set does not satisfy the ‘‘product form’’ assumption.

The single-dimensional graph Laplacian eigenvectors are shown in Figure 22.5. Notice that the signs of these single-dimensional eigenvectors decompose the square domain in a way similar to the axis parallel decision stumps. Several examples of such products are illustrated in Figure 22.6. In particular, the product of these eigenvectors provide a more powerful function basis such as squares, which can be obtained by the product of the third eigenvectors from the two dimensions (along  $x$  and  $y$ ). This square is enough to separate the two circles apart. Roughly speaking, the method is similar to decision stumps in AdaBoost. However, there are several differences. First, the products of eigenvectors provide a much richer basis than stumps alone. Second, these eigenvectors are data dependent, and are defined through unlabeled data in general. Third, these basis are real-valued functions instead of step functions.

**FIGURE 22.5**

The second and third graph Laplacian eigenvectors of the marginal.

**FIGURE 22.6**

$\text{Sign}(\cdot)$  functions of the single-dimensional graph Laplacian eigenvectors and their products. Grey areas are  $+1$ , while others are  $0$ .

This approximation transforms a  $d$ -dimensional problem to  $d$  one-dimensional problems. It not only eliminates the need to construct  $k$ NN graphs, which generally costs at least  $O(n^2)$ , but also removes the matrix inversion or eigen-decomposition, which costs  $O(n^3)$ .

Finally, several related themes in large scale SSL include, (a) different approximation methods, (b) large scale optimization techniques and online learning, e.g., [80], and (c) parallel computing, e.g., [81]. These areas also overlap with each other. For example, certain optimization techniques might require certain type of approximation, which might also determines whether it is possible for parallel computing.

## 1.22.5 Theoretical analysis overview

Some of the first work on the theoretical analysis of SSL appeared in [1–3], where the authors analyze parametric models based on the Gaussian mixture distributions. Error analysis of semi-supervised classification is further investigated in [82] under the more general cluster assumption. The main result is consistent with that of [1,2]: unlabeled data reduce the error with a polynomial rate of the form  $O(u^{-\beta})$  for some  $\beta > 0$ , while labeled may reduce the error exponentially fast.

Another result [83] shows that the pointwise mean squares error for a popular graph Laplacian regularization method has the same leading term as a regular supervised kernel smoother, which implies that the unlabeled data set does not help asymptotically.

On the other hand, Niyogi [84] studied SSL under the manifold assumption, and gives a constructive example of a class of distributions supported on manifolds where the error of any supervised learner is bounded from below by a constant, while a semi-supervised learner that can have error bounded from above by  $O(n^{-1/2})$ .

The value of unlabeled data is studied in a finite sample framework in [85], which evaluates the performance gains with SSL under the cluster assumption using finite sample error bounds, which involves finite labeled and unlabeled sets.

In a different approach, the value of unlabeled data was studied in [86] under the PAC model. The compatibility between concept class and the distribution is introduced to link unlabeled data in the analysis.

## 1.22.6 Challenges

In this chapter we have reviewed a number of popular SSL algorithms and various aspects of their analysis and implementation. Here we point out some of the key challenges for research and applications of SSL:

*Mode/parameter selection:* This is a common issue for all SSL algorithms. Model selection methods borrowed from supervised learning, such as cross-validation, may not work well in the SSL setting due to the limited amount of labeled data. Furthermore, many SSL models introduce several parameters which may be hard to choose appropriately for a new data domain.

*Scalability:* The premise of SSL is utilizing large amounts of unlabeled data to improve inference. Thus scalability is one of the most important issues facing SSL and is a key to making these algorithms widely used in various practical applications. While significant amount of research has gone into making SSL algorithms more scalable (see Section 1.22.4), there is a need for more work in that direction.

*Theoretical analysis:* The asymptotic analysis for SSL can shed light on various SSL algorithms and guide their applications. However, existing analyses are far from being satisfactory. There are two important questions for any SSL algorithm. First, what the estimators are. This is the problem of consistency, including how to define consistency. Second, how fast an empirical estimator converges to its limit, including how to define convergence. The rate should involve both  $l$  and  $u$ . Without consistency, no matter how fast the convergence rates are, it does not provide any guarantee. Most existing analyses focus on the large sample asymptotic analysis, which may not be sufficient for explaining the finite sample behaviors of some SSL algorithms.

With the recent advances in semi-supervised learning and as future developments addressing the challenges above come along, we expect that semi-supervised learning algorithms will become a key part in the toolbox of methods for large scale high-dimensional data analysis.

## Glossary

Graph Laplacian	also called the Laplacian matrix, is a matrix representation of a graph
Independent and identically distributed Laplacian	i.i.d.
Multiresolution analysis (MRA)	also called the Laplace operator, a differential operator given by the divergence of the gradient of a function on Euclidean space
Regularization	data analysis methods by constructing orthonormal bases at different scale
Semi-supervised learning (SSL)	any method of preventing overfitting of data by a model. Regularization involves introducing additional information in order to solve an ill-posed problem or to prevent overfitting
	a class of machine learning techniques that make use of both labeled and unlabeled data for training—typically a small amount of labeled data with a large amount of unlabeled data

## 1.23.1 Introduction

The notion of regularization has been widely used as a tool to address a number of problems that are usually encountered in Machine Learning. Improving the performance of an estimator by shrinking the norm of the Minimum Variance Unbiased (MVU) estimator, guarding against overfitting, coping with ill-conditioning, providing a solution to an underdetermined set of equations are some notable examples where regularization has provided successful answers. A notable example is the ridge regression concept, where the LS loss function is combined, in a tradeoff rationale, with the Euclidean norm of the desired solution.

In this chapter, our interest will be on alternatives to the Euclidean norms and in particular the focus will revolve around the  $\ell_1$  norm; this is the sum of the absolute values of the components comprising a vector. Although seeking a solution to a problem via the  $\ell_1$  norm regularization of a loss function has been known and used since the 1970s, it is only recently that has become the focus of attention of a massive volume of research in the context of compressed sensing. At the heart of this problem lies an underdetermined set of linear equations, which, in general, accepts an infinite number of solutions. However, in a number of cases, an extra piece of information is available: the true model, whose estimate we want to obtain, is sparse; that is, only a few of its coordinates are nonzero. It turns out that a large number of commonly used applications can be cast under such a scenario and can be benefited by a so-called sparse modeling.

Besides its practical significance, sparsity-aware processing has offered to the scientific community novel theoretical tools and solutions to problems that only a few years ago seemed to be intractable. This is also a reason that this is an interdisciplinary field of research encompassing scientists from, e.g., mathematics, statistics, machine learning, signal processing. Moreover, it has already been applied in many areas ranging from biomedicine, to communications and astronomy. At the time this chapter is compiled, there is a “research happening” in this field, which poses some difficulties in assembling related material together. We have made an effort to put together, in a unifying way, the basic notions and ideas that run across this new field. Our goal is to provide the reader with an overview of the major contributions which took place in the theoretical and algorithmic fronts and have been consolidated over the

\*This paper is based on a chapter of a new book on Machine Learning, by the first and third authors, which is currently under preparation.

last decade or so. Besides the methods and algorithms which are reviewed in this article, there is another path of methods based on the Bayesian learning rationale. Such techniques will be reviewed elsewhere.

### 1.23.2 Parameter estimation

Parameter estimation is at the heart of what is known as *Machine Learning*; a term that is used more and more as an umbrella for a number of scientific topics that have evolved over the years within different communities, such as Signal Processing, Statistical Learning, Estimation/Detection, Control, Neurosciences, Statistical Physics, to name but a few.

In its more general and formal setting, the parameter estimation task is defined as follows. Given a set of data points  $(y_n, \mathbf{x}_n)$ ,  $y_n \in \mathcal{R}$ ,  $\mathbf{x}_n \in \mathcal{R}^l$ ,  $n = 1, 2, \dots, N$ , known as the *training data*, and a parametric set of functions

$$\mathcal{F} := \{f_{\theta}, \theta \in \mathcal{A} \subseteq \mathcal{R}^k\},$$

find a function in  $\mathcal{F}$ , which will be denoted as  $f(\cdot) := f_{\theta_*}(\cdot)$ , such that given the value of  $\mathbf{x} \in \mathcal{R}^l$ ,  $f(\mathbf{x})$  best approximates the corresponding value of  $y \in \mathcal{R}$ . After all, the main goal of Machine Learning is *prediction*. In a more general setting,  $y$  can also be a vector  $\mathbf{y} \in \mathcal{R}^m$ . Most of our discussion here will be limited to real valued variables. Obviously, extensions to complex valued data are readily available.

Having adopted the parametric set of functions and given the training data set, the goal becomes that of *estimating* the values of the parameters  $\theta$  so that to “fit” the data in some (optimal) way. There are various paths to achieve this goal. In this chapter, our approach comprises the adoption of a *loss* function

$$\mathcal{L}(\cdot, \cdot) : \mathcal{R} \times \mathcal{R} \longmapsto [0, \infty),$$

and obtain  $\theta_*$  such that

$$\theta_* := \arg \min_{\theta} J(\theta),$$

where

$$J(\theta) := \sum_{n=1}^N \mathcal{L}(y_n, f_{\theta}(\mathbf{x})). \quad (23.1)$$

Our focus will be on the Least Squares loss function, i.e.,

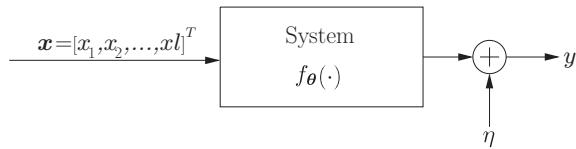

$$\mathcal{L}(y, f_{\theta}(\mathbf{x})) := (y - f_{\theta}(\mathbf{x}))^2.$$

Among the many parametric models, *regression* covers a large class of Machine Learning tasks. In linear regression, one models the relationship of a *dependent* variable  $y$ , which is considered as the output of a system, with a set of *independent* variables,  $x_1, x_2, \dots, x_l$ , which are thought as the respective inputs that activate the system in the presence of a noise (unobserved) disturbance,  $\eta$ , i.e.,

$$y = \theta_1 x_1 + \dots + \theta_l x_l + \theta_0 + \eta,$$

where  $\theta_0$  is known as the *bias* or *intercept*, see Figure 23.1. Very often the previous input-output relationship is written as

$$y = \mathbf{x}^T \boldsymbol{\theta} + \eta, \quad (23.2)$$

**FIGURE 23.1**

Block diagram showing the input-output relation in a regression model.

where

$$\boldsymbol{\theta} := [\theta_1, \dots, \theta_0]^T, \quad \text{and} \quad \mathbf{x} := [x_1, \dots, x_l, 1]^T. \quad (23.3)$$

Often,  $\mathbf{x}$  is called the *regressor*. Given the set of training data points,  $(y_n, \mathbf{x}_n), n = 1, 2, \dots, N$ , (23.2) can compactly written as

$$\mathbf{y} = \mathbf{X}\boldsymbol{\theta} + \boldsymbol{\eta}, \quad (23.4)$$

where

$$\mathbf{X} := \begin{bmatrix} \mathbf{x}_1^T \\ \vdots \\ \mathbf{x}_N^T \end{bmatrix}, \mathbf{y} = \begin{bmatrix} y_1 \\ \vdots \\ y_N \end{bmatrix}, \boldsymbol{\eta} = \begin{bmatrix} \eta_1 \\ \vdots \\ \eta_N \end{bmatrix}. \quad (23.5)$$

For such a model, the Least Squares cost function is written as

$$J(\boldsymbol{\theta}) = \sum_{n=1}^N (y_n - \boldsymbol{\theta}^T \mathbf{x}_n)^2 = \|\mathbf{y} - \mathbf{X}\boldsymbol{\theta}\|^2, \quad (23.6)$$

where  $\|\cdot\|$  denotes the Euclidean norm. Minimizing (23.6) with respect to  $\boldsymbol{\theta}$  results to the celebrated LS estimate

$$\hat{\boldsymbol{\theta}}_{LS} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y}, \quad (23.7)$$

assuming the matrix inversion is possible. However, for many practical cases, the cost function in (23.6) is augmented with a so called *regularization* term. There are a number of reasons that justify the use of a regularization term. Guarding against overfitting, purposely introducing bias in the estimator in order to improve the overall performance, dealing with the ill conditioning of the task are cases which the use of regularization has successfully addressed. *Ridge regression* is a celebrated example, where the cost function is augmented as

$$L(\boldsymbol{\theta}, \lambda) = \|\mathbf{y} - \mathbf{X}\boldsymbol{\theta}\|^2 + \lambda \|\boldsymbol{\theta}\|^2, \quad \lambda \geq 0$$

leading to the estimate

$$\hat{\boldsymbol{\theta}}_R = (\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^T \mathbf{y},$$

where  $\mathbf{I}$  is the identity matrix. Note that the first term in a regularized cost function measures the model misfit and the second one the “size” of the model.

The major goal of this review chapter is to focus at alternative norms in place of the Euclidean norm, which was employed in ridge regression. As we will see, there are many good reasons in doing that.

### 1.23.3 Searching for a norm

Mathematicians have been very imaginative in proposing various norms in order to equip linear spaces. Among the most popular norms used in functional analysis are the so-called  $\ell_p$  norms. To tailor things to our needs, given a vector  $\boldsymbol{\theta} \in \mathcal{R}^l$ , its  $\ell_p$  norm is defined as

$$\|\boldsymbol{\theta}\|_p := \left( \sum_{i=1}^l |\theta_i|^p \right)^{\frac{1}{p}}. \quad (23.8)$$

For  $p = 2$ , the Euclidean or  $\ell_2$  norm is obtained, and for  $p = 1$ , (23.8) results in the  $\ell_1$  norm, i.e.,

$$\|\boldsymbol{\theta}\|_1 = \sum_{i=1}^l |\theta_i|. \quad (23.9)$$

If we let  $p \rightarrow \infty$ , then we get the  $\ell_\infty$  norm; let  $|\theta_{i_{\max}}| := \max \{|\theta_1|, |\theta_2|, \dots, |\theta_l|\}$ , and notice that

$$\|\boldsymbol{\theta}\|_\infty := \lim_{p \rightarrow \infty} \left( |\theta_{i_{\max}}|^p \sum_{i=1}^l \left( \frac{|\theta_i|}{|\theta_{i_{\max}}|} \right)^p \right)^{\frac{1}{p}} = |\theta_{i_{\max}}|, \quad (23.10)$$

that is,  $\|\boldsymbol{\theta}\|_\infty$  is equal to the maximum of the absolute values of the coordinates of  $\boldsymbol{\theta}$ . One can show that all the  $\ell_p$  norms are true norms for  $p \geq 1$ ; they satisfy all four requirements that a function  $\mathcal{R}^l \rightarrow [0, \infty)$  must respect in order to be called a norm, i.e.,

1.  $\|\boldsymbol{\theta}\|_p \geq 0$ .
2.  $\|\boldsymbol{\theta}\|_p = 0 \Leftrightarrow \boldsymbol{\theta} = \mathbf{0}$ .
3.  $\|\alpha\boldsymbol{\theta}\|_p = |\alpha| \|\boldsymbol{\theta}\|_p, \forall \alpha \in \mathcal{R}$ .
4.  $\|\boldsymbol{\theta}_1 + \boldsymbol{\theta}_2\|_p \leq \|\boldsymbol{\theta}_1\|_p + \|\boldsymbol{\theta}_2\|_p$ .

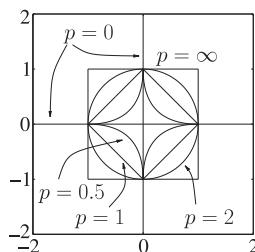

The third condition enforces the norm function to be (*positively*) *homogeneous* and the fourth one is the *triangle inequality*. These properties also guarantee that any function that is a norm is also a convex one. Although strictly speaking, if we allow  $p > 0$  to take values less than one in (23.8), the resulting function is easily shown not to be a true norm, we can still call them norms, albeit knowing that this is an abuse of the definition of a norm. An interesting case, which will be used extensively in this paper, is the  $\ell_0$  norm, which can be obtained as the limit, for  $p \rightarrow 0$ , of

$$\|\boldsymbol{\theta}\|_0 := \lim_{p \rightarrow 0} \|\boldsymbol{\theta}\|_p^p = \lim_{p \rightarrow 0} \sum_{i=1}^l |\theta_i|^p = \sum_{i=1}^l \chi_{(0,\infty)}(|\theta_i|), \quad (23.11)$$

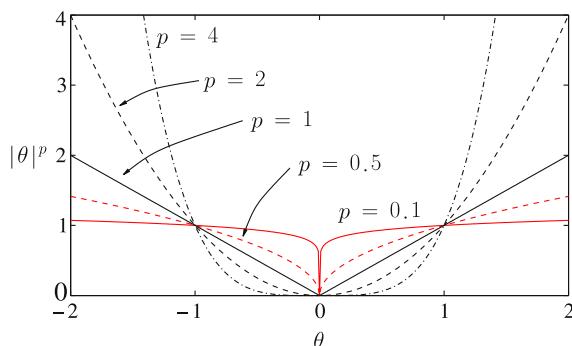

where  $\chi_{\mathcal{A}}(\cdot)$  is the characteristic function with respect to a set  $\mathcal{A}$ , defined as

$$\chi_{\mathcal{A}}(\tau) := \begin{cases} 1, & \text{if } \tau \in \mathcal{A}, \\ 0, & \text{if } \tau \notin \mathcal{A}. \end{cases}$$

That is, the  $\ell_0$  norm is equal to the number of nonzero components of the respective vector. It is very easy to check that this function is not a true norm. Indeed, this function is not homogeneous, i.e.,  $\|\alpha\boldsymbol{\theta}\|_0 \neq |\alpha| \|\boldsymbol{\theta}\|_0, \forall \alpha \neq 1$ . Figure 23.2 shows the isovalue curves, in the two-dimensional space, that correspond

**FIGURE 23.2**

The isovalue curves for  $\|\theta\|_p = 1$  and for various values of  $p$ , in the two dimensional space. Observe that for the  $\ell_0$  norm, the respective values cover the two axes with the exception of the point  $(0, 0)$ . For the  $\ell_1$  norm the isovalue curve is a rhombus and for the  $\ell_2$  (Euclidean) norm, it is a circle.

**FIGURE 23.3**

Observe that the epigraph, that is, the region above the graph, is nonconvex for values  $p < 1$ , indicating the nonconvexity of the respective  $|\cdot|^p$  function. The value  $p = 1$  is the smallest one for which convexity is retained. Also note that, for large values of  $p > 1$ , the contribution of small values of  $\theta$  to the respective norm becomes insignificant.

to  $\|\theta\|_p = \rho \equiv 1$ , for  $p = 0, 0.5, 1, 2$ , and  $\infty$ . Observe that for the Euclidean norm the isovalue curve has the shape of a “ball” and for the  $\ell_1$  norm the shape of a rhombus. We refer to them as the  $\ell_2$  and the  $\ell_1$  balls, respectively, by slightly “abusing” the meaning of a ball.<sup>1</sup> Observe that in the case of the  $\ell_0$  norm, the isovalue curve comprises both the horizontal and the vertical axes, excluding the  $(0, 0)$  element. If we restrict the size of the  $\ell_0$  norm to be less than one, then the corresponding set of points becomes a singleton, i.e.,  $(0, 0)$ . Also, the set of all the two-dimensional points that have  $\ell_0$  norm less than or equal to two, is the  $\mathcal{R}^2$  space. This, slightly “strange” behavior, is a consequence of the discrete nature of this “norm.”

Figure 23.3 shows the graph of  $|\cdot|^p$ , which is the individual contribution of each component of a vector to its  $\ell_p$  norm, for different values of  $p$ . Observe that: (a) for  $p < 1$ , the region which is formed

<sup>1</sup>Strictly speaking, a ball must also contain all the points in the interior.

above the graph (known as epigraph) is not a convex one, which verifies what we have already said; i.e., the respective function is not a true norm, (b) for values of the argument  $|\theta| > 1$ , the larger the value of  $p \geq 1$  and the larger the value of  $|\theta|$  the higher its respective contribution to the norm. Hence, if  $\ell_p$  norms,  $p \geq 1$ , are used to regularize a loss function, such large values become the dominant ones and the optimization algorithm will concentrate on these by penalizing them to get smaller, so that the overall cost to be reduced. On the other hand, for values of the argument  $|\theta| < 1$  and closer to zero, the  $\ell_1$  norm is the only one (among  $p \geq 1$ ) that retains relatively large values and, hence, the respective components can still have a say in the optimization process and can be penalized by being pushed to smaller values. Hence, if the  $\ell_1$  norm is used to replace the  $\ell_2$  one in the regularization equation, *only those components of the vector, that are really significant in reducing the model misfit measuring term in the regularized cost function, will be kept and the rest will be forced to zero.* The same tendency, yet more aggressive, is true for  $0 \leq p < 1$ . The extreme case is when one considers the  $\ell_0$  norm. Even a small increase of a component from zero, makes its contribution to the norm large, so the optimizing algorithm has to be very “cautious” in making an element nonzero.

From all the true norms ( $p \geq 1$ ), the  $\ell_1$  is the only one that shows respect to small values. The rest of the  $\ell_p$  norms,  $p > 1$ , just squeeze them, to make their values even smaller and care, mainly, for the large values. We will return to this point very soon.

### 1.23.4 The least absolute shrinkage and selection operator (LASSO)

We have already discussed some of the benefits in adopting the regularization method for enhancing the performance of an estimator. However, in this paper, we are going to see and study more reasons that justify the use of regularization. The first one refers to what is known as the *interpretation* power of an estimator. For example, in the regression task, we want to select those components,  $\theta_i$ , of  $\boldsymbol{\theta}$  that have the most important say in the formation of the output variable. This is very important if the number of parameters,  $l$ , is large and we want to concentrate on the most important of them. In a classification task [1], not all features are informative, hence one would like to keep the most informative of them and make the less informative ones equal to zero. Another related problem refers to those cases where we know, *a priori*, that a number of the components of a parameter vector are zero but we do not know which ones. The discussion we had at the end of the previous section starts now to become more meaningful. Can we use, while regularizing, an appropriate norm that can assist the optimization process (a) in unveiling such zeros or (b) to put more emphasis on the most significant of its components, those that play a decisive role in reducing the misfit measuring term in the regularized cost function, and set the rest of them equal to zero? Although the  $\ell_p$  norms, with  $p < 1$ , seem to be the natural choice for such a regularization, the fact that they are not convex makes the optimization process hard. The  $\ell_1$  norm is the one that is “closest” to them yet it retains the computationally attractive property of convexity.

The  $\ell_1$  norm has been used for such problems for a long time. In the seventies, it was used in seismology [2,3], where the reflected signal, that indicates changes in the various earth substrates, is a sparse one, i.e., very few values are relatively large and the rest are small and insignificant. Since then, it has been used to tackle similar problems in different applications, e.g., [4,5]. However, one can trace two papers that were really catalytic in providing the spark for the current strong interest around the  $\ell_1$  norm. One came from statistics, [6], which addressed the LASSO task (first formulated, to our

knowledge, in [5]), to be discussed next, and the other from the signal analysis community, [7], which formulated the *Basis Pursuit*, to be discussed in a later section.

We first address our familiar regression task

$$\mathbf{y} = \mathbf{X}\boldsymbol{\theta} + \boldsymbol{\eta}, \quad \mathbf{y}, \boldsymbol{\eta} \in \mathcal{R}^N, \quad \boldsymbol{\theta} \in \mathcal{R}^l,$$

and obtain the estimate of the unknown parameter  $\boldsymbol{\theta}$  via the LS loss, regularized by the  $\ell_1$  norm, i.e., for  $\lambda \geq 0$ ,

$$\hat{\boldsymbol{\theta}} := \arg \min_{\boldsymbol{\theta} \in \mathcal{R}^l} L(\boldsymbol{\theta}, \lambda) \quad (23.12)$$

$$\begin{aligned} &:= \arg \min_{\boldsymbol{\theta} \in \mathcal{R}^l} \left( \sum_{n=1}^N (y_n - \mathbf{x}_n^T \boldsymbol{\theta})^2 + \lambda \|\boldsymbol{\theta}\|_1 \right) \\ &= \arg \min_{\boldsymbol{\theta} \in \mathcal{R}^l} \left( (\mathbf{y} - \mathbf{X}\boldsymbol{\theta})^T (\mathbf{y} - \mathbf{X}\boldsymbol{\theta}) + \lambda \|\boldsymbol{\theta}\|_1 \right). \end{aligned} \quad (23.13)$$

In order to simplify the analysis, we will assume hereafter, without harming generality, that the data are centered. If this is not the case, the data can be centered by subtracting the sample mean  $\bar{y}$  from each one of the output values. The estimate of the bias term will be equal to the sample mean  $\bar{y}$ . The task in (23.13) can be *equivalently* written in the following two formulations

$$\begin{aligned} \hat{\boldsymbol{\theta}} : \min_{\boldsymbol{\theta} \in \mathcal{R}^l} & (\mathbf{y} - \mathbf{X}\boldsymbol{\theta})^T (\mathbf{y} - \mathbf{X}\boldsymbol{\theta}), \\ \text{s.t. } & \|\boldsymbol{\theta}\|_1 \leq \rho, \end{aligned} \quad (23.14)$$

or

$$\begin{aligned} \hat{\boldsymbol{\theta}} : \min_{\boldsymbol{\theta} \in \mathcal{R}^l} & \|\boldsymbol{\theta}\|_1, \\ \text{s.t. } & (\mathbf{y} - \mathbf{X}\boldsymbol{\theta})^T (\mathbf{y} - \mathbf{X}\boldsymbol{\theta}) \leq \epsilon, \end{aligned} \quad (23.15)$$

given the user-defined parameters  $\rho, \epsilon \geq 0$ . The formulation in (23.14) is known as the LASSO and the one in (23.15) as the *Basis Pursuit Denoising* (BPDN), e.g., [8]. All three formulations can be shown to be equivalent for specific choices of  $\lambda, \epsilon$ , and  $\rho$ . The minimized cost function in (23.13) corresponds to the Lagrangian of the formulations in (23.14) and (23.15). However, this functional dependence is hard to compute, unless the columns of  $\mathbf{X}$  are mutually orthogonal. Moreover, this equivalence does not necessarily imply that all three formulations are equally easy or difficult to solve. As we will see later on, algorithms have been developed along each one of the previous formulations. From now on, we will refer to all three formulations as the LASSO task, in a slight abuse of the standard terminology, and the specific formulation will be apparent from the context, if not stated explicitly.

As it was discussed before, the Ridge regression admits a closed form solution, i.e.,

$$\hat{\boldsymbol{\theta}}_R = \left( \mathbf{X}^T \mathbf{X} + \lambda I \right)^{-1} \mathbf{X}^T \mathbf{y}.$$

In contrast, this is not the case for LASSO and its solution requires iterative techniques. It is straightforward to see that LASSO can be formulated as a standard convex quadratic problem with linear

inequalities. Indeed, we can rewrite (23.13) as

$$\begin{aligned} \min_{\{\theta_i, u_i\}_{i=1}^l} \quad & (\mathbf{y} - X\boldsymbol{\theta})^T(\mathbf{y} - X\boldsymbol{\theta}) + \lambda \sum_{i=1}^l u_i \\ \text{s.t.} \quad & \begin{cases} -u_i \leq \theta_i \leq u_i, & i = 1, 2, \dots, l, \\ u_i \geq 0, \end{cases} \end{aligned}$$

which can be solved by any standard convex optimization method, e.g., [9, 10]. The reason that developing algorithms for the LASSO has been a hot research topic is due to the emphasis in obtaining *efficient* algorithms by exploiting the specific nature of this task, especially for cases where  $l$  is very large, as it is often the case in practice.

In order to get a better insight of the nature of the solution that is obtained by LASSO, let us assume that the regressors are mutually orthogonal and of unit norm, hence  $X^T X = I$ . Orthogonality of the input matrix helps to decouple the coordinates and results to  $l$  one-dimensional problems, that can be solved analytically. For this case, the LS estimator becomes

$$\hat{\boldsymbol{\theta}}_{\text{LS}} = (X^T X)^{-1} X^T \mathbf{y} = X^T \mathbf{y},$$

and the ridge regression gives

$$\hat{\boldsymbol{\theta}}_R = \frac{1}{1 + \lambda} \hat{\boldsymbol{\theta}}_{\text{LS}}, \quad (23.16)$$

that is, every component of the LS estimator is simply shrunk by the *same* factor,  $\frac{1}{1+\lambda}$ .

In the case of the  $\ell_1$  regularization, the minimized Lagrangian function is no more differentiable, due to the presence of the absolute values in the  $\ell_1$  norm. So, in this case, we have to consider the notion of the subdifferential (see Appendix). It is known that if the zero vector belongs to the subdifferential set of a convex function at a point, this means that this point corresponds to a minimum of the function. Taking the subdifferential of the Lagrangian defined in (23.13) and recalling that the subdifferential set of a differentiable function includes *only* the respective gradient, we obtain that

$$\mathbf{0} \in -2X^T \mathbf{y} + 2X^T X \boldsymbol{\theta} + \lambda \partial \|\boldsymbol{\theta}\|_1,$$

where  $\partial$  stands for the subdifferential operator (see Appendix). If  $X$  has orthonormal columns, the previous equation can be written component-wise as follows

$$0 \in -\hat{\theta}_{\text{LS},i} + \hat{\theta}_{1,i} + \frac{\lambda}{2} \partial |\hat{\theta}_{1,i}|, \quad \forall i, \quad (23.17)$$

where the subdifferential of the function  $|\cdot|$ , derived in Appendix, is given as

$$\partial |\theta| = \begin{cases} \{1\}, & \text{if } \theta > 0, \\ \{-1\}, & \text{if } \theta < 0, \\ [-1, 1], & \text{if } \theta = 0. \end{cases}$$

Thus, we can now write for each component of the LASSO optimal estimate

$$\hat{\theta}_{1,i} = \begin{cases} \hat{\theta}_{\text{LS},i} - \frac{\lambda}{2}, & \text{if } \hat{\theta}_{1,i} > 0, \\ \hat{\theta}_{\text{LS},i} + \frac{\lambda}{2}, & \text{if } \hat{\theta}_{1,i} < 0. \end{cases} \quad (23.18)$$

$$(23.19)$$

Notice that (36.18) can only be true if  $\hat{\theta}_{\text{LS},i} > \frac{\lambda}{2}$ , and (36.19) only if  $\hat{\theta}_{\text{LS},i} < -\frac{\lambda}{2}$ . Moreover, in the case where  $\hat{\theta}_{1,i} = 0$ , then (23.17) and the subdifferential of  $|\cdot|$  suggest that necessarily  $|\hat{\theta}_{\text{LS},i}| \leq \frac{\lambda}{2}$ . Concluding, we can write in a more compact way that

$$\hat{\theta}_{1,i} = \text{sgn}(\hat{\theta}_{\text{LS},i}) \left( |\hat{\theta}_{\text{LS},i}| - \frac{\lambda}{2} \right)_+, \quad (23.20)$$

where  $(\cdot)_+$  denotes the “positive part” of the respective argument; it is equal to the argument if this is non-negative, and zero otherwise. This is very interesting indeed. In contrast to the ridge regression that shrinks all coordinates of the unregularized LS solution by the same factor, LASSO forces all coordinates, whose absolute value is less than or equal to  $\lambda/2$ , to zero, and the rest of the coordinates are reduced, in absolute value, by the same amount  $\lambda/2$ . This is known as *soft thresholding*, to distinguish it from the *hard thresholding* operation; the latter is defined as  $\theta \cdot \chi_{(0,\infty)}(|\theta| - \frac{\lambda}{2})$ ,  $\theta \in \mathcal{R}$ , where  $\chi_{(0,\infty)}(\cdot)$  stands for the characteristic function with respect to the set  $(0, \infty)$ . Figure 23.4 shows the graphs illustrating the effect that the ridge regression, LASSO and hard thresholding have on the unregularized LS solution, as a function of its value (horizontal axis). Note that our discussion here, simplified via the orthonormal input matrix case, has quantified what we had said before about the tendency of the  $\ell_1$  norm to push small values to become *exactly zero*. This will be further strengthened, via a more rigorous mathematical formulation, in Section 1.23.6.

**Example 1.** Assume that the unregularized LS solution, for a given regression task,  $y = X\theta + \eta$ , is given by:

$$\hat{\theta}_{\text{LS}} = [0.2, -0.7, 0.8, -0.1, 1.0]^T.$$

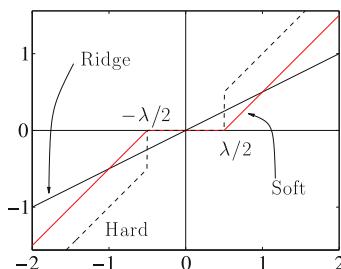

FIGURE 23.4

Output-input curves for the hard thresholding, soft thresholding operators together with the linear operator associated with the ridge regression, for the same value of  $\lambda = 1$ .

Derive the solutions for the corresponding ridge regression and  $\ell_1$  norm regularization tasks. Assume that the input matrix  $X$  has orthonormal columns and that the regularization parameter is  $\lambda = 1$ . Also, what is the result of hard thresholding the vector  $\hat{\theta}_{\text{LS}}$  with threshold equal to 0.5?

We know that the corresponding solution for the ridge regression is

$$\hat{\theta}_R = \frac{1}{1 + \lambda} \hat{\theta}_{\text{LS}} = [0.1, -0.35, 0.4, -0.05, 0.5]^T.$$

The solution for the  $\ell_1$  norm regularization is given by soft thresholding, with threshold equal to  $\lambda/2 = 0.5$ , hence the corresponding vector is

$$\hat{\theta}_1 = [0, -0.2, 0.3, 0, 0.5]^T.$$

The result of the hard thresholding operation is the vector  $[0, -0.7, 0.8, 0, 1.0]^T$ .

### Remarks 1.

- The hard and soft thresholding rules are only two possibilities out of a larger number of alternatives. Note that the hard thresholding operation is defined via a discontinuous function and this makes this rule to be unstable, in the sense of being very sensitive to small changes of the input. Moreover, this shrinking rule tends to exhibit large variance in the resulting estimates. The soft thresholding rule is a continuous function, but, as it is readily seen from the graph in Figure 23.4, it introduces bias even for the large values of the input argument. In order to ameliorate such shortcomings, a number of alternative thresholding operators have been introduced and studied both theoretically and experimentally. Although these are not within the mainstream of our interest, we provide two popular examples for the sake of completeness; the *Smoothly Clipped Absolute Deviation* (SCAD):

$$\hat{\theta}_{\text{SCAD}} = \begin{cases} \text{sgn}(\theta) (|\theta| - \lambda_{\text{SCAD}})_+, & |\theta| \leq 2\lambda_{\text{SCAD}}, \\ \frac{(\alpha-1)\theta - \alpha\lambda_{\text{SCAD}} \text{sgn}(\theta)}{\alpha-2}, & 2\lambda_{\text{SCAD}} < |\theta| \leq \alpha\lambda_{\text{SCAD}}, \\ \theta, & |\theta| > \alpha\lambda_{\text{SCAD}}, \end{cases}$$

and the *non-negative garrote* thresholding rule :

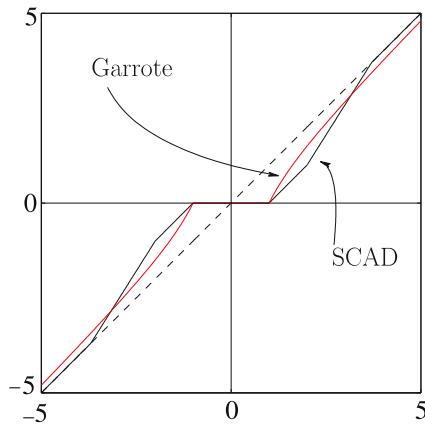

$$\hat{\theta}_{\text{garr}} = \begin{cases} 0, & |\theta| \leq \lambda_{\text{garr}}, \\ \theta - \frac{\lambda_{\text{garr}}^2}{\theta}, & |\theta| > \lambda_{\text{garr}}. \end{cases}$$

Figure 23.5 shows the respective graphs. Observe that, in both cases, an effort has been made to remove the discontinuity (associated with the hard thresholding) and to remove/reduce the bias for large values of the input argument. The parameter  $\alpha$  is a user-defined one. For a more detailed discussion on this topic, the interested reader can refer, for example, to [11].

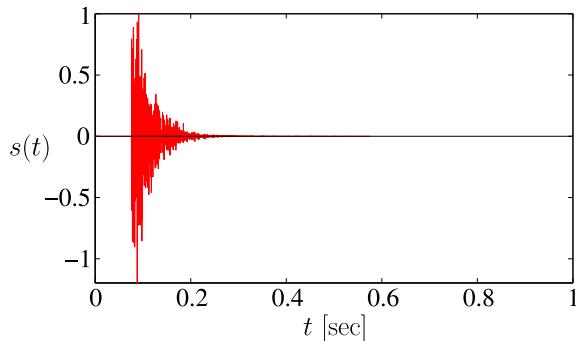

---

### 1.23.5 Sparse signal representation

In the previous section, we brought into our discussion the need for taking special care for zeros. Sparsity is an attribute that is met in a plethora of natural signals, since nature tends to be parsimonious. In this section, we will briefly present a number of application cases, where the existence of zeros in a

**FIGURE 23.5**

Output-input graph for the SCAD and nonnegative garrote rules with parameters  $\alpha = 3.7$ , and  $\lambda_{\text{SCAD}} = \lambda_{\text{garr}} = 1$ . Observe that both rules smooth out the discontinuity associated with the hard thresholding rule. Notice, also, that the SCAD rule removes the bias, associated with the soft thresholding rule, for large values of the input variable. On the contrary, the garrote thresholding rule allows some bias for large input values, which diminishes as  $\lambda_{\text{garr}}$  gets smaller and smaller.

**FIGURE 23.6**

The impulse response function of an echo-path in a telephone network. Observe that although it is of relatively short duration, it is not a priori known where exactly in time will occur.

mathematical expansion is of paramount importance, hence it justifies to further strengthen our search for and developing related analysis tools.

Echo cancelation is a major task in Communications. In a number of cases, the echo path, represented by a vector comprising the values of the impulse response samples, is a sparse one. This is the case, for example, in internet telephony and in acoustic and network environments, e.g., [12–14]. Figure 23.6 shows the impulse response of such an echo path. The impulse response of the echo path is of short duration; however, the delay with which it appears is not known. So, in order to model it, one has to

use a long impulse response, yet only a relatively small number of the coefficients will be significant and the rest will be close to zero. Of course, one could ask why not use an LMS or an RLS [15, 16] and eventually the significant coefficients will be identified. The answer is that this turns out not to be the most efficient way to tackle such problems, since the convergence of the algorithm can be very slow. In contrast, if one embeds, somehow, into the problem the a priori information concerning the existence of (almost) zero coefficients, then the convergence speed can be significantly increased and also better error floors can be attained.

A similar situation, as in the previous case, occurs in wireless communication systems, which involve multipath channels. A typical application is in high definition television (HDTV) systems, where the involved communications channels consist of a few non-negligible echoes, some of which may have quite large time delays with respect to the main signal, see, e.g., [17–20]. If the information signal is transmitted at high symbol rates through such a dispersive channel, then the introduced intersymbol interference (ISI) has a span of several tens up to hundreds of symbol intervals. This in turn implies that quite long channel estimators are required at the receiver's end in order to reduce effectively the ISI component of the received signal, although only a small part of it has values substantially different to zero. The situation is even more demanding whenever the channel frequency response exhibits deep nulls. More recently, sparsity has been exploited in channel estimation for multicarrier systems, both for single antenna as well as for MIMO systems [21, 22]. A thorough and in depth treatment related to sparsity in multipath communication systems is provided in [23].

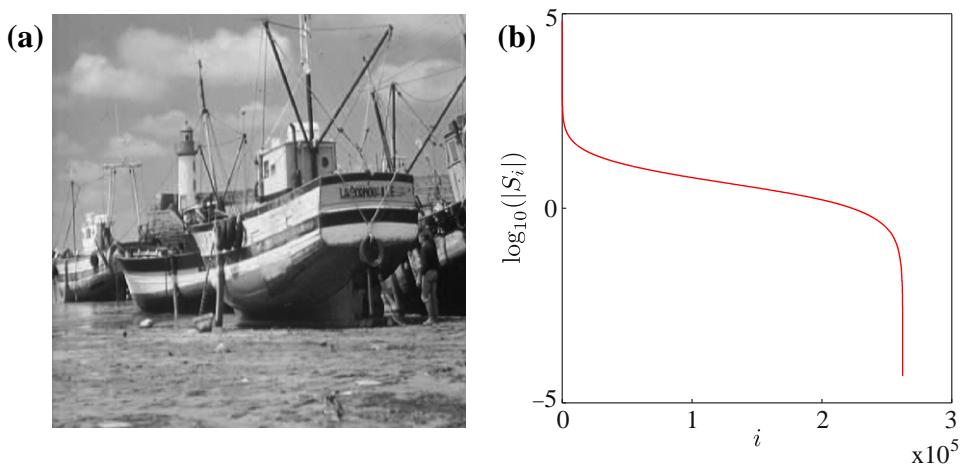

Another example, which might be more widely known, is that of signal compression. It turns out that if the signal modalities, with which we communicate, e.g., speech, and also we sense the world, e.g., images, audio, are transformed into a suitably chosen domain then they are sparsely represented; only a relatively small number of the signal components in this domain are large and the rest are close to zero. As an example, Figure 23.7a shows an image and Figure 23.7b the plot of the magnitude of the obtained Discrete Cosine Transform (DCT) components, which are computed by writing the corresponding image array as a vector in lexicographic order. Note that more than 95% of the total energy is contributed by only the 5% of the largest components. This is at the heart of any compression technique. Only the large coefficients are chosen to be coded and the rest are considered to be zero. Hence, significant gains are obtained in memory/bandwidth requirements while storing/transmitting such signals, without much perceptual loss. Depending on the modality, different transforms are used. For example, in JPEG-2000, an image array, represented in terms of a vector that contains the intensity of the gray levels of the image pixels, is transformed via the discrete wavelet transform (DWT) and results to a transform vector that comprises only a few large components. Such an operation is of the form

$$\mathbf{S} = \Phi^H \mathbf{s}, \quad \mathbf{s}, \mathbf{S} \in \mathcal{C}^l, \quad (23.21)$$

where  $\mathbf{s}$  is the vector of the “raw” signal samples,  $\mathbf{S}$  the (complex-valued) vector of the transformed ones, and  $\Phi$  is the  $l \times l$  transformation matrix. Often, this is an orthonormal matrix,  $\Phi^H \Phi = I$ . Basically, a transform is nothing else than a projection of a vector on a new set of coordinate axes, which comprise the columns of the transformation matrix  $\Phi$ . Celebrated examples of such transforms are the wavelet, the discrete Fourier (DFT) and the discrete cosine (DCT) transforms, e.g., [1]. In such cases, where the transformation matrix is orthonormal, one can write that

$$\mathbf{s} = \Psi \mathbf{S}, \quad (23.22)$$

where  $\Psi = \Phi$ . Eq. (23.21) is known as the *analysis* and (23.22) as the *synthesis* equation.

**FIGURE 23.7**

(a) A  $512 \times 512$  pixel image and (b) The magnitude of its Discrete Cosine Transform components in descending order and logarithmic scale. Note that more than 95% of the total energy is contributed by only the 5% of the largest components.

Compression via such transforms exploit the fact that many signals in nature, which are rich in context, can be *compactly* represented in an appropriately chosen basis, depending on the modality of the signal. Very often, the construction of such bases tries to “imitate” the sensory systems that the human (and not only) brain has developed in order to sense these signals; and we know that nature (in contrast to modern humans) does not like to waste resources. A standard compression task comprises the following stages: (a) Obtain the  $l$  components of  $S$ , via the analysis step (23.21), (b) keep the, say,  $k$  most significant of them, (c) code these values, as well as their respective locations in the transform vector  $S$ , and (d) obtain the (approximate) original signal  $s$ , when needed (after storage or transmission), via the synthesis Eq. (23.22), where in place of  $S$  only its  $k$  most significant components are used, which are the ones that were coded, while the rest are set equal to zero. However, there is something unorthodox in this process of compression, as it has been practised till very recently. One processes (transforms) large signal vectors of  $l$  coordinates, where  $l$  in practice can be quite large, and then uses only a small percentage of the transformed coefficients and the rest are simply ignored. Moreover, one has to store/transmit the location of the respective large coefficients that were finally coded. A natural question that is now raised is the following: Since  $S$  in the synthesis equation is (approximately) sparse, can one compute it via an alternative path than the analysis equation in (23.21)? The issue here is to investigate whether one could use a more informative way of obtaining measurements from the available raw data, so that less than  $l$  measurements are sufficient to recover all the necessary information. The ideal case would be to be able to recover it via a set of  $k$  such measurement samples, since this is the number of the significant free parameters. On the other hand, if this sounds a bit extreme, can one obtain  $N$  ( $k < N \ll l$ ) such signal-related measurements, from which one can obtain the  $k$  needed components of  $S$ ? It turns out that such an approach is possible and it leads to the solution of an *underdetermined* system of linear

equations, under the constraint that the unknown target vector is a sparse one. The importance of such techniques becomes even more apparent when, instead of an orthonormal basis, as discussed before, a more general type of expansion is adopted, in terms of what is known as *overcomplete dictionaries*.

A dictionary [24] is a collection of parameterized waveforms, which are discrete-time signal samples, represented as vectors  $\psi_i \in \mathcal{C}^l$ ,  $i \in \mathcal{I}$ . For example, the columns of a DFT or a DWT matrix comprise a dictionary. These are two examples of what is known as *complete* dictionaries, which consist of  $l$  (orthonormal) vectors, i.e., a number equal to the length of the signal vector. However, in many cases in practice, using such dictionaries is very restrictive. Let us take, for example, a segment of audio signal, from a news media or a video, that needs to be processed. This consists, in general, of different types of signals, namely speech, music, environmental sounds. For each type of these signals, different signal vectors may be more appropriate in the expansion for the analysis. For example, music signals are characterized by a strong harmonic content and the use of sinusoids seems to be best for compression, while for speech signals a Gabor type signal expansion (sinusoids of various frequencies weighted by sufficiently narrow pulses at different locations in time, [1, 25]), may be a better choice. The same applies when one deals with an image. Different parts of an image, e.g., parts which are smooth or contain sharp edges, may demand a different expansion vector set, for obtaining the best overall performance. The more recent tendency, in order to satisfy such needs, is to use *overcomplete* dictionaries. Such dictionaries can be obtained, for example, by concatenating different dictionaries together, e.g., a DFT and a DWT matrix to result in a combined  $l \times 2l$  transformation matrix. Alternatively, a dictionary can be “trained” in order to effectively represent a set of available signal exemplars, a task which is often referred to as dictionary learning [26–29]. While using such overcomplete dictionaries, the synthesis equation takes the form

$$\mathbf{s} = \sum_{i \in \mathcal{I}} \theta_i \psi_i. \quad (23.23)$$

Note that, now, the analysis is an ill-posed problem, since the elements  $\{\psi_i\}_{i \in \mathcal{I}}$  (usually called *atoms*) of the dictionary are not linearly independent, and there is not a unique set of coefficients  $\{\theta_i\}_{i \in \mathcal{I}}$  which generates  $\mathbf{s}$ . Moreover, we expect most of these coefficients to be (nearly) zero. Note that, in such cases, the cardinality of  $\mathcal{I}$  is larger than  $l$ . This necessarily leads to underdetermined systems of equations with infinite many solutions. The question that is now raised is whether we can exploit the fact that most of these coefficients are known to be zero, in order to come up with a unique solution, and if yes, under which conditions such a solution is possible?

Besides the previous examples, there is a number of cases where an underdetermined system of equations is the result of our inability to obtain a sufficiently large number of measurements, due to physical and technical constraints. This is for example the case in MRI imaging, which will be presented in more detail later on.

### 1.23.6 In quest for the sparsest solution

Inspired by the discussion in the previous section, we now turn our attention to the task of solving underdetermined systems of equations, by imposing the sparsity constraint on the solution [30]. We will develop the theoretical set up in the context of the regression task and we will adhere to the notation that has been adopted for this task. Moreover, we will focus on the real-valued data case, in order to

simplify the presentation. The theory can be readily extended to the more general complex data case, see, e.g., [31,32]. We assume that we are given a set of measurements,  $\mathbf{y} := [y_1, y_2, \dots, y_N]^T \in \mathcal{R}^N$ , according to the linear model

$$\mathbf{y} = X\boldsymbol{\theta}, \quad \mathbf{y} \in \mathcal{R}^N, \quad \boldsymbol{\theta} \in \mathcal{R}^l, \quad l > N, \quad (23.24)$$

where  $X$  is the  $N \times l$  input matrix, which is assumed to be of full row rank, i.e.,  $\text{rank}(X) = N$ . Our starting point is the noiseless case. The system in (23.24) is an underdetermined one and accepts an infinite number of solutions. The set of possible solutions lies in the intersection of the  $N$  hyperplanes<sup>2</sup> in the  $l$ -dimensional space,

$$\{\boldsymbol{\theta} \in \mathcal{R}^l : y_n = \mathbf{x}_n^T \boldsymbol{\theta}\}, \quad n = 1, 2, \dots, N.$$

We know from geometry, that the intersection of  $N$  non-parallel hyperplanes (which in our case is guaranteed by the fact that  $X$  has been assumed to be full row rank, hence  $\mathbf{x}_n$  are mutually independent) is a plane of dimensionality  $l - N$  (e.g., the intersection of two (non-parallel) (hyper) planes in the 3-dimensional space is a straight line; that is, a plane of dimensionality equal to one). In a more formal way, the set of all possible solutions, to be denoted as  $\Theta$ , is an *affine* set. An affine set is the translation of a linear subspace by a constant vector. Let us pursue this a bit further, since we will need it later on.

Let the null space of  $X$  be the set  $\text{null}(X)$ , defined as the linear subspace

$$\text{null}(X) = \left\{ \mathbf{z} \in \mathcal{R}^l : X\mathbf{z} = \mathbf{0} \right\}.$$

Obviously, if  $\boldsymbol{\theta}_0$  is a solution to (23.24), i.e.,  $\boldsymbol{\theta}_0 \in \Theta$ , then it is easy to verify that  $\forall \boldsymbol{\theta} \in \Theta, X(\boldsymbol{\theta} - \boldsymbol{\theta}_0) = \mathbf{0}$ , or  $\boldsymbol{\theta} - \boldsymbol{\theta}_0 \in \text{null}(X)$ . As a result,

$$\Theta = \boldsymbol{\theta}_0 + \text{null}(X),$$

and  $\Theta$  is an affine set. We also know from linear algebra basics that the null space of a full row rank matrix,  $N \times l, l > N$ , is a subspace of dimensionality  $l - N$ . Figure 23.8 illustrates the case for one measurement sample in the 2-dimensional space,  $l = 2$  and  $N = 1$ . The set of solutions  $\Theta$  is a line, which is the translation of the linear subspace crossing the origin (the  $\text{null}(X)$ ). Therefore, if one wants to determine a *single* point that lies in the affine set of solutions,  $\Theta$ , then an extra constraint/a priori knowledge has to be imposed

In the sequel, three such possibilities are examined.

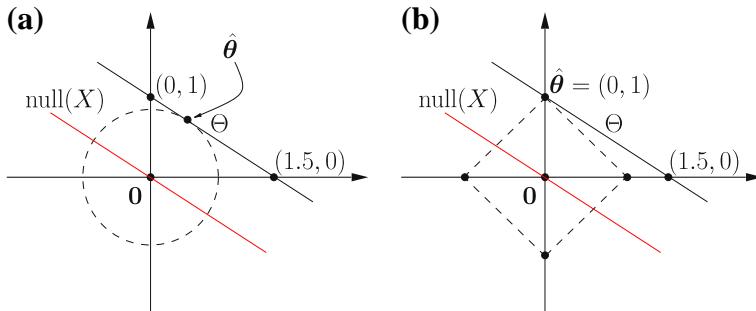

### 1.23.6.1 The $\ell_2$ norm minimizer

Our goal now becomes to pick a point in (the affine set)  $\Theta$ , that corresponds to the minimum  $\ell_2$  norm. This is equivalent to solving the following constrained task

$$\begin{aligned} \min_{\boldsymbol{\theta} \in \mathcal{R}^l} \quad & \|\boldsymbol{\theta}\|_2^2 \\ \text{s.t. } & \mathbf{x}_n^T \boldsymbol{\theta} = y_n, \quad n = 1, 2, \dots, N. \end{aligned} \quad (23.25)$$

---

<sup>2</sup>In  $\mathcal{R}^l$ , a hyperplane is of dimension  $l - 1$ . A plane has dimension lower than  $l - 1$ .

**FIGURE 23.8**

(a) The  $\ell_2$  norm minimizer. The dotted circle corresponds to the smallest  $\ell_2$  ball that intersects the set  $\Theta$ . As such, the intersection point,  $\hat{\theta}$ , is the  $\ell_2$  norm minimizer of the task (23.25). Notice that the vector  $\hat{\theta}$  contains no zero component. (b) The  $\ell_1$  norm minimizer. The dotted rhombus corresponds to the smallest  $\ell_1$  ball that intersects  $\Theta$ . Hence, the intersection point,  $\hat{\theta}$ , is the solution of the constrained  $\ell_1$  minimization task of (23.28). Notice that the obtained estimate  $\hat{\theta} = (0, 1)$  contains a zero.

The previous optimization task accepts a *unique* solution given in closed form as

$$\hat{\theta} = X^T (X X^T)^{-1} y. \quad (23.26)$$

The geometric interpretation of this solution is provided in Figure 23.8a, for the case of  $l = 2$  and  $N = 1$ . The radius of the Euclidean norm ball keeps increasing, till it touches the plane that contains the solutions. This point is the one with the minimum  $\ell_2$  norm or, equivalently, the point that lies closest to the origin. Equivalently, the point  $\hat{\theta}$  can be seen as the (metric) projection of  $\mathbf{0}$  onto  $\Theta$ .

Minimizing the  $\ell_2$  norm, in order to solve a linear set of underdetermined equations, has been used in various applications. The closest to us is in the context of determining the unknown coefficients in an expansion using an overcomplete dictionary of functions (vectors) [33]. A main drawback of this method is that it is not sparsity preserving. There is no guarantee that the solution in (23.26) will give zeros even if the true model vector  $\theta$  has zeros. Moreover, the method is *resolution limited* [7]. This means that, even if there may be a sharp contribution of specific atoms in the dictionary, this is not portrayed in the obtained solution. This is a consequence of the fact that the information provided by  $X X^T$  is a global one, containing all atoms of the dictionary in an “averaging” fashion, and the final result tends to smooth out the individual contributions, especially when the dictionary is overcomplete.

### 1.23.6.2 The $\ell_0$ norm minimizer

Now we turn our attention to the  $\ell_0$  norm (once more, it is pointed out that this is an abuse of the definition of the norm, as stated before), and we make sparsity our new flag under which a solution will be obtained. Recall from Section 1.23.5 that such a constraint is in line with the natural structure that underlies a number of applications. The task now becomes

$$\min_{\theta \in \mathcal{R}^l} \|\theta\|_0$$

$$\text{s.t. } \mathbf{x}_n^T \boldsymbol{\theta} = y_n, \quad n = 1, 2, \dots, N, \quad (23.27)$$

that is, from all the points that lie on the plane of all possible solutions find the *sparsest* one; i.e., the one with the least number of nonzero elements. As a matter of fact, such an approach is within the spirit of *Occam's razor* rule. It corresponds to the smallest number of parameters that can explain the obtained measurements. The points that are now raised are:

- Is a solution to this problem unique and under which conditions?
- Can a solution be obtained with low enough complexity in realistic time?

We postpone the answer to the first question later on. As for the second one, the news is no good. Minimizing the  $\ell_0$  norm under a set of linear constraints is a task of combinatorial nature and as a matter of fact the problem is, in general, NP-hard [34]. The way to approach the problem is to consider all possible combinations of zeros in  $\boldsymbol{\theta}$ , removing the respective columns of  $X$  in (23.24) and check whether the system of equations is satisfied; keep as solutions the ones with the smallest number of nonzero elements. Such a searching technique exhibits complexity of an exponential dependence on  $l$ . Figure 23.8a illustrates the two points ((1.5, 0) and (0, 1)) that comprise the solution set of minimizing the  $\ell_0$  norm for the single measurement (constraint) case.

### 1.23.6.3 The $\ell_1$ norm minimizer

The current task is now given by

$$\begin{aligned} & \min_{\boldsymbol{\theta} \in \mathcal{R}^l} \|\boldsymbol{\theta}\|_1 \\ & \text{s.t. } \mathbf{x}_n^T \boldsymbol{\theta} = y_n, \quad n = 1, 2, \dots, N. \end{aligned} \quad (23.28)$$

Figure 23.8b illustrates the geometry. The  $\ell_1$  ball is increased till it touches the affine set of the possible solutions. For this specific geometry, the solution is the point (0, 1). In our discussion in Section 1.23.3, we saw that the  $\ell_1$  norm is the one, out of all  $\ell_p$ ,  $p \geq 1$  norms, that bears some similarity with the sparsity favoring (nonconvex)  $\ell_p$ ,  $p < 1$  “norms.” Also, we have commented that the  $\ell_1$  norm encourages zeros, when the respective values are small. In the sequel, we will state one lemma, that establishes this zero-favoring property in a more formal way. The  $\ell_1$  norm minimizer is also known as *Basis Pursuit* and it was suggested for decomposing a vector signal in terms of the atoms of an overcomplete dictionary [7].

The  $\ell_1$  minimizer can be brought into the standard Linear Programming (LP) form and then can be solved by recalling any related method; the simplex method or the more recent interior point methods are two possibilities, see, e.g., [9, 35]. Indeed, consider the (LP) task

$$\begin{aligned} & \min_{\mathbf{x}} \mathbf{c}^T \mathbf{x} \\ & \text{s.t. } \mathbf{A}\mathbf{x} = \mathbf{b} \\ & \quad \mathbf{x} \geq \mathbf{0}. \end{aligned}$$

To verify that our  $\ell_1$  minimizer can be cast in the previous form, notice first that any  $l$ -dimensional vector  $\boldsymbol{\theta}$  can be decomposed as

$$\boldsymbol{\theta} = \mathbf{u} - \mathbf{v}, \quad \mathbf{u} \geq \mathbf{0}, \quad \mathbf{v} \geq \mathbf{0}.$$

Indeed, this holds true if, for example,

$$\mathbf{u} := \boldsymbol{\theta}_+, \quad \mathbf{v} := (-\boldsymbol{\theta})_+,$$

where  $\mathbf{x}_+$  stands for the vector obtained after taking the positive parts of the components of  $\mathbf{x}$ . Moreover, notice that

$$\|\boldsymbol{\theta}\|_1 = [1, 1, \dots, 1] \begin{bmatrix} \boldsymbol{\theta}_+ \\ (-\boldsymbol{\theta})_+ \end{bmatrix} = [1, 1, \dots, 1] \begin{bmatrix} \mathbf{u} \\ \mathbf{v} \end{bmatrix}.$$

Hence, our  $\ell_1$  minimization task can be recast in the LP form, if

$$\begin{aligned} \mathbf{c} &:= [1, 1, \dots, 1]^T, \quad \mathbf{x} := [\mathbf{u}^T, \mathbf{v}^T]^T, \\ \mathbf{A} &:= [X, -X], \quad \mathbf{b} := \mathbf{y}. \end{aligned}$$

#### 1.23.6.4 Characterization of the $\ell_1$ norm minimizer

**Lemma 1.** An element  $\boldsymbol{\theta}$  in the affine set,  $\Theta$ , of the solutions of the underdetermined linear system (23.24), has minimal  $\ell_1$  norm if and only if the following condition is satisfied:

$$\left| \sum_{i:\theta_i \neq 0} \operatorname{sgn}(\theta_i) z_i \right| \leq \sum_{i:\theta_i=0} |z_i|, \quad \forall \mathbf{z} \in \operatorname{null}(X). \quad (23.29)$$

Moreover, the  $\ell_1$  minimizer is unique if and only if the inequality in (23.29) is a strict one for all  $\mathbf{z} \neq \mathbf{0}$  (see, e.g., [36]).

**Remarks 2.** The previous lemma has a very interesting and important consequence. If  $\hat{\boldsymbol{\theta}}$  is the *unique* minimizer of (23.28), then

$$\operatorname{card}\{i : \hat{\theta}_i = 0\} \geq \dim(\operatorname{null}(X)), \quad (23.30)$$

where  $\operatorname{card}\{\cdot\}$  denotes the cardinality of a set. In words, the number of zero coordinates of the unique minimizer cannot be smaller than the dimension of the null space of  $X$ . Indeed, if this is not the case, then the unique minimizer could have less zeros than the dimensionality of  $\operatorname{null}(X)$ . As it can easily be shown, this means that we can always find a  $\mathbf{z} \in \operatorname{null}(X)$ , which has zeros in the same locations where the coordinates of the unique minimizer are zero, and at the same time it is not identically zero, i.e.,  $\mathbf{z} \neq \mathbf{0}$ . However, this would violate (23.29), which in the case of uniqueness holds as a strict inequality.

**Definition 1.** A vector  $\boldsymbol{\theta}$  is called  $k$ -sparse if it has *at most*  $k$  nonzero components.

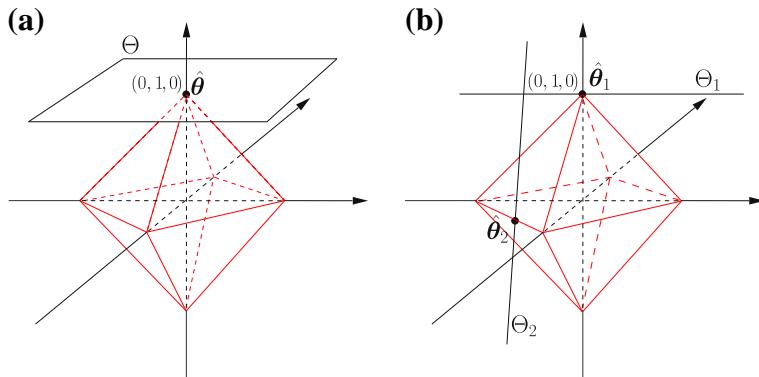

**Remarks 3.** If the minimizer of (23.28) is *unique*, then it is a  $k$ -sparse vector with

$$k \leq N.$$

This is a direct consequence of the Remark 2, and the fact that for the matrix  $X$ ,

$$\dim(\operatorname{null}(X)) = l - \operatorname{rank}(X) = l - N.$$

Hence, the number of the nonzero elements of the unique minimizer must be at most equal to  $N$ . If one resorts to geometry, all the previously stated results become crystal clear.

**FIGURE 23.9**

(a) The  $\ell_1$  ball intersecting with a plane. The only possible scenario, for the existence of a unique common intersecting point of the  $\ell_1$  ball with a plane in the Euclidean  $\mathcal{R}^3$  space, is for the point to be located at one of the corners of the  $\ell_1$  ball, i.e., to be an 1-sparse vector. (b) The  $\ell_1$  ball intersecting with lines. In this case, the sparsity level of the unique intersecting point is relaxed; it could be an 1- or a 2-sparse vector.

### 1.23.6.5 Geometric interpretation

Assume that our target solution resides in the 3-dimensional space and that we are given one measurement

$$y_1 = \mathbf{x}_1^T \boldsymbol{\theta} = x_{11}\theta_1 + x_{12}\theta_2 + x_{13}\theta_3.$$

Then the solution lies in the 2-dimensional (hyper)plane, which is described by the previous equation. To get the minimal  $\ell_1$  solution we keep increasing the size of the  $\ell_1$  ball<sup>3</sup> (the set of all points that have equal  $\ell_1$  norm) till it touches this plane. The only way that these two geometric objects have a single point in common (unique solution) is when they meet at a corner of the diamond. This is shown in Figure 23.9a. In other words, the resulting solution is 1-sparse, having two of its components equal to zero. This complies with the finding stated in Remark 3, since now  $N = 1$ . For any other orientation of the plane, this will either cut across the  $\ell_1$  ball or will share with the diamond an edge or a side. In both cases, there will be infinite many solutions.

Let us now assume that we are given an extra measurement,

$$y_2 = x_{21}\theta_1 + x_{22}\theta_2 + x_{23}\theta_3.$$

The solution now lies in the intersection of the two previous planes, which is a straight line. However, now, we have more alternatives for a unique solution. A line, e.g.,  $\Theta_1$ , can either touch the  $\ell_1$  ball at a corner (1-sparse solution) or, as it is shown in Figure 23.9b, it can touch the  $\ell_1$  ball at one of its edges, e.g.,  $\Theta_2$ . The latter case, corresponds to a solution that lies on a 2-dimensional subspace, hence it will be a 2-sparse vector. This also complies with the findings stated in Remark 3, since in this case, we have  $N = 2, l = 3$  and the sparsity level for a unique solution can be either 1 or 2.

<sup>3</sup>Observe that in the 3-dimensional space the  $\ell_1$  ball looks like a diamond.

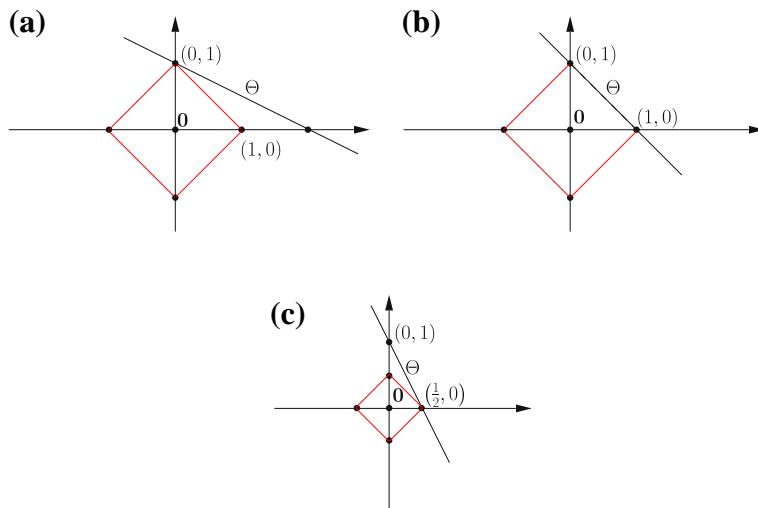

Note that uniqueness is associated with the particular geometry and orientation of the affine set, which is the set of all possible solutions of the underdetermined system of equations. For the case of the square  $\ell_2$  norm, the solution was always unique. This is a consequence of the (hyper)spherical shape formed by the Euclidean norm. From a mathematical point of view, the square  $\ell_2$  norm is a strict convex function. This is not the case for the  $\ell_1$  norm, which is convex, albeit not a strict convex function.

**Example 2.** Consider a sparse vector parameter  $[0, 1]^T$ , which we assume to be unknown. We will use one measurement to *sense* it. Based on this single measurement, we will use the  $\ell_1$  minimizer of (23.28) to recover its true value. Let us see what happens. We will consider three different values of the “sensing” (input) vector  $x$  in order to obtain the measurement  $y = x^T \theta$ : (a)  $x = [\frac{1}{2}, 1]^T$ , (b)  $x = [1, 1]^T$ , and (c)  $x = [2, 1]^T$ . The resulting measurement, after sensing  $\theta$  by  $x$ , is  $y = 1$  for all the three previous cases.

Case (a): The solution will lie on the straight line

$$\Theta = \left\{ [\theta_1, \theta_2]^T \in \mathbb{R}^2 : \frac{1}{2}\theta_1 + \theta_2 = 1 \right\},$$

which is shown in Figure 23.10a. For this setting, expanding the  $\ell_1$  ball, this will touch the line (our solutions’ affine set) at the corner  $[0, 1]^T$ . This is a unique solution, hence it is sparse, and it coincides with the true value.

**FIGURE 23.10**

(a) Sensing with  $x = [\frac{1}{2}, 1]^T$ , (b) sensing with  $x = [1, 1]^T$ , and (c) sensing with  $x = [2, 1]^T$ . The choice of the sensing vector  $x$  is crucial to unveiling the true sparse solution  $(0, 1)$ . Only the sensing vector  $x = [\frac{1}{2}, 1]^T$  identifies uniquely the desired  $(0, 1)$ .

Case (b): The solutions lies on the straight line

$$\Theta = \left\{ [\theta_1, \theta_2]^T \in \mathcal{R}^2 : \theta_1 + \theta_2 = 1 \right\},$$

which is shown in Figure 23.10b. For this set up, there is an infinite number of solutions, including two sparse ones.

Case (c): The affine set of solutions is described by

$$\Theta = \left\{ [\theta_1, \theta_2]^T \in \mathcal{R}^2 : 2\theta_1 + \theta_2 = 1 \right\},$$

which is sketched in Figure 23.10c. The solution in this case is sparse, but it is not the correct one.

This example is quite informative. *If we sense (measure) our unknown parameter vector with appropriate sensing (input) data, the use of the  $\ell_1$  norm can unveil the true value of the parameter vector, even if the system of equations is underdetermined, provided that the true parameter is sparse.* This now becomes our new goal. To investigate whether what we have just said can be generalized, and under which conditions holds true, if it does. In such a case, the choice of the regressors (which we just called them sensing vectors) and hence the input matrix (which, from now on, we will refer to, more and more frequently, as the sensing matrix) acquire an extra significance. It is not enough for the designer to care only for the rank of the matrix, i.e., the linear independence of the sensing vectors. One has to make sure that the corresponding affine set of the solutions has such an orientation, so that the touch with the  $\ell_1$  ball, as this increases from zero to meet this plane, is a “gentle” one, i.e., they meet at a single point, and more important at the correct one; that is, at the point that represents the true value of the sparse parameter, which we are searching for.

#### Remarks 4.

- Often in practice, the columns of the input matrix,  $X$ , are normalized to unit  $\ell_2$  norm. Although  $\ell_0$  norm is insensitive to the values of the nonzero components of  $\theta$ , this is not the case with the  $\ell_1$  and  $\ell_2$  norms. Hence, while trying to minimize the respective norms, and at the same time to fulfill the constraints, components that correspond to columns of  $X$  with high energy (norm) are favored more than the rest. Hence, the latter become more popular candidates to be pushed to zero. In order to avoid such situations, the columns of  $X$  are normalized to unity, by dividing each element of the column vector by the respective (Euclidean) norm.

---

## 1.23.7 Uniqueness of the $\ell_0$ minimizer

Our first goal is to derive *sufficient* conditions that guarantee uniqueness of the  $\ell_0$  minimizer, which has been defined in Section 1.23.6.

**Definition 2.** The *spark* of a full rank  $N \times l$  ( $l \geq N$ ) matrix,  $X$ , denoted as  $\text{spark}(X)$ , is the *smallest* number of its linearly dependent columns.

According to the previous definition, *any*  $m < \text{spark}(X)$  columns of  $X$  are, necessarily, *linearly independent*. The spark of a square,  $N \times N$ , full rank matrix is equal to  $N + 1$ .

**Remarks 5.**

- In contrast to the rank of a matrix, which can be easily determined, its spark can only be obtained by resorting to a combinatorial search over all possible combinations of the columns of the respective matrix, see, e.g., [8, 37]. The notion of the spark was used in the context of sparse representation, under the name of *Uniqueness Representation Property*, in [38]. The name “spark” was coined in [37]. An interesting discussion relating this matrix index with other indices, used in other disciplines, is given in [8].

**Example 3.** Consider the following matrix

$$X = \begin{bmatrix} 1 & 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 0 \end{bmatrix}.$$

The matrix has rank equal to 4 and spark equal to 3. Indeed, any pair of columns are linearly independent. On the other hand, the first, the second and the fifth columns are linearly dependent. The same is also true for the combination of the second, third and sixth columns.

**Lemma 2.** *If  $\text{null}(X)$  is the null space of  $X$ , then*

$$\|\boldsymbol{\theta}\|_0 \geq \text{spark}(X), \quad \forall \boldsymbol{\theta} \in \text{null}(X), \boldsymbol{\theta} \neq \mathbf{0}.$$

**Proof.** To derive a contradiction, assume that there exists a  $\mathbf{0} \neq \boldsymbol{\theta} \in \text{null}(X)$  such that  $\|\boldsymbol{\theta}\|_0 < \text{spark}(X)$ . Since by definition  $X\boldsymbol{\theta} = \mathbf{0}$ , there exists a number of  $\|\boldsymbol{\theta}\|_0$  columns of  $X$  that are linearly dependent. However, this contradicts the minimality of  $\text{spark}(X)$ , and the claim of Lemma 2 is established.

**Lemma 3.** *If a linear system of equations,  $X\boldsymbol{\theta} = \mathbf{y}$ , has a solution that satisfies*

$$\|\boldsymbol{\theta}\|_0 < \frac{1}{2}\text{spark}(X),$$

*then this is the sparsest possible solution. In other words, this is, necessarily, the unique solution of the  $\ell_0$  minimizer.*

**Proof.** Consider any other solution  $\mathbf{h} \neq \boldsymbol{\theta}$ . Then,  $\boldsymbol{\theta} - \mathbf{h} \in \text{null}(X)$ , i.e.,

$$X(\boldsymbol{\theta} - \mathbf{h}) = \mathbf{0}.$$

Thus, according to Lemma 2,

$$\text{spark}(X) \leq \|\boldsymbol{\theta} - \mathbf{h}\|_0 \leq \|\boldsymbol{\theta}\|_0 + \|\mathbf{h}\|_0. \tag{23.31}$$

Observe that although the  $\ell_0$  “norm” is not a true norm, it can be readily verified by simple inspection and reasoning that the triangular property is satisfied. Indeed, by adding two vectors together, the resulting

number of nonzero elements will always be at most equal to the total number of nonzero elements of the two vectors. Therefore, if  $\|\theta\|_0 < \frac{1}{2}\text{spark}(X)$ , then (23.31) suggests that

$$\|\boldsymbol{h}\|_0 > \frac{1}{2}\text{spark}(X) > \|\theta\|_0.$$

### Remarks 6.

- Lemma 3 is a very interesting result. We have a sufficient condition to check whether a solution is the unique optimal in a, generally, NP-hard problem. Of course, although this is nice from a theoretical point of view, is not of much use by itself, since the related bound (the spark) can only be obtained after a combinatorial search. Well, in the next section, we will see that we can relax the bound by involving another index, in place of the spark, which can be easily computed.
- An obvious consequence of the previous lemma is that if the unknown parameter vector is a sparse one with  $k$  nonzero elements, then if matrix  $X$  is chosen so that to have  $\text{spark}(X) > 2k$ , then the true parameter vector is necessarily the sparsest one that satisfies the set of equations, and the (unique) solution to the  $\ell_0$  minimizer.
- In practice, the goal is to sense the unknown parameter vector by a matrix that has as high a spark as possible, so that the previously stated sufficiency condition to cover a wide range of cases. For example, if the spark of the input matrix is, say, equal to three, then one can check for optimal sparse solutions up to a sparsity level of  $k = 1$ . From the respective definition, it is easily seen that the values of the spark are in the range  $1 < \text{spark}(X) \leq N + 1$ .
- Constructing an  $N \times l$  matrix  $X$  in a random manner, by generating i.i.d. entries, guarantees, with high probability, that  $\text{spark}(X) = N + 1$ ; that is, any  $N$  columns of the matrix are linearly independent.

#### 1.23.7.1 Mutual coherence

Since the spark of a matrix is a number that is difficult to compute, our interest shifts to another index, which can be derived easier and at the same time can offer a useful bound on the spark. The *mutual coherence* of an  $N \times l$  matrix  $X$  [24], denoted as  $\mu(X)$ , is defined as

$$\mu(X) := \max_{1 \leq i < j \leq l} \frac{|\mathbf{x}_i^T \mathbf{x}_j|}{\|\mathbf{x}_i\| \|\mathbf{x}_j\|}, \quad (23.32)$$

where  $\mathbf{x}_i$ ,  $i = 1, 2, \dots, l$ , denote the columns of  $X$  (notice the difference in notation between a row  $\mathbf{x}_i^T$  and a column  $\mathbf{x}_i$  of the matrix  $X$ ). This number reminds us of the correlation coefficient between two random variables. Mutual coherence is bounded as  $0 \leq \mu(X) \leq 1$ . For a square orthogonal matrix,  $X$ ,  $\mu(X) = 0$ . For general matrices, with  $l > N$ ,  $\mu(X)$  satisfies

$$\sqrt{\frac{l-N}{N(l-1)}} \leq \mu(X) \leq 1,$$

which is known as the *Welch bound* [39]. For large values of  $l$ , the lower bound becomes, approximately,  $\mu(X) \geq \frac{1}{\sqrt{N}}$ . Common sense reasoning guides us to construct input (sensing) matrices of mutual

coherence as small as possible. Indeed, the purpose of the sensing matrix is to “measure” the components of the unknown vector and “store” this information in the measurement vector  $\mathbf{y}$ . Thus, this should be done in such a way so that  $\mathbf{y}$  to retain as much information about the components of  $\boldsymbol{\theta}$  as possible. This can be achieved if the columns of the sensing matrix,  $X$ , are as “independent” as possible. Indeed,  $\mathbf{y}$  is the result of a combination of the columns of  $X$ , each one weighted by a different component of  $\boldsymbol{\theta}$ . Thus, if the columns are as much “independent” as possible then the information regarding each component of  $\boldsymbol{\theta}$  is contributed by a different direction making its recovery easier. This is easier understood if  $X$  is a square orthogonal matrix. In the more general case of a non-square matrix, the columns should be made as “orthogonal” as possible.

**Example 4.** Assume that  $X$  is an  $N \times 2N$  matrix, formed by concatenating two orthonormal bases together,

$$X = [I, W],$$

where  $I$  is the identity matrix, having as columns the vectors  $\mathbf{e}_i$ ,  $i = 1, 2, \dots, N$ , with elements equal to

$$\delta_{ir} = \begin{cases} 1, & \text{if } i = r, \\ 0, & \text{if } i \neq r, \end{cases}$$

for  $r = 1, 2, \dots, N$ . The matrix  $W$  is the orthonormal DFT matrix, defined as

$$W = \frac{1}{\sqrt{N}} \begin{bmatrix} 1 & 1 & \cdots & 1 \\ 1 & W_N & \cdots & W_N^{N-1} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & W_N^{N-1} & \cdots & W_N^{(N-1)(N-1)} \end{bmatrix},$$

where

$$W_N := \exp\left(-j\frac{2\pi}{N}\right).$$

Such an overcomplete dictionary could be used to represent signal vectors in terms of the expansion in (23.23), that comprise the sum of sinusoids with very narrow spiky-like pulses. The inner products between any two columns of  $I$  and between any two columns of  $W$  are zero, due to orthogonality. On the other hand, it is easy to see that the inner product between any column of  $I$  and any column of  $W$  has absolute value equal to  $\frac{1}{\sqrt{N}}$ . Hence, the mutual coherence of this matrix is  $\mu(X) = \frac{1}{\sqrt{N}}$ . Moreover, observe that the spark of this matrix is  $\text{spark}(X) = N + 1$ .

**Lemma 4.** For any  $N \times l$  matrix  $X$ , the following inequality holds

$$\text{spark}(X) \geq 1 + \frac{1}{\mu(X)}. \quad (23.33)$$

The proof is given in [37] and it is based on arguments that stem from matrix theory applied on the Gram matrix,  $X^T X$ , of  $X$ . A “superficial” look at the previous bound is that for very small values of  $\mu(X)$  the spark can be larger than  $N + 1$ ! Looking at the proof, it is seen that in such cases the spark of the matrix attains its maximum value  $N + 1$ .

The result complies with a common sense reasoning. The smaller the value of  $\mu(X)$  the more independent are the columns of  $X$ , hence the higher the value of its spark is expected to be. Based on this lemma, we can now state the following theorem, first given in [37]. Combining the way that Lemma 3 is proved and (23.33), we come to the following important theorem.

**Theorem 1.** *If the linear system of equations in (23.24) has a solution that satisfies the condition*

$$\|\theta\|_0 < \frac{1}{2} \left( 1 + \frac{1}{\mu(X)} \right), \quad (23.34)$$

*then this solution is the sparsest one.*

**Remarks 7.**

- The bound in (23.34) is “psychologically” important. It relates an easily computed bound to check whether the solution to a NP-hard task is the optimal one. However, it is not a particularly good bound and it restricts the range of values in which it can be applied. As we saw in Example 4, while the maximum possible value of the spark of a matrix was equal to  $N + 1$ , the minimum possible value of the mutual coherence was  $\frac{1}{\sqrt{N}}$ . Therefore, the bound based on the mutual coherence restricts the range of sparsity, i.e.,  $\|\theta\|_0$ , where one can check optimality, to around  $\frac{1}{2}\sqrt{N}$ . Moreover, as the previously stated Welch bound suggests, this  $\mathcal{O}(\frac{1}{\sqrt{N}})$  dependence of the mutual coherence seems to be a more general trend and not only the case for Example 4, see, e.g., [40]. On the other hand, as we have already stated in the Remarks 6, one can construct random matrices with spark equal to  $N + 1$ ; hence, using the bound based on the spark, one could expand the range of sparse vectors up to  $\frac{1}{2}N$ .

## 1.23.8 Equivalence of $\ell_0$ and $\ell_1$ minimizers: sufficiency conditions

We have now come to the crucial point and we will establish the conditions that guarantee the equivalence between the  $\ell_1$  and the  $\ell_0$  minimizers. Hence, under such conditions, a problem, that is in general NP-hard problem, *can be solved via a tractable convex optimization task*. Under these conditions, the zero value encouraging nature of the  $\ell_1$  norm, that has already been discussed, obtains a much higher stature; it provides the sparsest solution.

### 1.23.8.1 Condition implied by the mutual coherence number

**Theorem 2.** *Let the underdetermined system of equations*

$$y = X\theta,$$

*where  $X$  is an  $N \times l$  ( $N < l$ ) full row rank matrix. If a solution exists and satisfies the condition*

$$\|\theta\|_0 < \frac{1}{2} \left( 1 + \frac{1}{\mu(X)} \right), \quad (23.35)$$

*then this is the unique solution of both, the  $\ell_0$  as well the  $\ell_1$  minimizers.*

This is a very important theorem and it was shown independently in [37, 41]. Earlier versions of the theorem addressed the special case of a dictionary comprising two orthonormal bases, [40, 42]. A proof is also summarized in [8]. This theorem established, for a first time, what it was till then empirically known: often, the  $\ell_1$  and  $\ell_0$  minimizers result in the same solution.

### Remarks 8.

- The theory that we have presented so far is very satisfying, since it offers the theoretical framework and conditions that guarantee uniqueness of a sparse solution to an underdetermined system of equations. Now we know that, under certain conditions, the solution, which we obtain by solving the convex  $\ell_1$  minimization task, is the (unique) sparsest one. However, from a practical point of view, the theory, which is based on mutual coherence, does not say the whole story and falls short to predict what happens in practice. Experimental evidence suggests that the range of sparsity levels, for which the  $\ell_0$  and  $\ell_1$  tasks give the same solution, is much wider than the range guaranteed by the mutual coherence bound. Hence, there is a lot of theoretical happening in order to improve this bound. A detailed discussion is beyond the scope of this paper. In the sequel, we will present one of these bounds, since it is the one that currently dominates the scene. For more details and a related discussion the interested reader may consult, e.g., [43].

#### 1.23.8.2 The restricted isometry property (RIP)

**Definition 3.** For each integer  $k = 1, 2, \dots$ , define the *isometry constant*  $\delta_k$  of an  $N \times l$  matrix  $X$  as the *smallest* number such that

$$(1 - \delta_k) \|\boldsymbol{\theta}\|_2^2 \leq \|X\boldsymbol{\theta}\|_2^2 \leq (1 + \delta_k) \|\boldsymbol{\theta}\|_2^2, \quad (23.36)$$

holds true for *all*  $k$ -sparse vectors  $\boldsymbol{\theta}$ .

This definition was introduced in [44]. We loosely say that matrix  $X$  obeys the RIP of order  $k$  if  $\delta_k$  is not too close to one. When this property holds true, it implies that the Euclidean norm of  $\boldsymbol{\theta}$  is approximately *preserved*, after projecting it onto the rows of  $X$ . Obviously, if matrix  $X$  were orthonormal then  $\delta_k = 0$ . Of course, since we are dealing with non-square matrices this is not possible. However, the closer  $\delta_k$  is to zero, the closer to orthonormal *all* subsets of  $k$  columns of  $X$  are. Another view point of (23.36) is that it preserves Euclidean distances between  $k$ -sparse vectors. Let us consider two  $k$ -sparse vectors,  $\boldsymbol{\theta}_1, \boldsymbol{\theta}_2$  and apply (23.36) to their difference  $\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2$ , which, in general, is a  $2k$ -sparse vector. Then we obtain

$$(1 - \delta_{2k}) \|\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2\|_2^2 \leq \|X(\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2)\|_2^2 \leq (1 + \delta_{2k}) \|\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2\|_2^2. \quad (23.37)$$

Thus, when  $\delta_{2k}$  is small enough, the Euclidean distance is preserved after projection in the lower dimensional measurements' space. In words, if the RIP holds true, this means that searching for a sparse vector in the lower dimensional subspace formed by the measurements,  $\mathcal{R}^N$ , and not in the original  $l$ -dimensional space, one can still recover the vector since distances are preserved and the target vector is not "confused" with others. After projection onto the rows of  $X$ , the discriminatory power of the method is retained. It is interesting to point out that the RIP is also related to the condition

number of the Gramian matrix. In [44,45], it is pointed out that if  $X_r$  denotes the matrix that results by considering only  $r$  of the columns of  $X$ , then the RIP in (23.36) is equivalent with requiring the respective Gramian,  $X_r^T X_r$ ,  $r \leq k$ , to have its eigenvalues within the interval  $[1 - \delta_k, 1 + \delta_k]$ . Hence, the more well conditioned the matrix is, the better is for us to dig out the information hidden in the lower dimensional measurements space.

**Theorem 3.** *Assume that for some  $k$ ,  $\delta_{2k} < \sqrt{2} - 1$ . Then the solution to the  $\ell_1$  minimizer of (23.28), denoted as  $\boldsymbol{\theta}_*$ , satisfies the following two conditions*

$$\|\boldsymbol{\theta} - \boldsymbol{\theta}_*\|_1 \leq C_0 \|\boldsymbol{\theta} - \boldsymbol{\theta}_k\|_1, \quad (23.38)$$

and

$$\|\boldsymbol{\theta} - \boldsymbol{\theta}_*\|_2 \leq C_0 k^{-\frac{1}{2}} \|\boldsymbol{\theta} - \boldsymbol{\theta}_k\|_1, \quad (23.39)$$

for some constant  $C_0$ . In the previously stated formulas,  $\boldsymbol{\theta}$  is the true (target) vector that generates the measurements in (23.28) and  $\boldsymbol{\theta}_k$  is the vector that results from  $\boldsymbol{\theta}$  if we keep its  $k$  largest components and set the rest equal to zero, [44,46–48].

Hence, if the true vector is a sparse one, i.e.,  $\boldsymbol{\theta} = \boldsymbol{\theta}_k$ , then the  $\ell_1$  minimizer recovers the (unique) exact value. On the other hand, if the true vector is not a sparse one, then the minimizer results in a solution whose accuracy is dictated by a genie-aided procedure that knew in advance the locations of the  $k$  largest components of  $\boldsymbol{\theta}$ . This is a groundbreaking result. Moreover, it is deterministic, it is always true and not with high probability. Note that the isometry property of order  $2k$  is used, since at the heart of the method lies our desire to preserve the norm of the differences between vectors.

Let us now focus on the case where there is a  $k$ -sparse vector that generates the measurements, i.e.,  $\boldsymbol{\theta} = \boldsymbol{\theta}_k$ . Then it is shown in [46] that the condition  $\delta_{2k} < 1$  guarantees that the  $\ell_0$  minimizer has a unique  $k$ -sparse solution. In other words, in order to get the equivalence between the  $\ell_1$  and  $\ell_0$  minimizers, the range of values for  $\delta_{2k}$  has to be decreased to  $\delta_{2k} < \sqrt{2} - 1$ , according to Theorem 3. This sounds reasonable. If we relax the criterion and use  $\ell_1$  instead of  $\ell_0$ , then the sensing matrix has to be more carefully constructed. Although we are not going to provide the proofs of these theorems here, since their formulation is well beyond the scope of this chapter, it is interesting to follow what happens if  $\delta_{2k} = 1$ . This will give us a flavor of the essence behind the proofs. If  $\delta_{2k} = 1$ , the left hand side term in (23.37) becomes zero. In this case, there may exist two  $k$ -sparse vectors  $\boldsymbol{\theta}_1, \boldsymbol{\theta}_2$  such that  $X(\boldsymbol{\theta}_1 - \boldsymbol{\theta}_2) = \mathbf{0}$ , or  $X\boldsymbol{\theta}_1 = X\boldsymbol{\theta}_2$ . Thus, it is not possible to recover all  $k$ -sparse vectors, after projecting them in the measurements space, by any method.

The previous argument also establishes a connection between RIP and the spark of a matrix. Indeed, if  $\delta_{2k} < 1$ , this guarantees that any number of columns of  $X$  up to  $2k$  are linearly independent, since for any  $2k$ -sparse  $\boldsymbol{\theta}$ , (23.36) guarantees that  $\|X\boldsymbol{\theta}\|_2 > 0$ . This implies that  $\text{spark}(X) > 2k$ . A connection between RIP and the coherence is established in [49], where it is shown that if  $X$  has coherence  $\mu(X)$ , and unit norm columns, then  $X$  satisfies the RIP of order  $k$  with  $\delta_k \leq (k-1)\mu(X)$ .

### 1.23.8.2.1 Constructing matrices that obey the RIP of order $k$

It is apparent from our previous discussion that the higher the value of  $k$ , for which the RIP property of a matrix,  $X$ , holds true, the better, since a larger range of sparsity levels can be handled. Hence, a main goal towards this direction is to construct such matrices. It turns out that verifying the RIP for

a matrix of a general structure is a difficult task. This reminds us of the spark of the matrix, which is also a difficult task to compute. However, it turns out that for a certain class of random matrices, the RIP follows fairly easy. Thus, constructing such sensing matrices has dominated the scene of related research. We will present a few examples of such matrices, which are also very popular in practice, without going into details of the proofs, since this is out of our scope and the interested reader may dig this information from the related references.

Perhaps, the most well known example of a random matrix is the Gaussian one, where the entries  $X(i, j)$  of the sensing matrix are i.i.d. realizations from a Gaussian pdf  $\mathcal{N}(0, \frac{1}{N})$ . Another popular example of such matrices is constructed by sampling i.i.d. entries from a Bernoulli, or related, distributions

$$X(i, j) = \begin{cases} \frac{1}{\sqrt{N}}, & \text{with probability } \frac{1}{2}, \\ -\frac{1}{\sqrt{N}}, & \text{with probability } \frac{1}{2}, \end{cases}$$

or

$$X(i, j) = \begin{cases} +\sqrt{\frac{3}{N}}, & \text{with probability } \frac{1}{6}, \\ 0, & \text{with probability } \frac{2}{3}, \\ -\sqrt{\frac{3}{N}}, & \text{with probability } \frac{1}{6}. \end{cases}$$

Finally, one can adopt the uniform distribution and construct the columns of  $X$  by sampling uniformly at random on the unit sphere in  $\mathbb{R}^N$ . It turns out, that such matrices obey the RIP of order  $k$ , with overwhelming probability, provided that the number of measurements,  $N$ , satisfy the following inequality

$$N \geq Ck \ln(l/k), \quad (23.40)$$

where  $C$  is some constant, which depends on the isometry constant  $\delta_k$ . In words, having such a matrix at our disposal, one can recover a  $k$ -sparse vector from  $N < l$  measurements, where  $N$  is larger than the sparsity level by an amount controlled by the inequality (23.40). More on these issues can be obtained from, e.g., [45, 50].

Besides random matrices, one can construct other matrices that obey the RIP. One such example includes the partial Fourier matrices, which are formed by selecting uniformly at random  $N$  rows drawn from the  $l \times l$  DFT matrix. Although the required number of samples for the RIP to be satisfied may be larger than the bound in (23.40) (see, [51]), Fourier-based sensing matrices offer certain computational advantages, when it comes to storage ( $\mathcal{O}(N \ln l)$ ) and matrix-vector products ( $\mathcal{O}(l \ln l)$ ), [52]. In [53], the case of random Toeplitz sensing matrices, containing statistical dependencies across rows, is considered and it is shown that they can also satisfy the RIP with high probability. This is of particular importance in signal processing and communications applications, where it is very common for a system to be excited in its input via a time series, hence independence between successive input rows cannot be assumed. In [54, 55], the case of separable matrices is considered where the sensing matrix is the result of a Kronecker product of matrices, which satisfy the RIP individually. Such matrices are of interest for multidimensional signals, in order to exploit the sparsity structure along each one of the involved

dimensions. For example, such signals may occur while trying to “encode” information associated with an event whose activity spreads across the temporal, spectral, spatial, etc., domains.

In spite of their theoretical elegance, the derived bounds, that determine the number of the required measurements for certain sparsity levels, fall short of what is the experimental evidence, e.g., [43]. In practice, a rule of thumb is to use  $N$  of the order of  $3k - 5k$ , e.g., [46]. For large values of  $l$ , compared to the sparsity level, the analysis in [56] suggests that we can recover most sparse signals when  $N \approx 2k \ln(l/N)$ . In an effort to overcome the shortcomings associated with the RIP, a number of other techniques have been proposed, e.g., [43, 57–59]. Furthermore, in specific applications, the use of an empirical study may be a more appropriate path.

Note that, in principle, the minimum number of measurements that are required to recover a  $k$  sparse vector from  $N < l$  measurements is  $N \geq 2k$ . Indeed, in the spirit of the discussion after Theorem 3, the main requirement that a sensing matrix must fulfill is the following: not to map two different  $k$ -sparse vectors to the same measurement vector  $\mathbf{y}$ . Otherwise, one can never recover both vectors from their (common) measurements. If we have  $2k$  measurements and a sensing matrix that guarantees that any  $2k$  columns are linearly independent, then the previously stated requirement is readily seen that it is satisfied. However, the bounds on the number of measurements set in order the respective matrices to satisfy the RIP are higher. This is because RIP accounts also for the stability of the recovery process. We will come to this issue soon, in Section 1.23.10, where we talk about *stable* embeddings.

### 1.23.9 Robust sparse signal recovery from noisy measurements

In the previous section, our focus was on recovering a sparse solution from an underdetermined system of equations. In the formulation of the problem, we assumed that there is no noise in the obtained measurements. Having acquired some experience and insight from a simpler problem, we now turn our attention to the more realistic task, where uncertainties come into the scene. One type of uncertainty may be due to the presence of noise and our measurements’ model comes back to the standard regression form

$$\mathbf{y} = \mathbf{X}\boldsymbol{\theta} + \boldsymbol{\eta}, \quad (23.41)$$

where  $\mathbf{X}$  is our familiar non-square  $N \times l$  matrix. A sparsity-aware formulation for recovering  $\boldsymbol{\theta}$  from (23.41) can be cast as

$$\begin{aligned} \min_{\boldsymbol{\theta} \in \mathcal{R}^l} \quad & \|\boldsymbol{\theta}\|_1 \\ \text{s.t.} \quad & \|\mathbf{y} - \mathbf{X}\boldsymbol{\theta}\|_2^2 \leq \epsilon, \end{aligned} \quad (23.42)$$

which coincides with the LASSO task given in (23.15). Such a formulation implicitly assumes that the noise is bounded and the respective range of values is controlled by  $\epsilon$ . One can consider a number of different variants. For example, one possibility would be to minimize the  $\|\cdot\|_0$  norm instead of the  $\|\cdot\|_1$ , albeit loosing the computational elegance of the latter. An alternative route would be to replace the Euclidean norm in the constraints with another one.

Besides the presence of noise, one could see the previous formulation from a different perspective. The unknown parameter vector,  $\boldsymbol{\theta}$ , may not be exactly sparse, but it may consist of a few large components,

while the rest are small and close to, yet not necessarily equal to, zero. Such a model misfit can be accommodated by allowing a deviation of  $\mathbf{y}$  from  $X\boldsymbol{\theta}$ .

In this relaxed setting of a sparse solution recovery, the notions of uniqueness and equivalence, concerning the  $\ell_0$  and  $\ell_1$  solutions, no longer apply. Instead, the issue that now gains in importance is that of *stability* of the solution. To this end, we focus on the computationally attractive  $\ell_1$  task. The counterpart of Theorem 3 is now expressed as follows.

**Theorem 4.** *Assume that the sensing matrix,  $X$ , obeys the RIP with  $\delta_{2k} < \sqrt{2} - 1$ , for some  $k$ . Then the solution  $\boldsymbol{\theta}_*$  of (23.42) satisfies the following ([47, 48]),*

$$\|\boldsymbol{\theta} - \boldsymbol{\theta}_*\|_2 \leq C_0 k^{-\frac{1}{2}} \|\boldsymbol{\theta} - \boldsymbol{\theta}_k\|_1 + C_1 \sqrt{\epsilon}, \quad (23.43)$$

for some constants  $C_1, C_0$ .

This is also an elegant result. If the model is exact and  $\epsilon = 0$  we obtain (23.39). If not, the higher the uncertainty (noise) term in the model, the higher our ambiguity about the solution. Note, also, that the ambiguity about the solution depends on how far the true model is from  $\boldsymbol{\theta}_k$ . If the true model is  $k$ -sparse, the first term on the right hand side of the inequality is zero. The values of  $C_1, C_0$  depend on  $\delta_{2k}$  but they are small, e.g., close to five or six, [48].

The important conclusion, here, is that *the LASSO formulation for solving inverse problems (which in general tend to be ill-conditioned) is a stable one and the noise is not amplified excessively during the recovery process*.

## 1.23.10 Compressed sensing: the glory of randomness

The way in which this paper was deplored followed, more or less, the sequence of developments that took place during the evolution of the sparsity-aware parameter estimation field. We intentionally made an effort to follow such a path, since this is also indicative of how science evolves in most cases. The starting point had a rather strong mathematical flavor: to develop conditions for the solution of an underdetermined linear system of equations, under the sparsity constraint and in a mathematically tractable way, i.e., using convex optimization. In the end, the accumulation of a sequence of individual contributions revealed that the solution can be (uniquely) recovered if the unknown quantity is sensed via randomly chosen data samples. This development has, in turn, given birth to a new field with strong theoretical interest as well as with an enormous impact on practical applications. This new emerged area is known as *compressed sensing* or *compressive sampling* (CS). Although CS builds around the LASSO and Basis Pursuit (and variants of them, as we will soon see), it has changed our view on how to sense and process signals efficiently.

### 1.23.10.1 Compressed sensing

In compressed sensing, the goal is to directly acquire as few samples as possible that encode the minimum information, which is needed to obtain a compressed signal representation. In order to demonstrate this, let us return to the data compression example, which was discussed in Section 1.23.5. There, it was commented that the “classical” approach to compression was rather unorthodox, in the sense that first

all (i.e., a number of  $l$ ) samples of the signal are used, then they are processed to obtain  $l$  transformed values, from which only a small subset is used for coding. In the CS setting, the procedure changes to the following one.

Let  $X$  be an  $N \times l$  sensing matrix, which is applied to the (unknown) signal vector,  $s$ , in order to obtain the measurements,  $y$ , and  $\Psi$  be the dictionary matrix that describes the domain where the signal  $s$  accepts a sparse representation, i.e.,

$$\begin{aligned} s &= \Psi\theta, \\ y &= Xs. \end{aligned} \quad (23.44)$$

Assuming that at most  $k$  of the components of  $\theta$  are nonzero, this can be obtained by the following optimization task

$$\begin{aligned} \min_{\theta \in \mathcal{R}^l} \quad & \|\theta\|_1 \\ \text{s.t. } & y = X\Psi\theta, \end{aligned} \quad (23.45)$$

*provided that the combined matrix  $X\Psi$  complies with the RIP and the number of measurements,  $N$ , satisfies the associated bound given in (23.40).* Note that  $s$  needs not to be stored and can be obtained any time, once  $\theta$  is known. Moreover, as we will soon discuss, the measurements,  $y_n$ ,  $n = 1, 2, \dots, N$ , can be acquired directly from an analog signal  $s(t)$ , prior to obtaining its sample (vector) version,  $s$ ! Thus, from such a perspective, CS fuses the data acquisition and the compression steps together.

There are different ways to obtain a sensing matrix,  $X$ , that leads to a product  $X\Psi$ , which satisfies the RIP. It can be shown, that if  $\Psi$  is orthonormal and  $X$  is a random matrix, which is constructed as discussed at the end of Section 1.23.8.2, then the product  $X\Psi$  obeys the RIP, provided that (23.40) is satisfied, [48]. An alternative way to obtain a combined matrix, that respects the RIP, is to consider another orthonormal matrix  $\Phi$ , whose columns have low coherence with the columns of  $\Psi$  (coherence between two matrices is defined in (23.32), where, now, the pace of  $\mathbf{x}_i$  is taken by a column of  $\Phi$  and that of  $\mathbf{x}_j$  by a column of  $\Psi$ ). For example,  $\Phi$  could be the DFT matrix and  $\Psi = I$  or vice versa. Then choose  $N$  rows of  $\Phi$  uniformly at random to form  $X$  in (23.44). In other words, for such a case, the sensing matrix can be written as  $R\Phi$ , where  $R$  is a  $N \times l$  matrix that extracts  $N$  coordinates uniformly at random. The notion of incoherence (low coherence) between the sensing and the basis matrices is closely related to RIP. The more incoherent the two matrices are, the less the number of the required measurements for the RIP to hold, e.g., [51, 60]. Another way to view incoherence is that the rows of  $\Phi$  cannot be sparsely represented in terms of the columns of  $\Psi$ . It turns out that if the sensing matrix  $X$  is a random one, formed as it has already been described in Section 1.23.8.2.1, then RIP and the incoherence with any  $\Psi$  are satisfied with high probability.

The news get even better to say that all the previously stated philosophy can be extended to the more general type of signals, which are not, necessarily, sparse or sparsely represented in terms of the atoms of a dictionary, and they are known as *compressible*. A signal vector is said to be compressible if its expansion in terms of a basis consists of just a few large coefficients  $\theta_i$  and the rest are small. In other words, the signal vector is *approximately* sparse in some basis. Obviously, this is the most interesting case in practice, where exact sparsity is scarcely (if ever) met. Reformulating the arguments used in

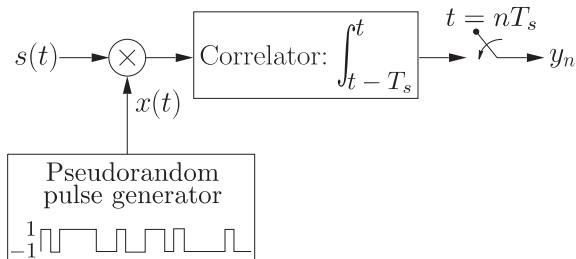

Section 1.23.9, the CS task for this case can be cast as:

$$\begin{aligned} \min_{\boldsymbol{\theta} \in \mathcal{R}^l} & \|\boldsymbol{\theta}\|_1 \\ \text{s.t. } & \|\mathbf{y} - \mathbf{X}\Psi\boldsymbol{\theta}\|_2^2 \leq \epsilon, \end{aligned} \quad (23.46)$$

and everything that has been said in Section 1.23.9 is also valid for this case, if in place of  $\mathbf{X}$  we consider the product  $\mathbf{X}\Psi$ .

### Remarks 9.

- An important property in compressed sensing is that the sensing matrix, which provides the measurements, may be chosen independently on the matrix  $\Psi$ ; that is, the basis/dictionary in which the signal is sparsely represented. In other words, the sensing matrix can be “universal” and can be used to provide the measurements for reconstructing any sparse or sparsely represented signal in any dictionary, provided RIP is not violated.
- Each measurement,  $y_n$ , is the result of an inner product (projection) of the signal vector with a row,  $\mathbf{x}_n^T$ , of the sensing matrix,  $\mathbf{X}$ . Assuming that the signal vector,  $s$ , is the result of a sampling process on an analog signal,  $s(t)$ , then  $y_n$  can be directly obtained, to a good approximation, by taking the inner product (integral) of  $s(t)$  with a sensing waveform,  $x_n(t)$ , that corresponds to  $\mathbf{x}_n$ . For example, if  $\mathbf{X}$  is formed by  $\pm 1$ , as described in Section 1.23.8.2.1, then the configuration shown in Figure 23.11 can result to  $y_n$ . An important aspect of this approach, besides avoiding to compute and store the  $l$  components of  $s$ , is that multiplying by  $\pm 1$  is a relatively easy operation. It is equivalent with changing the polarity of the signal and it can be implemented by employing inverters and mixers. It is a process that can be performed, in practice, at much higher rates than sampling (we will come to it soon). If such a scenario is adopted, one could obtain measurements of an analog signal at much lower rates than required for classical sampling, since  $N$  is much lower than  $l$ . The only condition is that the signal vector must be sparse, in the DFT dictionary, [61]. The dictionary is required only during the reconstruction of  $s$ . Thus, in the CS rationale, processing complexity is removed from the “front end” and is transferred to the “back end,” by exploiting  $\ell_1$  optimization.

**FIGURE 23.11**

Sampling an analog signal  $s(t)$  in order to generate the measurement  $y_n$  at the time instant  $n$ . The sampling period  $T_s$  is much lower than that required by the Nyquist sampling.

One of the very first applications that were inspired by the previous approach, is the so-called *one pixel camera* [62]. This was one among the most catalytic examples, that spread the rumor about the practical power of CS. CS is an example of what is commonly said: “There is nothing more practical than a good theory”!

### 1.23.10.2 Dimensionality reduction and stable embeddings

We are now going to shed light to what we have said so far in this paper from a different view. In both cases, either when the unknown quantity was a  $k$ -sparse vector in a high dimensional space,  $\mathcal{R}^l$ , or if the signal  $s$  was (approximately) sparsely represented in some dictionary ( $s = \Psi\theta$ ), we chose to work in a lower dimensional space ( $\mathcal{R}^N$ ); that is, the space of the measurements,  $y$ . This is a typical task of dimensionality reduction. The main task in any (linear) dimensionality reduction technique is to choose the proper matrix  $X$ , that dictates the projection to the lower dimensional space. In general, there is always a loss of information by projecting from  $\mathcal{R}^l$  to  $\mathcal{R}^N$ , with  $N < l$ , in the sense that we cannot recover any vector,  $\theta_l \in \mathcal{R}^l$ , from its projection  $\theta_N \in \mathcal{R}^N$ . Indeed, take any vector  $\theta_{l-N} \in \text{null}(X)$ , that lies in the  $(l-N)$ -dimensional null space of the (full rank)  $X$  (see Section 1.23.6). Then, all vectors  $\theta_l + \theta_{l-N} \in \mathcal{R}^l$  share the same projection in  $\mathcal{R}^N$ . However, what we have discovered in our tour in this chapter is that if the original vector is sparse then we can recover it exactly. This is because all the  $k$ -sparse vectors do not lie anywhere in  $\mathcal{R}^l$ , but rather in a subset of it; that is, in a *union of subspaces*, each one having dimensionality  $k$ . If the signal  $s$  is sparse in some dictionary  $\Psi$ , then one has to search for it in the union of all possible  $k$ -dimensional subspaces of  $\mathcal{R}^l$ , which are spanned by  $k$  column vectors from  $\Psi$ , [63, 64]. Of course, even in this case, where sparse vectors are involved, not any projection can guarantee unique recovery. The guarantee is provided if the projection in the lower dimensional space is a *stable embedding*. A stable embedding in a lower dimensional space must guarantee that if  $\theta_1 \neq \theta_2$ , then their projections remain also different. Yet this is not enough. A stable embedding must guarantee that distances are (approximately) preserved; that is, vectors that lie far apart in the high dimensional space, have projections that also lie far apart. Such a property guarantees robustness to noise. Well, the sufficient conditions, which have been derived and discussed throughout this paper, and guarantee the recovery of a sparse vector lying in  $\mathcal{R}^l$  from its projections in  $\mathcal{R}^N$ , are conditions that guarantee stable embeddings. The RIP and the associated bound on  $N$  provides a condition on  $X$  that leads to stable embeddings. We commented on this norm-preserving property of RIP in the related section. The interesting fact that came out from the theory is that we can achieve such stable embeddings via random projection matrices.

Random projections for dimensionality reduction are not new and have extensively been used in pattern recognition, clustering and data mining, see, e.g., [1, 65–67]. More recently, the spirit underlying compressed sensing has been exploited in the context of pattern recognition, too. In this application, one needs not to return to the original high dimensional space, after the information-digging activity in the low dimensional measurements subspace. Since the focus in pattern recognition is to identify the class of an object/pattern, this can be performed in the measurements subspace, provided that there is no class-related information loss. In [68], it is shown, using compressed sensing arguments, that if the data is approximately linearly separable in the original high dimensional space and the data has a sparse representation, even in an unknown basis, then projecting randomly in the measurements subspace retains the structure of linear separability.

*Manifold learning* is another area where random projections have been recently applied. A manifold is, in general, a nonlinear  $k$ -dimensional surface, embedded in a higher dimensional (ambient) space. For example, the surface of a sphere is a two-dimensional manifold in a three-dimensional space. More on linear and nonlinear techniques for manifold learning can be found in, e.g., [1]. In [69, 70], the compressed sensing rationale is extended to signal vectors that live along a  $k$ -dimensional submanifold of the space  $\mathcal{R}^l$ . It is shown that choosing a matrix,  $X$ , to project and a sufficient number,  $N$ , of measurements, then the corresponding submanifold has a stable embedding in the measurements subspace, under the projection matrix,  $X$ ; that is, pairwise Euclidean and geodesic distances are approximately preserved after the projection mapping. More on these issues can be found in the given references and in, e.g., [63].

### 1.23.10.3 Sub-Nyquist sampling: analog-to-information conversion

In our discussion in the Remarks presented before, we touched a very important issue; that of going from the analog domain to the discrete one. The topic of analog-to-digital (A/D) conversion has been at the forefront of research and technology since the seminal works of Shannon, Nyquist, Whittaker and Kotelnikof were published, see, for example, [71] for a thorough related review. We all know that if the highest frequency of an analog signal,  $s(t)$ , is less than  $F/2$ , then Shannon's theorem suggests that no loss of information is achieved if the signal is sampled, at least, at the Nyquist rate of  $F = 1/T$ , where  $T$  is the corresponding sampling period, and the signal can be perfectly recovered by its samples

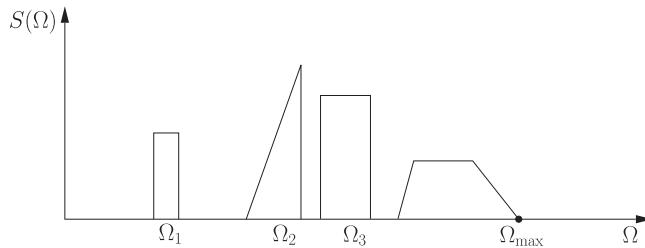

$$s(t) = \sum_n s(nT) \text{sinc}(Ft - n),$$

where  $\text{sinc}(\cdot)$  is the sampling function

$$\text{sinc}(t) = \frac{\sin(\pi t)}{\pi t}.$$

While this has been the driving force behind the development of signal acquisition devices, the increasing complexity of emerging applications demands increasingly higher sampling rates, that cannot be accommodated by today's hardware technology. This is the case, for example, in wideband communications, where conversion speeds, as dictated by Shannon's bound, have become more and more difficult to obtain. Consequently, alternatives to high rate sampling are attracting a strong interest with the goal to reduce the sampling rate by exploiting the *underlying structure* of the signals at hand. In many applications, the signal comprises a few frequencies or bands, see Figure 23.12 for an illustration. In such cases, sampling at the Nyquist rate is inefficient. This is an old problem and it has been addressed by a number of authors, in the case where the locations of the nonzero bands in the frequency spectrum are known, see, e.g., [72–74]. CS theory has inspired research to study cases where the locations (carrier frequencies) of the bands are not known a priori. A typical application of this kind, of high practical interest, lies within the field of Cognitive radio, e.g., [75–77]. In contrast to what we have studied so far in this paper, the sparsity now characterizes the analog signal, and this poses a number of challenges that need to be addressed. In other words, one can consider that

$$s(t) = \sum_{i \in \mathcal{I}} \theta_i \psi_i(t),$$

**FIGURE 23.12**

The Fourier transform of an analog signal,  $s(t)$ , which is sparse in the frequency domain; only a limited number of frequency bands contribute to its spectrum content  $S(\Omega)$ , where  $\Omega$  stands for the angular frequency. Nyquist's theory guarantees that sampling at a frequency larger than or equal to twice the maximum  $\Omega_{\max}$  is sufficient to recover the original analog signal. However, this theory does not exploit information related to the sparse structure of the signal in the frequency domain.

where  $\psi_i(t)$ ,  $i \in \mathcal{I}$ , are the functions that comprise the dictionary, and only a small subset of the coefficients  $\theta_i$  are nonzero. Note that although each one of the dictionary functions can be of high bandwidth, the true number of degrees of freedom of the signal is low. Hence, one would like to sample the signal not at the Nyquist rate but at a rate determined by the sparsity level of the coefficients' set. We refer to such a scenario as *Analog-to-Information* sampling or *sub-Nyquist* sampling.

An approach inspired directly by the theory of CS was first presented in [78] and later improved and theoretically developed in [61]. The approach builds around the assumption that the signal consists of a sum of sinusoids and the *random demodulator* of Figure 23.11 is adopted. In [75, 79], the more general case of a signal consisting of a number of frequency bands, instead of tones, was treated. In addition, the task of extracting each band of the signal from the compressed measurements, that enables (low rate) baseband processing, is addressed. In principle, CS related theory would enable far fewer data samples than traditionally required when capturing signals with relatively high bandwidth, but with a low information rate. However, from a practical point of view, there are still a number of hardware implementation related issues, such as sampling jitter, to be solved first, e.g., [80, 81].

An alternative path to sub-Nyquist sampling embraces a different class of analog signals known as *multipulse* signals; that is, signals that consist of a stream of short pulses. Sparsity now refers to the time domain, and such signals may not even be bandlimited. Signals of this type can be met in a number of applications, such as in radar, ultrasound, bioimaging and neuronal signal processing, see, e.g., [82]. An approach, known as *finite rate of innovation sampling*, passes an analog signal, having  $k$  degrees of freedom per second, through a linear time invariant filter and then samples at a rate of  $2k$  samples per second. Reconstruction is performed via rooting a high-order polynomial, see, e.g., [83, 84] and the references therein. In [85], the task of sub-Nyquist sampling is treated using CS theory arguments and an expansion in terms of Gabor functions; the signal is assumed to consist of a sum of a few pulses of finite duration, yet of unknown shape and time positions.

The task of sparsity-aware learning in the analog domain is still in its early stages and there is currently a lot of on-going activity; more on this topic can be obtained in [86, 87] and the references there in.

### 1.23.11 Sparsity-promoting algorithms

In the previous sections, our emphasis was to highlight the most important aspects underlying the theory of sparse signal/vector recovery from an underdetermined set of linear equations. We now turn our attention to the algorithmic aspects of the problem [30]. The issue now becomes that of discussing *efficient* algorithmic schemes, which can achieve the recovery of the unknown set of parameters. In Sections 1.23.4 and 1.23.6, we saw that the constrained  $\ell_1$  norm minimization (Basis Pursuit) can be solved via Linear Programming techniques and the LASSO task via convex optimization schemes. However, such general purpose techniques tend to be inefficient, since, often, they require many iterations to converge and the respective computational resources can be excessive for practical applications, especially in high dimensional spaces,  $\mathcal{R}^l$ . As a consequence, a huge research effort has been invested with the goal to develop efficient algorithms, that are tailored-made to these specific tasks. This is still a hot on-going area of research and definite conclusions are still risky to be drawn. Our aim here is to provide the reader with some general trends and philosophies that characterize the related activity. We will focus on the most commonly used and cited algorithms, which at the same time are structurally simple and the reader can follow them, without requiring a deeper knowledge on optimization. Moreover, these algorithms involve, in one way or another, arguments that are directly related to points and notions that we have already used while presenting the theory; thus, they can also be exploited from a pedagogical point of view, in order to strengthen the reader's understanding of the topic. We start our review with the class of batch algorithms, where all data are assumed to be available prior to the application of the algorithm, and then we will move onto online/time-adaptive schemes. Furthermore, our emphasis is on algorithms that are appropriate for any sensing matrix. This is stated in order to point out that in the literature efficient algorithms have also been developed for specific forms of highly structured sensing matrices; exploiting their particular structure can lead to reduced computational demands, [88, 89].

There are currently three rough types of families along which this algorithmic activity is growing: (a) greedy algorithms, (b) iterative shrinkage schemes, and (c) convex optimization techniques. We have used the word rough, since, in some cases, it may be difficult to assign an algorithm to a specific family.

#### 1.23.11.1 Greedy algorithms

Greedy algorithms have a long history, see, for example, [90] for a comprehensive list of references. In the context of dictionary learning, a greedy algorithm known as *Matching Pursuit* was introduced in [24]. A greedy algorithm is built upon a series of *locally* optimal *single-term* updates. In our context, the goals are: (a) to unveil the “active” columns of the sensing matrix  $X$ ; that is, those columns that correspond to the nonzero locations of the unknown parameters and (b) to estimate the respective sparse parameter vector. The set of indices which correspond to the nonzero vector components is also known as the *support*. To this end, the set of active columns of  $X$  (and the support) is increased by one at each iteration step. In the sequel, an updated estimate of the unknown sparse vector is obtained. Let us assume that, at the  $(i - 1)$ th iteration step, the algorithm has selected the columns denoted as  $\mathbf{x}_{j_1}, \mathbf{x}_{j_2}, \dots, \mathbf{x}_{j_{i-1}}$ , with  $j_1, j_2, \dots, j_{i-1} \in \{1, 2, \dots, l\}$ . These indices are the elements of the currently available support,  $S^{(i-1)}$ . Let  $X^{(i-1)}$  be the  $N \times (i - 1)$  matrix having  $\mathbf{x}_{j_1}, \mathbf{x}_{j_2}, \dots, \mathbf{x}_{j_{i-1}}$  as its columns. Let, also, the current estimate of the solution be  $\boldsymbol{\theta}^{(i-1)}$ , which is a  $(i - 1)$ -sparse vector, with zeros at all locations with index outside the support.

**Algorithm 1 (Orthogonal Matching Pursuit (OMP)).**

The algorithm is initialized with  $\boldsymbol{\theta}^{(0)} := \mathbf{0}$ ,  $\mathbf{e}^{(0)} := \mathbf{y}$  and  $S^{(0)} := \emptyset$ . At iteration step  $i$ , the following computational steps are performed:

1. Select the column  $\mathbf{x}_{j_i}$  of  $X$ , which is *maximally* correlated to (forms the least angle with) the respective error vector,  $\mathbf{e}^{(i-1)} := \mathbf{y} - X\boldsymbol{\theta}^{(i-1)}$ , i.e.,

$$\mathbf{x}_{j_i} : j_i := \arg \max_{j=1,2,\dots,l} \frac{|\mathbf{x}_j^T \mathbf{e}^{(i-1)}|}{\|\mathbf{x}_j\|_2}.$$

2. Update the support and the corresponding set of active columns:  $S^{(i)} = S^{(i-1)} \cup \{j_i\}$ , and  $X^{(i)} = [X^{(i-1)}, \mathbf{x}_{j_i}]$ .
3. Update the estimate of the parameter vector: Solve the Least-Squares (LS) problem that minimizes the norm of the error, using the active columns of  $X$  only, i.e.,

$$\tilde{\boldsymbol{\theta}} := \arg \min_{\mathbf{z} \in \mathcal{R}^i} \left\| \mathbf{y} - X^{(i)} \mathbf{z} \right\|_2^2.$$

Obtain  $\boldsymbol{\theta}^{(i)}$  by inserting the elements of  $\tilde{\boldsymbol{\theta}}$  in the respective locations ( $j_1, j_2, \dots, j_i$ ), which comprise the support (the rest of the elements of  $\boldsymbol{\theta}^{(i)}$  retain their zero values).

4. Update the error vector

$$\mathbf{e}^{(i)} := \mathbf{y} - X\boldsymbol{\theta}^{(i)}.$$

The algorithm terminates if the norm of the error becomes less than a preselected user-defined constant,  $\epsilon_0$ . The following observations are in order.

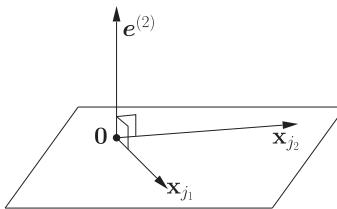

**Remarks 10.**

- Since  $\boldsymbol{\theta}^{(i)}$ , in Step 3, is the result of a LS task, it is known that the error vector is orthogonal to the subspace spanned by the active columns involved, i.e.,

$$\mathbf{e}^{(i)} \perp \text{span} \{ \mathbf{x}_{j_1}, \dots, \mathbf{x}_{j_i} \}.$$

This guarantees that taking the correlation, in the next step, of the columns of  $X$  with  $\mathbf{e}^{(i)}$  none of the previously selected columns will be reselected; they result to zero correlation, being orthogonal to  $\mathbf{e}^{(i)}$ , see Figure 23.13.

- It can be shown that the column, which has maximal correlation (maximum absolute value of the inner product) with the currently available error vector, is the one that maximally reduces (compared to any other column) the  $\ell_2$  norm of the error, when  $\mathbf{y}$  is approximated by linearly combining the currently available active columns. This is the point where the heart of the greedy strategy beats. This minimization is with respect to a *single term*, keeping the rest fixed, as they have been obtained from the previous iteration steps [8].
- Starting with all the components being zero, if the algorithm stops after  $k_0$  iteration steps, the result will be a  $k_0$ -sparse solution.

**FIGURE 23.13**

The error vector at the  $i$ th iteration is orthogonal to the subspace spanned by the currently available set of active columns. Here is an illustration for the case of the 3-dimensional Euclidean space  $\mathcal{R}^3$ , and for  $i = 2$ .

- Note that there is no optimality in this searching strategy. The only guarantee is that the  $\ell_2$  norm of the error vector is decreased at every iteration step. In general, there is no guarantee that the algorithm can obtain a solution close to the true one, see, e.g., [91]. However, under certain constraints on the structure of  $X$ , performance bounds can be obtained, see, e.g., [92–94].
- The complexity of the algorithm amounts to  $\mathcal{O}(k_0 l N)$  operations, which are contributed by the computations of the correlations, plus the demands raised by the solution of the LS task, in Step 3, whose complexity depends on the specific algorithm used. The  $k_0$  is the sparsity level of the delivered solution and, hence, the total number of iteration steps that are performed.

Another more qualitative argument, that justifies the selection of the columns based on their correlation with the error vector, is the following. Assume that the matrix  $X$  is orthonormal. Let also  $\mathbf{y} = X\boldsymbol{\theta}$ . Then,  $\mathbf{y}$  lies in the subspace spanned by the active columns of  $X$ , i.e., those which correspond to the nonzero components of  $\boldsymbol{\theta}$ . Hence, the rest of the columns are orthogonal to  $\mathbf{y}$ , since  $X$  is assumed to be orthonormal. Taking the correlation of  $\mathbf{y}$ , at the first iteration step, with all the columns, it is certain that one among the active columns will be chosen. The inactive columns result in zero correlation. A similar argument holds true for all subsequent steps, since all the activity takes place in a subspace that is orthogonal to all the inactive columns of  $X$ . In the more general case, where  $X$  is not orthonormal, we can still use the correlation as a measure that quantifies geometric similarity. The smaller the correlation/the magnitude of the inner product is, the more orthogonal two vectors are. This brings us back to the notion of mutual coherence, which is a measure of the maximum correlation (least angle) among the columns of  $X$ .

#### 1.23.11.1.1 OMP can recover optimal sparse solutions: sufficiency condition

We have already stated that, in general, there are no guarantees that OMP will recover optimal solutions. However, when the unknown vector is sufficiently sparse, with respect to the structure of the sensing matrix  $X$ , then OMP can exactly solve the  $\ell_0$  minimization task in (23.27) and recover the solution in  $k_0$  steps, where  $k_0$  is the sparsest solution that satisfies the associated linear set of equations.

**Theorem 5.** *Let the mutual coherence (Section 1.23.7.1) of the sensing matrix,  $X$ , be  $\mu(X)$ . Assume, also, that the linear system,  $\mathbf{y} = X\boldsymbol{\theta}$ , accepts a solution such as*

$$\|\boldsymbol{\theta}\|_0 < \frac{1}{2} \left( 1 + \frac{1}{\mu(X)} \right). \quad (23.47)$$

Then, OMP guarantees to recover the sparsest solution in  $k_0 = \|\theta\|_0$  steps.

We know from Section 1.23.7.1 that, under the previous condition, any other solution will be necessarily less sparse. Hence, there is a unique way to represent  $y$  in terms of  $k_0$  columns of  $X$ . Without harming generality, let us assume that the true support corresponds to the first  $k_0$  columns of  $X$ , i.e.,

$$y = \sum_{j=1}^{k_0} \theta_j \mathbf{x}_j, \quad \theta_j \neq 0, \quad \forall j \in \{1, \dots, k_0\}.$$

The theorem is a direct consequence of the following proposition:

**Proposition 1.** *If the condition (23.47) holds true, then the OMP algorithm will never select a column with index outside the true support, see, e.g., [93]. In a more formal way, this is expressed as*

$$j_i = \arg \max_{j=1,2,\dots,l} \frac{|\mathbf{x}_j^T \boldsymbol{\epsilon}^{(i-1)}|}{\|\mathbf{x}_j\|_2} \in \{1, \dots, k_0\}.$$

A geometric interpretation of this proposition is the following: if the angles formed between all the possible pairs among the columns of  $X$  are large enough in the  $\mathcal{R}^l$  space, which guarantees that  $\mu(X)$  is small enough, then  $y$  will lean more (form smaller angle) towards any one of the active columns, which contribute to its formation, compared to the rest, which are inactive and do not participate in the linear combination that generates  $y$ . Figure 23.14 illustrates the geometry, for the extreme case of mutually orthogonal vectors (Figure 23.14a) and for the more general case, where the vectors are not orthogonal, yet the angle between any pair of columns is large enough (Figure 23.14b).

In a nutshell, the previous proposition guarantees that, during the first iteration, a column corresponding to the true support will be selected. In a similar way, this is also true for all subsequent iterations. In the second step, another, different from the previously selected column (as it has already been stated), will be chosen. At step  $k_0$ , the last remaining active column, corresponding to the true support, is selected and this necessarily results to zero error. To this end, it suffices to set  $\epsilon_0$  equal to zero.

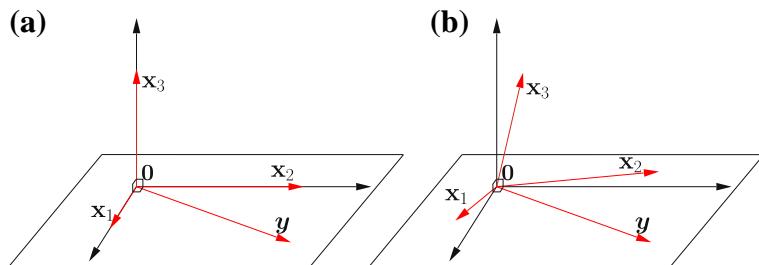

FIGURE 23.14

- (a) In the case of an orthogonal matrix, the measurement vector  $y$  will be orthogonal to any inactive column; here,  $x_3$ .
- (b) In the more general case, it is expected to “lean” closer (form smaller angles) to the active than to the inactive columns.

### 1.23.11.1.2 The LARS algorithm

The Least Angle Regression (LARS) algorithm, [95], shares the first two steps with OMP. It selects  $j_i$  to be an index outside the currently available active set so that to maximize the correlation with the residual vector. However, instead of performing an LS fit to compute the nonzero components of  $\theta^{(i)}$ , these are computed so that the residual to be equicorrelated with all the columns in the active set, i.e.,

$$|\mathbf{x}_j^T(\mathbf{y} - X\theta^{(i)})| = \text{constant}, \quad \forall j \in S^{(i)},$$

where we have assumed that the columns of  $X$  are normalized, as it is common in practice (recall, also, the Remarks 4). In other words, in contrast to the OMP, where the error vector is forced to be orthogonal to the active columns, LARS demands this error to form equal angles with each one of them. Likewise OMP, it can be shown that, provided the target vector is sufficiently sparse and under incoherence of the columns of  $X$ , LARS can exactly recover the sparsest solution, [96].

A further small modification leads to the so-called LARS-LASSO algorithm. According to this version, a previously selected index in the active set can be removed at a later stage. This gives the algorithm the potential to “recover” from a previously bad decision. Hence, this modification departs from the strict rationale that defines the greedy algorithms. It turns out that this version solves the LASSO optimization task. This algorithm is the same as the one suggested in [97] and it is known as *homotopy* algorithm. Homotopy methods are based on a continuous transformation from one optimization task to another. The solutions to this sequence of tasks lie along a continuous parameterized path. The idea is that, while the optimization tasks may be difficult to solve by themselves, one can trace this path of solutions by slowly varying the parameters. For the LASSO task, it is the  $\lambda$  parameter which is varying, see, e.g., [98–100]. Take as an example the LASSO task in its regularized version in (23.13). For  $\lambda = 0$ , the task minimizes the  $\ell_2$  norm and for  $\lambda \rightarrow \infty$  the task minimizes the  $\ell_1$  norm, and for this case the solution tends to zero. It turns out that the solution path, as  $\lambda$  changes from large to small values, is polygonal. Vertices on this solution path correspond to vectors having nonzero elements only on a subset of entries. This subset remains unchanged, till  $\lambda$  reaches the next critical value, which corresponds to a new vertex of the polygonal path and to a new subset of potential nonzero values. Thus, the solution is obtained via this sequence of steps along this polygonal path.

### 1.23.11.1.3 Compressed Sensing Matching Pursuit (CSMP) algorithms

Strictly speaking, these algorithms are not greedy, yet, as it is stated in [89], they are at heart greedy algorithms. Instead of performing a single term optimization per iteration step, in order to increase the support by one, as it is the case with OMP, these algorithms attempt to obtain first an estimate of the support and then use this information to compute a least squares estimate of the target vector, constrained on the respective active columns. The quintessence of the method lies in the near-orthogonal nature of the sensing matrix, assuming that this obeys the RIP.

Assume that  $X$  obeys the RIP for some small enough value  $\delta_k$  and sparsity level,  $k$ , of the unknown vector. Let, also, that the measurements are exact, i.e.,  $\mathbf{y} = X\theta$ . Then,  $X^T\mathbf{y} = X^T X\theta \approx \theta$ . Therefore, intuition indicates that it is not unreasonable to select, in the first iteration step, the  $t$  (a user-defined parameter) largest in magnitude components of  $X^T\mathbf{y}$  as indicative of the nonzero positions of the sparse target vector. This reasoning carries on for all subsequent steps, where, at the  $i$ th iteration, the place of  $\mathbf{y}$  is taken by the residual  $e^{(i-1)} := \mathbf{y} - X\theta^{(i-1)}$ , where  $\theta^{(i-1)}$  indicates the estimate of the target vector

at the  $(i - 1)$ th iteration. Basically, this could be considered as a generalization of the OMP. However, as we will soon see, the difference between the two mechanisms is more substantial.

**Algorithm 2 (The CSMP Scheme).**

1. Select the value of  $t$ .
2. Initialize the algorithm:  $\boldsymbol{\theta}^{(0)} = \mathbf{0}$ ,  $\mathbf{e}^{(0)} = \mathbf{y}$ .
3. For  $i = 1, 2, \dots$ , execute the following.

- a. Obtain the current support:

$$S^{(i)} := \text{supp}(\boldsymbol{\theta}^{(i-1)}) \cup \left\{ \begin{array}{l} \text{indices of the } t \text{ largest in magnitude} \\ \text{components of } X^T \mathbf{e}^{(i-1)} \end{array} \right\}.$$

- b. Select the active columns: Construct  $X^{(i)}$  to comprise the active columns of  $X$  in accordance to  $S^{(i)}$ . Obviously,  $X^{(i)}$  is a  $N \times r$  matrix, where  $r$  denotes the cardinality of the support set  $S^{(i)}$ .
- c. Update the estimate of the parameter vector: solve the LS task

$$\tilde{\boldsymbol{\theta}} := \arg \max_{\mathbf{z} \in \mathcal{R}^r} \left\| \mathbf{y} - X^{(i)} \mathbf{z} \right\|_2^2.$$

Obtain  $\hat{\boldsymbol{\theta}}^{(i)} \in \mathcal{R}^l$  having the  $r$  elements of  $\tilde{\boldsymbol{\theta}}$  in the respective locations, as indicated by the support, and the rest of the elements being zero.

- d.  $\boldsymbol{\theta}^{(i)} := H_k(\hat{\boldsymbol{\theta}}^{(i)})$ . The mapping  $H_k$  denotes the *hard thresholding* operator; that is, it returns a vector with the  $k$  largest in magnitude components of the argument, and the rest are forced to zero.
- e. Update the error vector:  $\mathbf{e}^{(i)} = \mathbf{y} - X \boldsymbol{\theta}^{(i)}$ .

The algorithm requires as input the sparsity level  $k$ . Iterations carry on until a halting criterion is met. The value of  $t$ , that determines the largest in magnitude values in Steps 1 and 3a, depends on the specific algorithm. In CoSaMP (Compressive Sampling Matching Pursuit, [89]),  $t = 2k$  and in the SP (Subspace Pursuit, [101]),  $t = k$ .

Having stated the general scheme, a major difference with OMP becomes readily apparent. In OMP, only one column is selected per iteration step. Moreover, this remains in the active set for all subsequent steps. If, for some reason, this was not a good choice, the scheme cannot recover from such a bad decision. In contrast, the support and hence the active columns of  $X$  are continuously updated in CSMP and the algorithm has the ability to correct a previously bad decision, as more information is accumulated and iterations progress. In [101], it is shown that if the measurements are exact ( $\mathbf{y} = X \boldsymbol{\theta}$ ) then SP can recover the  $k$ -sparse true vector in a finite number of iteration steps, provided that  $X$  satisfies the RIP with  $\delta_{3k} < 0.205$ . If the measurements are noisy, performance bounds have been derived, which hold true for  $\delta_{3k} < 0.083$ . For the CoSaMP, performance bounds have been derived for  $\delta_{4k} < 0.1$ .

### 1.23.11.2 Iterative shrinkage algorithms (ISTA)

This family of algorithms have also a long history, see, e.g., [102–105]. However, in the “early” days, the developed algorithms had some sense of heuristic flavor, without establishing a clear bridge with

optimizing a cost function. Later attempts were substantiated by sound theoretical arguments concerning issues such as convergence and convergence rate, e.g., [106–109].

The general form of this algorithmic family has a striking resemblance with the classical linear algebra iterative schemes for approximating the solution of large linear systems of equations, known as *stationary iterative* or *iterative relaxation* methods. The classical Gauss-Seidel and Jacobi algorithms, e.g., [110], in numerical analysis can be considered as members of this family. Given a linear system of  $l$  equations with  $l$  unknowns,  $\mathbf{z} = A\mathbf{x}$ , the basic iteration at step  $i$  has the following form

$$\begin{aligned}\mathbf{x}^{(i)} &= (I - QA)\mathbf{x}^{(i-1)} + Q\mathbf{z} \\ &= \mathbf{x}^{(i-1)} + Q\mathbf{e}^{(i-1)}, \quad \mathbf{e}^{(i-1)} := \mathbf{z} - A\mathbf{x}^{(i-1)},\end{aligned}$$

which does not come as a surprise. It is of the same form as most of the iterative schemes for numerical solutions! The matrix  $Q$  is chosen so that to guarantee convergence and different choices lead to different algorithms with their pros and cons. It turns out that this algorithmic form can also be applied to underdetermined systems of equations,  $\mathbf{y} = X\boldsymbol{\theta}$ , with a “minor” modification, which is imposed by the sparsity constraint of the target vector. This leads to the following general form of iterative computation

$$\boldsymbol{\theta}^{(i)} = T_i(\boldsymbol{\theta}^{(i-1)} + Q\mathbf{e}^{(i-1)}), \quad \mathbf{e}^{(i-1)} = \mathbf{y} - X\boldsymbol{\theta}^{(i-1)},$$

starting from an initial guess of  $\boldsymbol{\theta}^{(0)}$  (usually  $\boldsymbol{\theta}^{(0)} = \mathbf{0}, \mathbf{e}^{(0)} = \mathbf{y}$ ). In certain cases,  $Q$  can be made to be iteration-dependent. The operator  $T_i(\cdot)$  is a nonlinear thresholding operator, that is applied *entry-wise*, i.e., *component-wise*. Depending on the specific scheme, this can be either the hard thresholding operator, denoted as  $H_k$ , or the soft thresholding operator, denoted as  $S_\alpha$ . Hard thresholding, as we already know, keeps the  $k$  largest components of a vector unaltered and sets the rest equal to zero. Soft thresholding was introduced in Section 1.23.4. All components with magnitude less than  $\alpha$  are forced to zero and the rest are reduced in magnitude by  $\alpha$ ; that is, the  $j$ th component of a vector,  $\boldsymbol{\theta}$ , after soft thresholding becomes

$$(S_\alpha(\boldsymbol{\theta}))_j = \text{sgn}(\theta_j)(|\theta_j| - \alpha)_+.$$

Depending on (a) the choice of  $T_i$ , (b) the specific value of the parameter  $k$  or  $\alpha$ , and (c) the matrix  $Q$ , different instances occur. A most common choice for  $Q$  is  $\mu X^T$  and the generic form of the main iteration becomes

$$\boldsymbol{\theta}^{(i)} = T_i(\boldsymbol{\theta}^{(i-1)} + \mu X^T \mathbf{e}^{(i-1)}), \tag{23.48}$$

where  $\mu$  is a relaxation (user-defined) parameter, which can also be left to vary with each iteration step. The choice of  $X^T$  is intuitively justified, once more, by the near-orthogonal nature of  $X$ . For the first iteration step and for a linear system of the form  $\mathbf{y} = X\boldsymbol{\theta}$ , starting from a zero initial guess, we have  $X^T\mathbf{y} = X^T X\boldsymbol{\theta} \approx \boldsymbol{\theta}$  and we are close to the solution.

Although intuition is most important in scientific research, it is not enough, by itself, to justify decisions and actions. The generic scheme in (23.48) has been reached from different paths, following different perspectives that lead to different choices of the respective parameters. Let us spend some more time on that, with the aim to make the reader more familiar with techniques that address optimization

tasks of non-differentiable loss functions. The term in the parenthesis in (23.48) coincides with the gradient descent iteration step if the cost function were the unregularized LS loss, i.e.,

$$J(\boldsymbol{\theta}) = \frac{1}{2} \|\mathbf{y} - X\boldsymbol{\theta}\|_2^2.$$

In this case, the gradient descent rationale leads to

$$\begin{aligned} \boldsymbol{\theta}^{(i-1)} - \mu \frac{\partial J(\boldsymbol{\theta}^{(i-1)})}{\partial \boldsymbol{\theta}} &= \boldsymbol{\theta}^{(i-1)} - \mu X^T (X\boldsymbol{\theta}^{(i-1)} - \mathbf{y}) \\ &= \boldsymbol{\theta}^{(i-1)} + \mu X^T \mathbf{e}^{(i-1)}. \end{aligned}$$

It is well known and it can easily be shown that the gradient descent can alternatively be viewed as the result of minimizing a regularized version of the linearized loss function, i.e.,

$$\begin{aligned} \boldsymbol{\theta}^{(i)} = \arg \min_{\boldsymbol{\theta} \in \mathcal{R}^l} \left\{ J(\boldsymbol{\theta}^{(i-1)}) + (\boldsymbol{\theta} - \boldsymbol{\theta}^{(i-1)})^T \frac{\partial J(\boldsymbol{\theta}^{(i-1)})}{\partial \boldsymbol{\theta}} \right. \\ \left. + \frac{1}{2\mu} \|\boldsymbol{\theta} - \boldsymbol{\theta}^{(i-1)}\|_2^2 \right\}. \end{aligned} \quad (23.49)$$

One can adopt this view of the gradient descent philosophy as a kick-off point to minimize iteratively the following LASSO task, i.e.,

$$\min_{\boldsymbol{\theta} \in \mathcal{R}^l} \left\{ L(\boldsymbol{\theta}, \lambda) = \frac{1}{2} \|\mathbf{y} - X\boldsymbol{\theta}\|_2^2 + \lambda \|\boldsymbol{\theta}\|_1 = J(\boldsymbol{\theta}) + \lambda \|\boldsymbol{\theta}\|_1 \right\}.$$

The difference now is that the loss function comprises two terms. One which is smooth (differentiable) and a non-smooth one. Let the current estimate be  $\boldsymbol{\theta}^{(i-1)}$ . The updated estimate is obtained by

$$\begin{aligned} \boldsymbol{\theta}^{(i)} = \arg \min_{\boldsymbol{\theta} \in \mathcal{R}^l} \left\{ J(\boldsymbol{\theta}^{(i-1)}) + (\boldsymbol{\theta} - \boldsymbol{\theta}^{(i-1)})^T \frac{\partial J(\boldsymbol{\theta}^{(i-1)})}{\partial \boldsymbol{\theta}} \right. \\ \left. + \frac{1}{2\mu} \|\boldsymbol{\theta} - \boldsymbol{\theta}^{(i-1)}\|_2^2 + \lambda \|\boldsymbol{\theta}\|_1 \right\}, \end{aligned}$$

which, after ignoring constants, becomes

$$\boldsymbol{\theta}^{(i)} = \arg \min_{\boldsymbol{\theta} \in \mathcal{R}^l} \left\{ \frac{1}{2} \|\boldsymbol{\theta} - \tilde{\boldsymbol{\theta}}\|_2^2 + \lambda \mu \|\boldsymbol{\theta}\|_1 \right\}, \quad (23.50)$$

where

$$\tilde{\boldsymbol{\theta}} := \boldsymbol{\theta}^{(i-1)} - \mu \frac{\partial J(\boldsymbol{\theta}^{(i-1)})}{\partial \boldsymbol{\theta}}. \quad (23.51)$$

Following exactly the same steps as those that led to the derivation of (23.20) from (23.13) (after replacing  $\hat{\boldsymbol{\theta}}_{LS}$  with  $\tilde{\boldsymbol{\theta}}$ ) we obtain

$$\boldsymbol{\theta}^{(i)} = S_{\lambda\mu}(\tilde{\boldsymbol{\theta}}) = S_{\lambda\mu} \left( \boldsymbol{\theta}^{(i-1)} - \mu \frac{\partial J(\boldsymbol{\theta}^{(i-1)})}{\partial \boldsymbol{\theta}} \right) \quad (23.52)$$

$$= S_{\lambda\mu} \left( \boldsymbol{\theta}^{(i-1)} + \mu X^T \mathbf{e}^{(i-1)} \right). \quad (23.53)$$

This is very interesting and practically useful. The only effect of the presence of the non-smooth  $\ell_1$  norm in the loss function is an extra simple thresholding operation, which as we know is an operation performed *individually* on each component. It can be shown, e.g., [111], that this algorithm converges to a minimizer  $\boldsymbol{\theta}_*$  of the LASSO (23.13), provided that  $\mu \in (0, 1/\lambda_{\max}(X^T X))$ , where  $\lambda_{\max}(\cdot)$  denotes the maximum eigenvalue of  $X^T X$ . The convergence rate is dictated by the rule

$$L(\boldsymbol{\theta}^{(i)}, \lambda) - L(\boldsymbol{\theta}_*, \lambda) \approx O(1/i),$$

which is known as *sublinear* global rate of convergence. Moreover, it can be shown that

$$L(\boldsymbol{\theta}^{(i)}, \lambda) - L(\boldsymbol{\theta}_*, \lambda) \leq \frac{C \|\boldsymbol{\theta}^{(0)} - \boldsymbol{\theta}_*\|_2^2}{2i}.$$

The latter result indicates that if one wants to achieve an accuracy of  $\epsilon$ , then this can be obtained by at most  $\left\lfloor \frac{C \|\boldsymbol{\theta}^{(0)} - \boldsymbol{\theta}_*\|_2^2}{2\epsilon} \right\rfloor$  iterations, where  $\lfloor \cdot \rfloor$  denotes the floor operator.

In [107], (23.48) was obtained from a nearby corner, building upon arguments from the classical *proximal-point* methods in optimization theory, e.g., [112]. The original LASSO regularized cost function is modified to the so called *surrogate objective*,

$$J(\boldsymbol{\theta}, \tilde{\boldsymbol{\theta}}) = \frac{1}{2} \|\mathbf{y} - X\boldsymbol{\theta}\|_2^2 + \lambda \|\boldsymbol{\theta}\|_1 + \frac{1}{2} d(\boldsymbol{\theta}, \tilde{\boldsymbol{\theta}}),$$

where

$$d(\boldsymbol{\theta}, \tilde{\boldsymbol{\theta}}) := c \|\boldsymbol{\theta} - \tilde{\boldsymbol{\theta}}\|_2^2 - \|X\boldsymbol{\theta} - X\tilde{\boldsymbol{\theta}}\|_2^2.$$

If  $c$  is appropriately chosen (larger than the largest eigenvalue of  $X^T X$ ), the surrogate objective is guaranteed to be strictly convex. Then it can be shown that the minimizer of the surrogate objective is given by

$$\hat{\boldsymbol{\theta}} = S_{\lambda/c} \left( \tilde{\boldsymbol{\theta}} + \frac{1}{c} X^T (\mathbf{y} - X\tilde{\boldsymbol{\theta}}) \right). \quad (23.54)$$

In the iterative formulation,  $\tilde{\boldsymbol{\theta}}$  is selected to be the previously obtained estimate; in this way, one tries to keep the new estimate close to the previous one. The procedure readily results to our generic scheme in (23.48), using soft thresholding with parameter  $\lambda/c$ . It can be shown that such a strategy converges to a minimizer of the original LASSO problem. The same algorithm was reached in [109], using *majorization-minimization* techniques from optimization theory. So, from this perspective, the IST family has strong ties with algorithms that belong to the convex optimization category.

In [31], the *Sparse Reconstruction by Separable Approximation* (SpaRSA) algorithm is proposed, which is a modification of the standard IST scheme. The starting point is (23.49); however, the multiplying factor,  $\frac{1}{2\mu}$ , instead of being constant is now allowed to change from iteration to iteration according to a rule. This results in a speed up in the convergence of the algorithm. Moreover, inspired by the homotopy family of algorithms, where  $\lambda$  is allowed to vary, SpaRSA can be extended to solve a sequence of problems which are associated with a corresponding sequence of values of  $\lambda$ . Once a solution has been

obtained for a particular value of  $\lambda$ , it can be used as a “warm-start” for a nearby value. Solutions can therefore be computed for a range of values, at a small extra computational cost, compared to solving for a single value from a “cold start.” This technique abides with the so-called *continuation strategy*, which has been used in the context of other algorithms as well, e.g., [113]. Continuation has been shown to be a very successful tool to increase the speed of convergence.

An interesting modification of the basic IST scheme has been proposed in [111], which improves the convergence rate to  $O(1/i^2)$ , by only a simple modification with almost no extra computational burden. The scheme is known as *Fast Iterative Shrinkage-Thresholding Algorithm* (FISTA). This scheme is an evolution of [114], which introduced the basic idea for the case of differentiable costs, and consists of the following steps:

$$\begin{aligned}\boldsymbol{\theta}^{(i)} &= S_{\lambda\mu} \left( \mathbf{z}^{(i)} + \mu X^T (\mathbf{y} - X\mathbf{z}^{(i)}) \right), \\ \mathbf{z}^{(i+1)} &:= \boldsymbol{\theta}^{(i)} + \frac{t_i - 1}{t_{i+1}} \left( \boldsymbol{\theta}^{(i)} - \boldsymbol{\theta}^{(i-1)} \right),\end{aligned}$$

where

$$t_{i+1} := \frac{1 + \sqrt{1 + 4t_i^2}}{2},$$

with initial points  $t_1 = 1$  and  $\mathbf{z}^{(1)} = \boldsymbol{\theta}^{(0)}$ . In words, in the thresholding operation,  $\boldsymbol{\theta}^{(i-1)}$  is replaced by  $\mathbf{z}^{(i)}$ , which is a specific linear combination of two successive updates of  $\boldsymbol{\theta}$ . Hence, at a marginal increase of the computational cost, a substantial increase in convergence speed is achieved.

In [115] the hard thresholding version has been used, with  $\mu = 1$  and the thresholding operator  $H_k$  uses the sparsity level  $k$  of the target solution, that is assumed to be known. In a later version, [116], the relaxation parameter is left to change so that, at each iterations step, the error is maximally reduced. It has been shown that the algorithm converges to a local minimum of the cost function  $\|\mathbf{y} - X\boldsymbol{\theta}\|_2$ , under the constraint that  $\boldsymbol{\theta}$  is a  $k$ -sparse vector. Moreover, the latter version is a stable one and it results to a near optimal solution if a form of RIP is fulfilled.

A modified version of the generic scheme given in (23.48), that evolves along the lines of [117], obtains the updates component-wise, one vector component at a time. Thus, a “full” iteration consists of  $l$  steps. The algorithm is known as *coordinate descent* and its basic iteration has the form

$$\theta_j^{(i)} = S_{\lambda/\|\mathbf{x}_j\|_2^2} \left( \theta_j^{(i-1)} + \frac{\mathbf{x}_j^T \boldsymbol{\epsilon}^{(i-1)}}{\|\mathbf{x}_j\|_2^2} \right), \quad j = 1, 2, \dots, l. \quad (23.55)$$

This algorithm replaces the constant  $c$ , in the previously reported soft thresholding algorithm, with the norm of the respective column of  $X$ , if the columns of  $X$  are not normalized to unit norm. It has been shown that the parallel coordinate descent algorithm also converges to a LASSO minimizer of (23.13), [108]. Improvements of the algorithm, using line search techniques to determine the most descent direction for each iteration, have also been proposed, see, [118].

The main contribution to the complexity for the iterative shrinkage algorithmic family comes from the two matrix-vector products, which amounts to  $\mathcal{O}(Nl)$ , unless  $X$  has a special structure, e.g., DFT, that can be exploited to reduce the load.

In [119], the so-called Two Stage Thresholding (TST) scheme is presented, which brings together arguments from the iterative shrinkage family and the OMP. This algorithmic scheme involves two stages of thresholding. The first step is exactly the same as in (23.48). However, this is now used only for determining “significant” nonzero locations, just as in Compressed Sensing Matching Pursuit (CSMP) algorithms, presented in the previous subsection. Then, a LS problem is solved to provide the updated estimate, under the constraint of the available support. This is followed by a second step of thresholding. The thresholding operations in the two stages can be different. If hard thresholding,  $H_k$ , is used in both steps, this results to the algorithm proposed in [120]. For this latter scheme, convergence and performance bounds are derived if the RIP holds for  $\delta_{3k} < 0.58$ . In other words, the basic difference between the TST and CSMP approaches is that, in the latter case, the most significant nonzero coefficients are obtained by looking at the correlation term  $X^T \mathbf{e}^{(i-1)}$  and in the TST family at  $\theta^{(i-1)} + \mu X^T \mathbf{e}^{(i-1)}$ . The differences among different approaches can be minor and the crossing lines among the different algorithmic categories are not necessarily crispy clear. However, from a practical point of view, sometimes small differences may lead to substantially improved performance.

### Remarks 11.

- The minimization in (23.52) bridges the IST algorithmic family with another powerful tool in convex optimization, which builds upon the notion of *proximal mapping* or *Moreau envelopes*, see, e.g., [112, 121]. Given a convex function  $h : \mathcal{R}^l \rightarrow \mathcal{R}$ , and a  $\mu > 0$ , the proximal mapping,  $\text{Prox}_{\mu h} : \mathcal{R}^l \rightarrow \mathcal{R}^l$ , with respect to  $h$ , and of index  $\mu$ , is defined as the (unique) minimizer

$$\text{Prox}_{\mu h}(\mathbf{x}) := \arg \min_{\mathbf{u} \in \mathcal{R}^l} \left\{ h(\mathbf{u}) + \frac{1}{2\mu} \|\mathbf{x} - \mathbf{u}\|_2^2 \right\}, \quad \forall \mathbf{x} \in \mathcal{R}^l. \quad (23.56)$$

Let us now assume that we want to minimize a convex function, which is given as the sum

$$f(\boldsymbol{\theta}) = J(\boldsymbol{\theta}) + h(\boldsymbol{\theta}),$$

where  $J(\cdot)$  is convex and differentiable, and  $h(\cdot)$  is also a convex, but not necessarily a smooth one. Then it can be shown that the following iterations converge to a minimizer of  $f(\cdot)$ ,

$$\boldsymbol{\theta}^{(i)} = \text{Prox}_{\mu h} \left( \boldsymbol{\theta}^{(i-1)} - \mu \frac{\partial J(\boldsymbol{\theta}^{(i-1)})}{\partial \boldsymbol{\theta}} \right), \quad (23.57)$$

where  $\mu > 0$  and it can also be made iteration dependent, i.e.,  $\mu_i > 0$ . If we now use this scheme to minimize our familiar cost, i.e.,

$$J(\boldsymbol{\theta}) + \lambda \|\boldsymbol{\theta}\|_1,$$

we obtain (23.52); this is so, because the proximal operator of  $h(\boldsymbol{\theta}) := \lambda \|\boldsymbol{\theta}\|_1$  is shown ([106, 121]) to be identical to the soft thresholding operator, i.e.,

$$\text{Prox}_h(\boldsymbol{\theta}) = S_\lambda(\boldsymbol{\theta}).$$

In order to feel more comfortable with this operator, note that if  $h(\mathbf{x}) := 0$ , its proximal operator is equal to  $\mathbf{x}$ , and in this case (23.57) becomes our familiar gradient descent algorithm.

- All the non-greedy algorithms, which have been discussed so far, have been developed to solve the task defined in the formulation (23.13). This is mainly because this is an easier task to solve; once  $\lambda$  has been fixed, it is an unconstrained optimization task. However, there are algorithms which have been developed to solve the alternative formulations.

The NESTA algorithm has been proposed in [122] and solves the task in its (23.15) formulation. Adopting this path can have an advantage since  $\epsilon$  may be given as an estimate of the uncertainty associated with the noise, which can readily be obtained in a number of practical applications. In contrast, selecting a priori the value for  $\lambda$  is more intricate. In [7], the value  $\lambda = \sigma_\eta \sqrt{2 \ln l}$ , where  $\sigma_\eta$  is the noise standard deviation, is argued to have certain optimality properties; however this argument hinges on the assumption of the orthogonality of  $X$ . NESTA relies heavily on Nesterov's generic scheme ([114]), hence its name. The original Nesterov's algorithm performs a constrained minimization of a smooth convex function  $f(\boldsymbol{\theta})$ , i.e.,

$$\min_{\boldsymbol{\theta} \in Q} f(\boldsymbol{\theta}),$$

where  $Q$  is a convex set, and in our case this is associated with the quadratic constraint in (23.15). The algorithm consists of three basic steps. The first one is similar with the step in (23.49), i.e.,

$$\mathbf{w}^{(i)} = \arg \min_{\boldsymbol{\theta} \in Q} \left\{ (\boldsymbol{\theta} - \boldsymbol{\theta}^{(i-1)})^T \frac{\partial J(\boldsymbol{\theta}^{(i-1)})}{\partial \boldsymbol{\theta}} + \frac{L}{2} \|\boldsymbol{\theta} - \boldsymbol{\theta}^{(i-1)}\|_2^2 \right\}, \quad (23.58)$$

where  $L$  is an upper bound on the Lipschitz coefficient, which the gradient of  $f(\cdot)$  has to satisfy. The difference with (23.49) is that the minimization is now a constrained one. However, Nesterov has also added a second step involving another auxiliary variable,  $\mathbf{z}^{(i)}$ , which is computed in a similar way as  $\mathbf{w}^{(i)}$  but the linearized term is now replaced by a weighted cumulative gradient,

$$\sum_{k=0}^{i-1} \alpha_k (\boldsymbol{\theta} - \boldsymbol{\theta}^{(k)})^T \frac{\partial J(\boldsymbol{\theta}^{(k)})}{\partial \boldsymbol{\theta}}.$$

The effect of this term is to smooth out the “zig-zagging” of the path towards the solution, whose effect is to increase significantly the convergence speed. The final step of the scheme involves an averaging of the previously obtained variables,

$$\boldsymbol{\theta}^{(i)} = t_i \mathbf{z}^{(i)} + (1 - t_i) \mathbf{w}^{(i)}.$$

The values of the parameters  $\alpha_k$ ,  $k = 0, \dots, i-1$ , and  $t_i$  result from the theory so that convergence is guaranteed. As it was the case with its close relative FISTA, the algorithm enjoys an  $O(1/i^2)$  convergence rate. In our case, where the function to be minimized,  $\|\boldsymbol{\theta}\|_1$ , is not smooth, NESTA uses a smoothed prox-function of it. Moreover, it turns out that close-form updates are obtained for  $\mathbf{z}^{(i)}$  and  $\mathbf{w}^{(i)}$ . If  $X$  is chosen so that to have orthonormal rows, the complexity per iteration is  $O(l)$  plus the computations needed for performing the product  $X^T X$ , which is the most computational thirsty part. However, this complexity can substantially be reduced if the sensing matrix is chosen to

be a submatrix of a unitary transform, which admits fast matrix-vector product computations, e.g., a subsampled DFT matrix. For example, for the case of a subsampled DFT matrix, the complexity amounts to  $O(l)$  plus the load to perform the two Fast Fourier Transforms (FFT). Moreover, the continuation strategy can also be employed to accelerate convergence. In [122], it is demonstrated that NESTA exhibits good accuracy results, while retaining a complexity that is competitive with algorithms developed around the (23.15) formulation and scales in an affordable way for large size problems. Furthermore, NESTA, and in general Nesterov's scheme, enjoy a generality that allows their use to other optimization tasks as well.

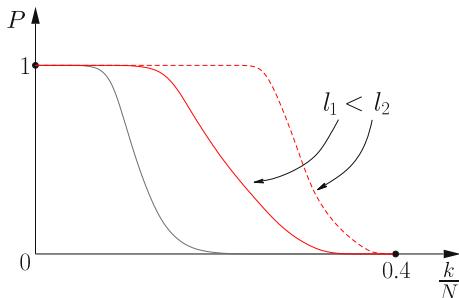

- The task in (23.14) has been considered in [97, 123]. In the former, the algorithm comprises a projection on the  $\ell_1$  ball  $\|\theta\|_1 \leq \rho$  (see also, Section 1.23.13.4) per iteration step. The most computationally dominant part of the algorithm consists of matrix-vector products. In [97], a homotopy algorithm is derived for the same task, where now the bound  $\rho$  becomes the homotopy parameter which is left to vary. This algorithm is also referred as the LARS-LASSO, as it has already been reported before.

### 1.23.11.3 Which algorithm then: some practical hints

We have already discussed a number of algorithmic alternatives to obtain solutions to the  $\ell_0$  or  $\ell_1$  norm minimization tasks. Our focus was on schemes whose computational demands are rather low and they scale well to very large problem sizes. We have not touched more expensive methods such as interior point methods for solving the  $\ell_1$  convex optimization task. A review of such methods is provided in [124]. Interior point methods evolve along the Newton-type recursion and their complexity per iteration step is at least of the order  $\mathcal{O}(l^3)$ . As it is most often the case, there is a trade off. Schemes of higher complexity tend to result in enhanced performance. However, such schemes become impractical in problems of large size. Some examples of other algorithms, that were not discussed, can be found in [31, 123, 125, 126]. Talking about complexity, it has to be pointed out that what really matters at the end is not so much the complexity per iteration step but the overall required resources in computer time/memory for the algorithm to converge to a solution within a specified accuracy. For example, an algorithm may be of low complexity per iteration step but it may need an excessive number of iterations to converge.

Computational load is only one among a number of indices that characterize the performance of an algorithm. Other performance measures, refer to convergence rate, tracking speed (for the adaptive algorithms), and stability with respect to the presence of noise and/or finite word length computations. No doubt, all these performance measures are also of interest here, too. However, there is an additional aspect that is of particular importance when quantifying performance of sparsity-promoting algorithms. This is related to the so called *undersampling-sparsity tradeoff* or the *phase transition curve*.

One of the major issues, on which we focused in this chapter, was to derive and present the conditions that guarantee uniqueness of the  $\ell_0$  minimization and its equivalence with the  $\ell_1$  minimization task, under an underdetermined set of measurements,  $\mathbf{y} = \mathbf{X}\boldsymbol{\theta}$ , for the recovery of sparse enough signals/vectors. While discussing the various algorithms in this section, we reported a number of different RIP-related conditions that some of the algorithms have to satisfy in order to recover the target sparse vector. As a matter of fact, it has to be admitted that this was quite confusing, since each algorithm had to satisfy its own conditions. In addition, in practice, these conditions are not easy to be verified. Although such results are, no doubt, important to establish convergence and make us more confident and also

**FIGURE 23.15**

For any algorithm, the transition between the regions of 100% success and of a complete failure is very sharp. For the algorithm corresponding to the middle curve, this transition occurs at higher sparsity values and, from this point of view, it is a better algorithm than the one associated with the curve on the left. Also, given a algorithm, the higher the dimensionality the higher the sparsity level where this transition occurs, as indicated by the middle and the dotted curve on the right.

understand better why and how an algorithm works, one needs further experimental evidence in order to establish good performance bounds for an algorithm. Moreover, all the conditions that we have dealt with, including coherence and RIP, are sufficient conditions. In practice, it turns out that sparse signal recovery is possible with sparsity levels much higher than those predicted by the theory, for given  $N$  and  $l$ . Hence, proposing a new algorithm or selecting an algorithm from an available palette, one has to demonstrate experimentally the range of sparsity levels that can be recovered by the algorithm, as a percentage of the number of measurements and the dimensionality. Thus, in order to select an algorithm, one should cast his/her vote for the algorithm which, for given  $l$  and  $N$ , has the potential to recover  $k$ -sparse vectors with  $k$  being as high as possible, for most of the cases, that is, with *high probability*.

Figure 23.15 illustrates the type of curve that is expected to result in practice. The vertical axis is the probability of exact recovery of a target  $k$ -sparse vector and the horizontal axis shows the ratio  $k/N$ , for a given number of measurements,  $N$ , and the dimensionality of the ambient space,  $l$ . Three curves are shown. The middle curve and the one on the right correspond to the same algorithm, for two different values of the dimensionality,  $l$ , and the curve on the left corresponds to another algorithm. Curves of this shape are expected to result from experiments of the following set up. Assume that we are given a sparse vector,  $\theta_0$ , with  $k$  nonzero components in the  $l$ -dimensional space. Using a sensing matrix  $X$ , we generate  $N$  measurements  $y = X\theta_0$ . The experiment is repeated a number of, say,  $M$  times, each time using a different realization of the sensing matrix and a different  $k$ -sparse vector. For each instance, the algorithm is run to recover the target sparse vector. This is not always possible. We count the number,  $m$ , of successful recoveries, and compute the corresponding percentage of successful recovery (probability),  $m/M$ , which is plotted on the vertical axis of Figure 23.15. The procedure is repeated for a different value of  $k$ ,  $1 \leq k \leq N$ . A number of issues now jump into the stage: (a) How one selects the ensemble of sensing matrices and (b) how one selects the ensemble of sparse vectors. There are different scenarios and some typical examples are described next.

1. The  $N \times l$  sensing matrices  $X$  are formed by:

- a. Different i.i.d. realizations with elements drawn from a Gaussian  $\mathcal{N}(0, 1/N)$ .
  - b. Different i.i.d. realizations from the uniform distribution on the unit sphere in  $\mathcal{R}^N$ , which is also known as the uniform spherical ensemble.
  - c. Different i.i.d. realizations with elements drawn from Bernoulli type distributions.
  - d. Different i.i.d. realizations of partial Fourier matrices, each time using a different set of  $N$  rows.
2. The  $k$ -sparse target vector  $\theta_0$  is formed by selecting the locations of at most  $k$  nonzero elements randomly, by “tossing a coin” with probability  $p = k/l$ , and fill the values of the nonzero elements according to a statistical distribution, e.g., Gaussian, uniform, double exponential, Cauchy.

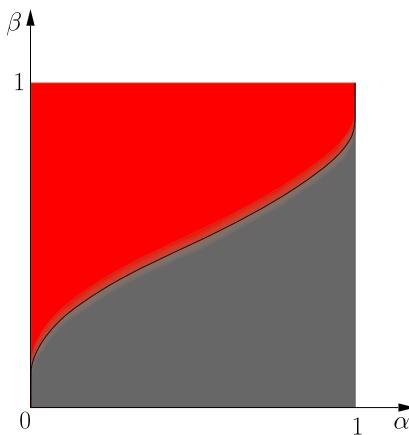

Other scenarios are also possible. Some authors set all nonzero values to one, [66], or to  $\pm 1$ , with the randomness imposed on the choice of the sign. It must be stressed out that the performance of an algorithm may vary significantly under different experimental scenarios, and this may be indicative of the stability of an algorithm. In practice, a user may be interested in a specific scenario, which is more representative of the available data.

Looking at Figure 23.15, the following conclusions are in order. In all curves, there is a sharp transition between two levels. From the 100% success to the 0% success. Moreover, the higher the dimensionality, the sharper the transition is. This has also been shown theoretically in [127]. For the algorithm corresponding to the two curves on the right, this transition occurs at higher values of  $k$ , compared to the algorithm that generates the curve on the left. Provided that the computational complexity of the former algorithm can be accommodated by the resources, which are available for a specific application, this seems to be the more sensible choice between the two algorithms. However, if the resources are limited, concessions are unavoidable.

Another way to “interrogate” and demonstrate the performance of an algorithm, with respect to its robustness to the range of values of sparsity levels that can be successfully recovered, is via the so-called *phase transition curve*. To this end define:

- $\alpha := \frac{N}{l}$ , which is a normalized measure of the problem indeterminacy.
- $\beta := \frac{k}{N}$ , which is a normalized measure of sparsity.

In the sequel, plot a graph having  $\alpha \in [0, 1]$  in the horizontal axis and  $\beta \in [0, 1]$  in the vertical one. For each point,  $(\alpha, \beta)$ , in the  $[0, 1] \times [0, 1]$  region, compute the probability of the algorithm to recover a  $k$ -sparse target vector. In order to compute the probability, one has to adopt one of the previously stated scenarios. In practice, one has to form a grid of points that cover densely enough the region  $[0, 1] \times [0, 1]$  in the graph. Use a varying intensity level scale to color the corresponding  $(\alpha, \beta)$  point. Gray (lower region) corresponds to probability one and red (upper region) to probability zero. Figure 23.16, illustrates the type of graph that is expected to be recovered in practice, for large values of  $l$ . That is, the transition from the region (phase) of “success” (gray/lower region) to that of “fail” (red/upper region) is very sharp. As a matter of fact, there is a curve that separates the two regions. The theoretical aspects of this curve have been studied in the context of combinatorial geometry in [127] for the asymptotic case,  $l \rightarrow \infty$ , and in [128] for finite values of  $l$ . Observe that the larger the value of  $\alpha$  (larger percentage of measurements) the larger the value of  $\beta$  at which the transition occurs. This is in line with what we have said so far in this paper, and the problem gets increasingly harder as one moves

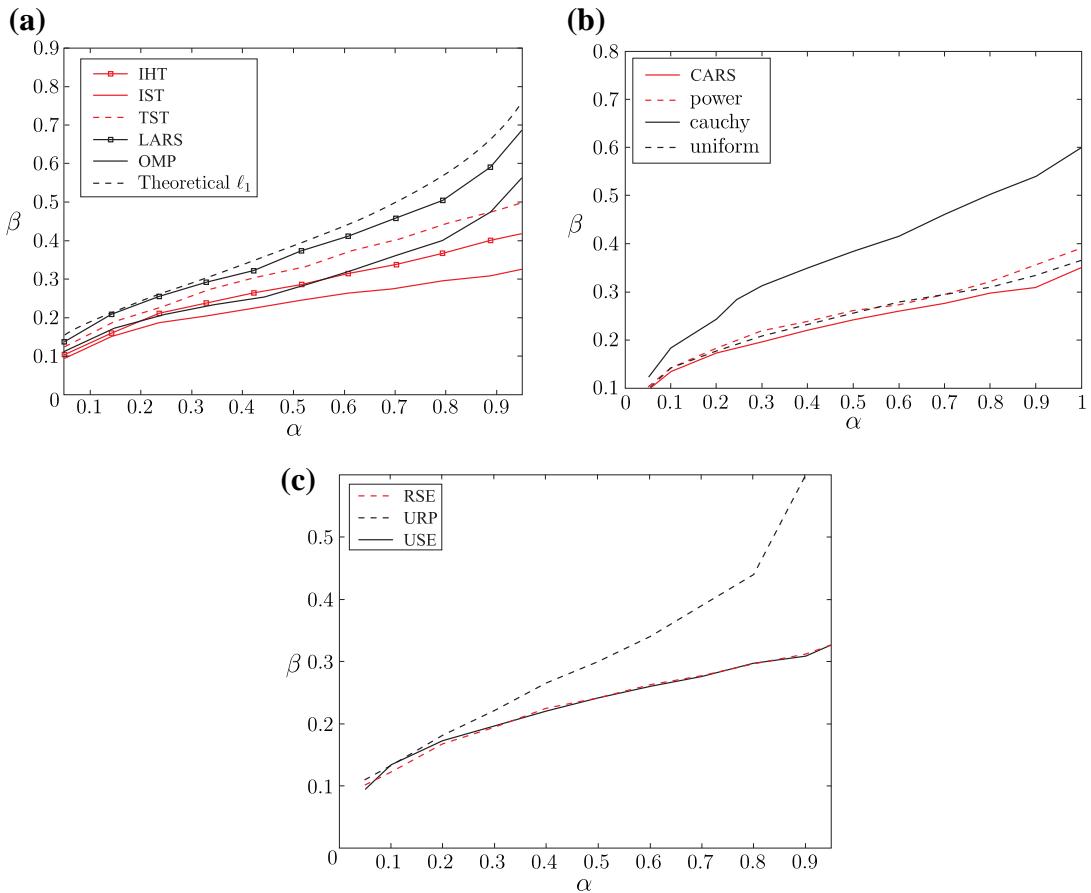

**FIGURE 23.16**

Typical phase transition behavior of a sparsity promoting algorithm. Gray (lower region) corresponds to 100% success of recovering the sparsest solution and red (upper region) to 0%. For high dimensional spaces, the transition is very sharp, as it is the case in the figure. For lower dimensionality spaces, the transition from gray (lower region) to red (upper region) is smoother and involves a region of varying color intensity. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this book.)

up and to the left in the graph. In practice, for smaller values of  $l$ , the transition region between the two regions is smoother, and it gets narrower as  $l$  increases. In practice, one can draw an approximate curve that separates the “success” and “fail” regions, using regression techniques, see, e.g., [119].

The reader may already be aware of the fact that, so far, we have avoided to talk about the performance of individual algorithms. We have just discussed some “typical” behavior that algorithms tend to exhibit in practice. What the reader might have expected is to discuss comparative performance tests and draw related conclusions. We have not done it since we feel that it is early in time to have “definite” performance conclusions, and this field is still in an early stage. Most authors compare their newly suggested algorithm with a few other algorithms, usually within a certain algorithmic family and, more important, under some specific scenarios, where the advantages of the newly suggested algorithm are documented. However, the performance of an algorithm can change significantly by changing the experimental scenario, under which the tests are carried out. The most comprehensive comparative performance study, so far, has been carried out in [119]. However, even in this one, the scenario of exact measurements has been considered and there are no experiments concerning the robustness of individual algorithms to the presence of noise. It is important to say that this study involved a huge effort of computation. We will comment on some of the findings from this study, which will also reveal to the reader that different experimental scenarios can significantly affect the performance of an algorithm.

Figure 23.17a shows the obtained phase transition curves for (a) the iterative hard thresholding (IHT), (b) the iterative soft thresholding scheme of (23.48) (IST), (c) the Two-Stage-Thresholding scheme (TST), as discussed earlier on, (d) the LARS, and (e) the OMP algorithms, together with the

**FIGURE 23.17**

(a) The obtained phase transition curves for different algorithms under the same experimental scenario, together with the theoretical one. (b) Phase transition curve for the IST algorithm under different experimental scenarios for generating the target sparse vector. (c) The phase transition for the IST algorithms under different experimental scenarios for generating the sensing matrix  $X$ .

theoretically obtained one using  $\ell_1$  minimization. All algorithms were tuned with the optimal values, with respect to the required user-defined parameters, after extensive experimentation. The results in the Figure correspond to the uniform spherical scenario, for the generation of the sensing matrices. Sparse vectors were generated according to the  $\pm 1$  scenario, for the nonzero coefficients. The interesting observation is that, although the curves deviate from each other as we move to larger values of  $\beta$ , for smaller values, the differences in their performance become less and less. This is also true for computationally simple schemes, such as the IHT one. The performance of LARS is close to the

optimal one. However, this comes at the cost of computational increase. The required computational time for achieving the same accuracy, as reported in [119], favor the TST algorithm. In some cases, LARS required excessively longer time to reach the same accuracy, in particular when the sensing matrix was the partial Fourier one and fast schemes to perform matrix vector products can be exploited. For such matrices, the thresholding schemes (IHT, IST, TST) exhibited a performance that scales very well to large size problems.

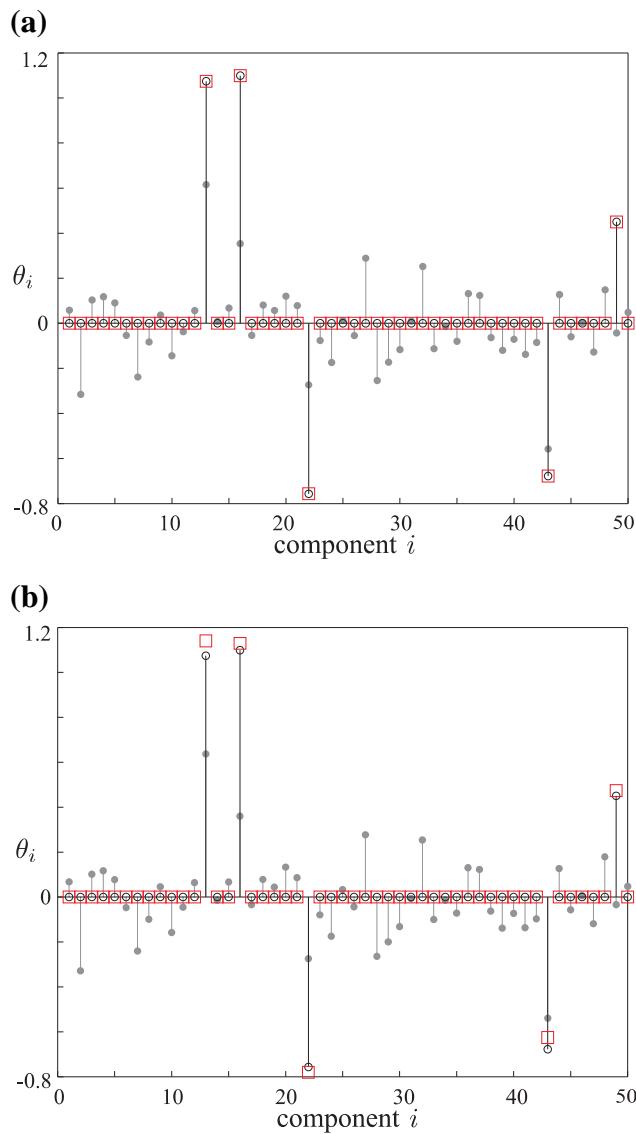

Figure 23.17b indicates the phase transition curve for one of the algorithms (IST) as we change the scenarios for generating the sparse (target) vectors, using different distributions; (a)  $\pm 1$ , with equiprobable selection of signs (Constant Amplitude Random Selection (CARS)), (b) double exponential (power), (c) Cauchy, and (d) uniform in  $[-1, 1]$ . This is indicative and typical for other algorithms as well, with some of them being more sensitive than others. Finally, Figure 23.17c shows the transition curves for the IST algorithm by changing the sensing matrix generation scenario. Three curves are shown corresponding to (a) uniform spherical ensemble (USE), (b) random sign ensemble (RSE), where the elements are  $\pm 1$  with signs uniformly distributed, and (c) the uniform random projection (URP) ensemble. Once more, one can observe the possible variations that are expected due to the use of different matrix ensembles. Moreover, changing ensembles affects each algorithm in a different way.

Concluding this section it must be emphasized that the field of algorithmic development is still an ongoing research field and it is early to come with definite and concrete comparative performance conclusions. Moreover, besides the algorithmic front, existing theories often fall short to predict what is observed in practice, with respect to their phase transition performance. For a related discussion, see, e.g., [43].

**Example 5.** We are given a set of  $N = 20$  measurements stacked in the  $\mathbf{y} \in \mathcal{R}^N$  vector. These were taken by applying a sensing matrix  $X$  on an “unknown” vector in  $\mathcal{R}^{50}$ , which is known to be sparse with  $k = 5$  nonzero components; the location of these nonzero components in the unknown vector are not known. The sensing matrix was a random matrix with elements drawn from a normal distribution  $\mathcal{N}(0, 1)$  and then the columns were normalized to unit norm. There are two scenarios for the measurements. In the first one, we are given the exact measurements while in the second one white Gaussian noise of variance  $\sigma^2 = 0.025$  was added.

In order to recover the unknown sparse vector, the CoSaMP algorithm was used for both scenarios.

The results are shown in Figures 23.18a and 23.18b for the noiseless and noisy scenarios, respectively. The values of the true unknown vector  $\boldsymbol{\theta}$  are represented with black stems topped with open circles. Note that all but five of them are zero. In Figure 23.18a exact recovery of the unknown values is succeeded; the estimated values of  $\theta_i$ ,  $i = 1, 2, \dots, 50$ , are indicated with squares in red color (for the web version). In the noisy case of Figure 23.18b, the resulted estimates, which are denoted with squares, deviate from the correct values. Note that estimated values very close to zero ( $|\theta| \leq 0.01$ ) have been omitted from the figure in order to facilitate visualizing. In both figures, the stemmed gray filled circles correspond to the minimum  $\ell_2$  norm LS solution. The advantages of adopting a sparsity-promoting approach to recover the solution are obvious. The CoSaMP algorithm was provided with the exact number of sparsity. The reader is advised to play with this example by experimenting with different values of the parameters and see how results are affected.

**FIGURE 23.18**

(a) Noiseless case. The values of the true vector, which generated the data for the Example 5, are shown with stems topped with open circles. The recovered points, using the CoSaMP, are shown with squares. An exact recovery of the signal has been obtained. The stems topped with gray filled circles correspond to the minimum Euclidean norm LS solution. (b) This figure corresponds to the noisy counterpart of that in (a). In the presence of noise, exact recovery is not possible and the more the power of the noise is the less accurate the results are.

### 1.23.12 Variations on the sparsity-aware theme

In our tour, so far, we have touched a number of aspects of the sparsity-aware learning that come from the main stream of the theoretical developments. However, more and more variants appear, which are developed with the goal to address problems of a more special structure and/or to propose alternatives, which can be beneficial in boosting the performance in practice, by serving the needs of specific applications. These variants focus either on the regularization term in (23.13) or on the misfit-measuring term or on both. Once more, research activity in this direction is dense and our purpose is to simply highlight possible alternatives and make the reader alert of the various possibilities that spring from the basic theory.

In a number of tasks, it is a priori known that the nonzero coefficients in the target signal/vector occur in groups and they are not randomly spread in all possible positions. Such a typical example is the echo path in internet telephony, where the nonzero coefficients of the impulse response tend to cluster together, see Figure 23.6. Other examples of “structured” sparsity can be traced in DNA microarrays, MIMO channel equalization, source localization in sensor networks, magnetoencephalography or in neuroscience problems, e.g., [63, 129–131]. As it is always the case in Machine Learning, being able to incorporate a priori information in the optimization can only be of benefit for improving performance, since the estimation task is externally assisted in its effort to search for the target solution.

The *group LASSO*, [132–135] addresses the task where it is a priori known that the nonzero components occur in groups. The unknown vector  $\boldsymbol{\theta}$  is divided into, say,  $L$  groups, i.e.,

$$\boldsymbol{\theta}^T = [\boldsymbol{\theta}_1^T, \dots, \boldsymbol{\theta}_L^T]^T,$$

each of them of a predetermined size,  $s_i, i = 1, 2, \dots, L$ , with  $\sum_{i=1}^L s_i = l$ . The regression model can then be written as

$$\mathbf{y} = \mathbf{X}\boldsymbol{\theta} + \boldsymbol{\eta} = \sum_{i=1}^L \mathbf{X}_i \boldsymbol{\theta}_i + \boldsymbol{\eta},$$

where each  $\mathbf{X}_i$  is a submatrix of  $\mathbf{X}$  comprising the corresponding  $s_i$  columns. The solution of the group LASSO is given by the following LS regularized task

$$\hat{\boldsymbol{\theta}} = \arg \min_{\boldsymbol{\theta} \in \mathcal{R}^l} \left( \left\| \mathbf{y} - \sum_{i=1}^L \mathbf{X}_i \boldsymbol{\theta}_i \right\|_2^2 + \lambda \sum_{i=1}^L \sqrt{s_i} \|\boldsymbol{\theta}_i\|_2 \right), \quad (23.59)$$

where  $\|\boldsymbol{\theta}_i\|_2$  is the Euclidean norm (not the squared one) of  $\boldsymbol{\theta}_i$ , i.e.,

$$\|\boldsymbol{\theta}_i\|_2 = \sqrt{\sum_{j=1}^{s_i} |\theta_{i,j}|^2}.$$

In other words, the individual components of  $\boldsymbol{\theta}$  that contribute to the formation of the  $\ell_1$  norm, in the standard LASSO formulation are now replaced by the square root of the energy of each individual block. In this setting, it is not the individual components but blocks of them which are forced to zero,

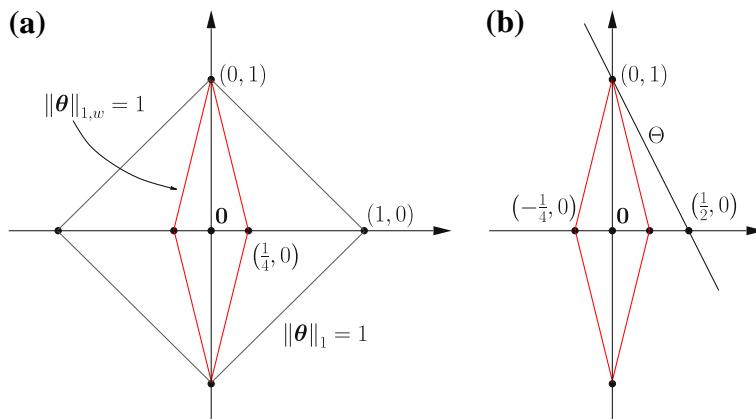

when their contribution to the LS misfit measuring term is not significant. Sometimes, this type of regularization is coined as the  $\ell_1/\ell_2$  regularization. It is straightforward to see that if  $L = l$ , then the group LASSO becomes the standard LASSO method. An alternative formulation of the group sparse model using greedy algorithms is considered in [136]. Theoretical results that extend the RIP to the so-called block RIP have been developed and reported, see, e.g., [64, 137].

In [129, 138], the so-called *model based* Compressed Sensing is addressed. The  $(k, C)$  model allows the significant coefficients of a  $k$ -sparse signal to appear in at most  $C$  clusters, whose size is unknown. This is a major difference with the group LASSO, that was reported before. In Section 1.23.10, it was commented that searching for a  $k$ -sparse solution takes place in a union of subspaces, each one of dimensionality  $k$ . Imposing a certain structure on the target solution restricts the searching in a subset of these subspaces and leaves a number of these out of the game. This obviously facilitates the optimization task. In [138], a dynamic programming technique is adopted to obtain the solution. In [139], structured sparsity is considered in terms of graphical models. An even more advanced block sparsity model is the C-HiLasso, which allows each block to have a sparse structure itself, [140].

In [141], it is suggested to replace the  $\ell_1$  norm by a weighted version of it. To justify such a choice, let us recall Example 2 and the case where the “unknown” system was sensed using  $x = [2, 1]^T$ , shown in Figure 23.10c. We have seen that by “blowing” up the  $\ell_1$  ball, the wrong sparse solution was obtained. Let us now replace the  $\ell_1$  norm in (23.28) with its weighted version

$$\|\theta\|_{1,w} := w_1|\theta_1| + w_2|\theta_2|, \quad w_1, w_2 > 0,$$

and set  $w_1 = 4$  and  $w_2 = 1$ . Figure 23.19a shows the isovalue curve  $\|\theta\|_{1,w} = 1$ , together with that resulting from the standard  $\ell_1$  norm. The weighted one is sharply “pinched” around the vertical axis, and the larger the value of  $w_1$  is, compared to that of  $w_2$ , the sharper the corresponding ball will be.

**FIGURE 23.19**

(a) The isovalue curves for the  $\ell_1$  and the weighted  $\ell_1$  norms for the same value. The weighted  $\ell_1$  is sharply pinched around one of the axis, depending on the weights. (b) Adopting to minimize the weighted  $\ell_1$  norm, for the setup of Figure 23.10 the correct sparse solution is obtained.

Figure 23.19b shows what happens when “blowing” the weighted  $\ell_1$  ball. It will first touch the point  $(0, 1)$ , which is the true solution. Basically, what we have done is to “squeeze” the  $\ell_1$  ball to be aligned more to the axis that contains the (sparse) solution. For the case of our example, any weight  $w_1 > 2$  would do the job.

Considering now the general case of a weighted norm

$$\|\boldsymbol{\theta}\|_{1,w} := \sum_{j=1}^l w_j |\theta_j|, \quad w_j > 0.$$

The ideal choice of the weights would be

$$w_j = \begin{cases} \frac{1}{|\theta_{0,j}|}, & \theta_{0,j} \neq 0, \\ \infty, & \theta_{0,j} = 0, \end{cases}$$

where  $\boldsymbol{\theta}_0$  is the target true vector, and where we have silently assumed that  $0 \cdot \infty = 0$ . In other words, the smaller a coefficient is the larger the respective weight becomes. This is justified, since large weighting will force respective coefficients towards zero during the minimization process. Of course, in practice, the values of the true vector are not known, so it is suggested to use their estimates during each iteration of the minimization procedure. The resulting scheme is of the following form.

### Algorithm 3.

1. Initialize weights to unity,  $w_j^{(0)} = 1, j = 1, 2, \dots, l$ .
2. Minimize the weighted  $\ell_1$  norm,

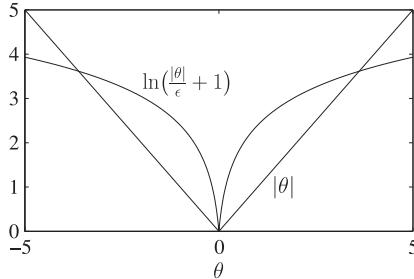

$$\begin{aligned} \boldsymbol{\theta}^{(i)} &= \arg \min_{\boldsymbol{\theta} \in \mathcal{R}^l} \|\boldsymbol{\theta}\|_{1,w} \\ \text{s.t. } \mathbf{y} &= X\boldsymbol{\theta}. \end{aligned}$$

3. Update the weights

$$w_j^{(i+1)} = \frac{1}{|\theta_j^{(i)}| + \epsilon}, \quad j = 1, 2, \dots, l.$$

4. Terminate when a stopping criterion is met, otherwise return to step 2.

The constant  $\epsilon$  is a small user-defined parameter to guarantee stability when the estimates of the coefficients take very small values. Note that if the weights have constant preselected values, the task retains its convex nature; this is no longer true when the weights are changing. It is interesting to point out that this intuitively motivated weighting scheme can result if the  $\ell_1$  norm is replaced by  $\sum_{j=1}^l \ln(|\theta_j| + \epsilon)$  as the regularizing term of (23.13). Figure 23.20 shows the respective graph, in the one-dimensional space together with that of the  $\ell_1$  norm. The graph of the logarithmic function reminds us of the  $\ell_p$ ,  $p < 0 < 1$ , “norms” and the comments made in Section 1.23.3. This is no more a convex function and the iterative scheme, given before, is the result of a majorization-minimization procedure in order to solve the resulting non-convex task, [141].

**FIGURE 23.20**

One-dimensional graphs of the  $\ell_1$  norm and the logarithmic regularizer  $\ln\left(\frac{|\theta|}{\epsilon} + 1\right) = \ln(|\theta| + \epsilon) - \ln\epsilon$ , with  $\epsilon = 0.1$ . The term  $\ln\epsilon$  was subtracted for illustration purposes only and does not affect the optimization. Notice the nonconvex nature of the logarithmic regularizer.

The concept of the iterative weighting, as used before, has also been applied in the context of the *iterative reweighted least squares algorithm*. Observe that the  $\ell_1$  norm can be written as

$$\|\boldsymbol{\theta}\|_1 = \sum_{j=1}^l |\theta_j| = \boldsymbol{\theta}^T \mathcal{W}_\theta \boldsymbol{\theta},$$

where

$$\mathcal{W}_\theta = \begin{bmatrix} \frac{1}{|\theta_1|} & 0 & \cdots & 0 \\ 0 & \frac{1}{|\theta_2|} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \frac{1}{|\theta_l|} \end{bmatrix},$$

and where in the case of  $\theta_i = 0$ , for some  $i \in \{1, 2, \dots, l\}$ , the respective coefficient of  $\mathcal{W}_\theta$  is defined to be 1. If  $\mathcal{W}_\theta$  were a constant weighting matrix, i.e.,  $\mathcal{W}_\theta := \mathcal{W}_{\tilde{\theta}}$ , for some fixed  $\tilde{\theta}$ , then obtaining the minimum

$$\hat{\boldsymbol{\theta}} = \arg \min_{\boldsymbol{\theta} \in \mathcal{R}^l} \|\mathbf{y} - X\boldsymbol{\theta}\|_2^2 + \lambda \boldsymbol{\theta}^T \mathcal{W}_{\tilde{\theta}} \boldsymbol{\theta},$$

is straightforward and similar to the ridge regression. In the iterative reweighted scheme,  $\mathcal{W}_\theta$  is replaced by  $\mathcal{W}_{\theta^{(i)}}$ , formed by using the respected estimates of the coefficients, which have been obtained from the previous iteration, i.e.,  $\tilde{\boldsymbol{\theta}} := \boldsymbol{\theta}^{(i)}$ , as we did before. In the sequel, each iteration solves a weighted ridge regression task. Variants of this basic iteratively weighting scheme have also been proposed, see, e.g., [125] and the references therein.

In [142], the LASSO task is modified by replacing the square error term with one involving correlations and the minimization task becomes

$$\begin{aligned} \hat{\boldsymbol{\theta}} : \min_{\boldsymbol{\theta} \in \mathcal{R}^l} & \quad \|\boldsymbol{\theta}\|_1 \\ \text{s.t. } & \quad \|X^T(\mathbf{y} - X\boldsymbol{\theta})\|_\infty \leq \epsilon, \end{aligned}$$

where  $\epsilon$  is related to  $l$  and the noise variance. This task is known as the *Dantzig selector*. That is, instead of constraining the energy of the error, the constraint, now, imposes an upper limit to the correlation of the error vector with any of the columns of  $X$ . In [57, 143], it is shown that under certain conditions the LASSO estimator and the Dantzig selector become identical.

*Total Variation (TV)* [144] is a closely related to  $\ell_1$  sparsity promotion notion and it has been widely used in image processing. Most of the grayscale image arrays,  $I \in \mathcal{R}^{l \times l}$ , consist of slowly varying pixel intensities except at the edges. As a consequence, the discrete gradient of an image array will be approximately sparse (compressible). The discrete directional derivatives of an image array are defined pixel-wise as

$$\nabla_x(I)(i, j) := I(i+1, j) - I(i, j), \quad \forall i \in \{1, 2, \dots, l-1\}, \quad (23.60)$$

$$\nabla_y(I)(i, j) := I(i, j+1) - I(i, j), \quad \forall j \in \{1, 2, \dots, l-1\}, \quad (23.61)$$

and

$$\nabla_x(I)(l, j) := \nabla_y(I)(i, l) := 0, \quad \forall i, j \in \{1, 2, \dots, l-1\}. \quad (23.62)$$

The discrete gradient transform

$$\nabla : \mathcal{R}^{l \times l} \rightarrow \mathcal{R}^{l \times 2l},$$

is defined in terms of a matrix form as

$$\nabla(I)(i, j) := [\nabla_x(I)(i, j), \nabla_y(I)(i, j)], \quad \forall i, j \in \{1, 2, \dots, l\}. \quad (23.63)$$

The total variation of the image array is defined as the  $\ell_1$  norm of the *magnitudes* of the elements of the discrete gradient transform, i.e.,

$$\|I\|_{TV} := \sum_{i=1}^l \sum_{j=1}^l \|\nabla(I)(i, j)\|_2 = \sum_{i=1}^l \sum_{j=1}^l \sqrt{\nabla_x(I)^2(i, j) + \nabla_y(I)^2(i, j)}. \quad (23.64)$$

Note that this is a mixture of  $\ell_2$  and  $\ell_1$  norms. The sparsity promoting optimization around the total variation is defined as

$$\begin{aligned} I_* &\in \arg \min_I \|I\|_{TV} \\ &\text{s.t. } \|\mathbf{y} - \mathcal{F}(I)\|_2 \leq \epsilon, \end{aligned} \quad (23.65)$$

where  $\mathbf{y} \in \mathcal{R}^N$  is the measurements vector and  $\mathcal{F}(I)$  denotes the result in vectorized form of the application of a linear operator on  $I$ . For example, this could be the result of the action of a partial two-dimensional DFT on the image. Subsampling of the DFT matrix as a means to form sensing matrices has already been discussed in Section 1.23.8.2. The task in (23.65) retains its convex nature and it basically expresses our desire to reconstruct an image which is as smooth as possible given the available measurements. The NESTA algorithm can be used for solving the total variation minimization task; besides it, other efficient algorithms for this task can be found in, e.g., [145, 146].

It has been shown in [52], for the exact measurements case ( $\epsilon = 0$ ), and in [147], for the erroneous measurements case, that conditions and bounds which guarantee recovery of an image array from the task in (23.65) can be derived and are very similar with those that we have discussed for the case of the  $\ell_1$  norm.

**Example 6 (Magnetic Resonance Imaging (MRI)).** In contrast to ordinary imaging systems, which directly acquire pixel samples, MRI scanners sense the image in an encoded form. Specifically, MRI scanners sample components in the spatial frequency domain, known as “ $k$ -space” in the MRI nomenclature. If all the components in this transform domain were available, one could apply the inverse 2D-DFT to recover the exact MR image in the pixel domain. Sampling in the  $k$ -space is realized along particular trajectories in a number of successive acquisitions. This process is time consuming, merely due to physical constraints. As a result, techniques for efficient image recovery from a *limited number of measurements* is of high importance, since they can reduce the required acquisition time for performing the measurements. Long acquisition times are not only inconvenient but even impossible, since the patients have to stay still for long time intervals. Thus, MRI was among the very first applications where compressed sensing found its way to offer its elegant solutions.

Figure 23.21a shows the “famous” Shepp-Logan phantom, and the goal is to recover it via a limited number of (measurements) samples in its frequency domain. The MRI measurements are taken across 17 radial lines in the spatial frequency domain, as shown in Figure 23.21b. A “naive” approach to recover the image from this limited number of measuring samples would be to adopt a zero-filling rationale for the missing components. The recovered image according to this technique is shown in Figure 23.21c. Figure 23.21d shows the recovered image using the approach of minimizing the total variation, as

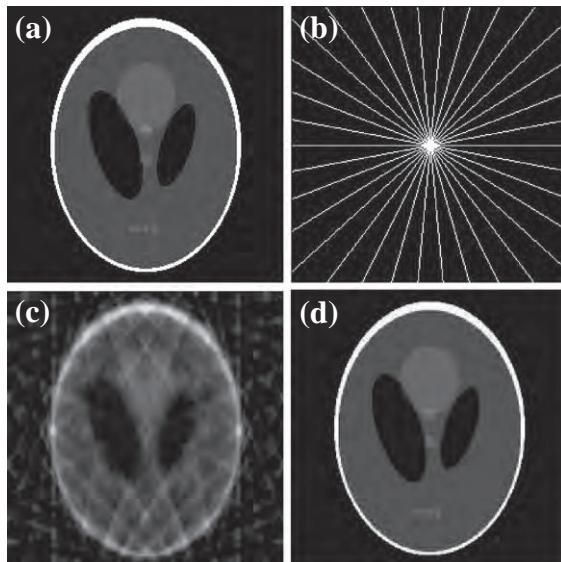

FIGURE 23.21

(a) The original Shepp-Logan image phantom. (b) The white lines indicate the directions across which the sampling in the spatial Fourier transform were obtained. (c) The recovered image after applying the inverse DFT having first filled with zeros the missing values in the DFT transform. (d) The recovered image using the total variation minimization approach.

explained before. Observe that the results for this case are astonishingly good. The original image is almost perfectly recovered. The constrained minimization was performed via the NESTA algorithm. Note that if the minimization of the  $\ell_1$  norm of the image array were used in place of the total variation, the results would not be as good; the phantom image is sparse in the discrete gradient domain, since it contains large sections which share constant intensities.

---

### 1.23.13 Online time-adaptive sparsity-promoting algorithms

In this section, online (time-recursive) schemes for sparsity-aware learning are presented. There is a number of reasons that one has to resort to such schemes in various signal processing tasks, for example, when the data arrive sequentially. Under such a scenario, using batch processing techniques to obtain an estimate of an unknown target parameter vector would be highly inefficient, since the number of training points keeps increasing. Such an approach is prohibited for real time applications. Moreover, time-recursive schemes can easily incorporate the notion of adaptivity, when the learning environment is not stationary but it undergoes changes as time evolves. Besides signal processing applications, there is an increasing number of machine learning applications where online processing is of paramount importance, such as bioinformatics, hyperspectral imaging, and data mining. In such applications, the number of training points easily amounts to a few thousand up to hundred of thousand points. Concerning the dimensionality of the ambient (feature) space, one can claim numbers that lie in similar ranges. For example, in [148], the task is to search for sparse solutions in feature spaces with dimensionality as high as  $10^9$  having access to data sets as large as  $10^7$  points. Using batch techniques, in a single computer, is out of question with today's technology.

Let us assume that there is an unknown parameter vector that generates data according to the standard regression model

$$y_n = \mathbf{x}_n^T \boldsymbol{\theta} + \eta_n, \quad \forall n,$$

and the training samples are received sequentially  $(y_n, \mathbf{x}_n), n = 1, 2, \dots$ . In the case of a stationary environment, we would expect our algorithm to converge, asymptotically as  $n \rightarrow \infty$ , to or “near to” the true parameter vector that gives birth to the measurements,  $y_n$ , when it is sensed by  $\mathbf{x}_n$ . For time varying environments, the algorithms should be able to track the underlying changes as time goes by. Before we proceed, a comment is important. Since the time index,  $n$ , is left to grow, all we have said in the previous sections with respect to underdetermined systems of equations, loses its meaning. Sooner or later we are going to have more measurements than the dimensionality of the space. Our major concern here becomes the issue of asymptotic convergence, for the case of stationary environments. The obvious question, that is now raised, is why not using a standard algorithm, e.g., LMS, RLS, or APSM [15, 16, 149], since we know that these algorithms converge to, or near enough in some sense, to the solution; that is, the algorithm will identify the zeros asymptotically. The answer is that if such algorithms are modified to be aware for the underlying sparsity, convergence is significantly speeded up; in real life applications, one has not the “luxury” to wait long time for the solution. In practice, a good algorithm should be able to provide a good enough solution, and in the case of sparse solutions to *obtain the support*, after a reasonably small number of iteration steps. In this section, the powerful theory around the  $\ell_1$  norm regularization will be used to obtain sparsity-promoting time adaptive schemes.

### 1.23.13.1 LASSO: asymptotic performance

The notions of bias, variance and consistency, are major indices for assessing the performance of an estimator. In a number of cases, such performance measures are derived asymptotically. For example, it is well known that the maximum likelihood estimator is asymptotically unbiased and consistent [1]. Also the LS estimator is asymptotically consistent. Moreover, under the assumption that the noise samples are i.i.d., the LS estimate,  $\hat{\theta}_N$ , that is obtained using  $N$  measurement (training) samples, is itself a random vector, that satisfies the  $\sqrt{N}$ -estimation consistency, e.g., [150], i.e.,

$$\sqrt{N} (\hat{\theta}_N - \theta_0) \xrightarrow{d} \mathcal{N}(\mathbf{0}, \sigma^2 \Sigma^{-1}),$$

where  $\theta_0$  is the true vector that generates the measurements,  $\sigma^2$  denotes the variance of the noise source and  $\Sigma$  is the covariance matrix  $E[\mathbf{x}\mathbf{x}^T]$  of the input sequence, which has been assumed to be zero mean and the limit denotes convergence in distribution.

The LASSO in (23.13) is the task of minimizing the  $\ell_1$  norm regularized version of the LS cost. However, nothing has been said, so far, about the statistical properties of this estimator. The only performance measure that we referred to was the error norm bound given in (23.43). However, this bound, although important in the context it was proposed for, does not provide much statistical information. Since the introduction of the LASSO estimator, a number of papers have addressed problems related to its statistical performance, see, e.g., [151–154].

When dealing with sparsity-promoting estimators, such as the LASSO, two crucial issues emerge: (a) whether the estimator, even asymptotically, can obtain the support, if the true vector parameter is a sparse one and (b) quantify the performance of the estimator with respect to the estimates of the nonzero coefficients, i.e., those whose index belongs to the support. Especially for LASSO, the latter issue becomes to study whether LASSO behaves as well as the unregularized LS with respect to these nonzero components. This task was addressed, for a first time and in a more general setting, in [153]. Let the support of the true, yet unknown,  $k$ -sparse parameter vector  $\theta_0$  be denoted as  $S$ . Let also  $\Sigma|_S$  be the  $k \times k$  covariance matrix  $E[\mathbf{x}|_S \mathbf{x}|_S^T]$ , where  $\mathbf{x}|_S \in \mathcal{R}^k$  is the vector that contains only the  $k$  components of  $\mathbf{x}$ , with indices in the support  $S$ . Then, we say that an estimator satisfies asymptotically the *oracle properties* if:

- $\lim_{N \rightarrow \infty} \text{Prob} \left\{ S_{\hat{\theta}_N} = S \right\} = 1$ . This is known as *support consistency*.
- $\sqrt{N} (\hat{\theta}_{N|S} - \theta_{0|S}) \xrightarrow{d} \mathcal{N}(\mathbf{0}, \sigma^2 \Sigma|_S^{-1})$ . This is the  $\sqrt{N}$ -estimation consistency.

We denote as  $\theta_{0|S}$  and  $\theta_{N|S}$  the  $k$ -dimensional vectors which result from  $\theta_0, \hat{\theta}_N$ , respectively, if we keep the components whose indices lie in the support  $S$ . In other words, according to the oracle properties, a good sparsity-promoting estimator should be able (a) to predict, asymptotically, the true support and (b) its performance with respect to the nonzero components should be as good as that of a genie-aided LS estimator, which is informed, in advance, of the positions of the nonzero coefficients.

Unfortunately, the LASSO estimator *cannot* satisfy simultaneously both conditions. It has been shown, [152–154] that:

- For support consistency, the regularization parameter  $\lambda := \lambda_N$  should be time varying such as

$$\lim_{N \rightarrow \infty} \frac{\lambda_N}{\sqrt{N}} = \infty, \quad \lim_{N \rightarrow \infty} \frac{\lambda_N}{N} = 0.$$

That is,  $\lambda_N$  must grow faster than  $\sqrt{N}$ , but slower than  $N$ .

- For  $\sqrt{N}$ -consistency,  $\lambda_N$  must grow as

$$\lim_{N \rightarrow \infty} \frac{\lambda_N}{\sqrt{N}} = 0,$$

i.e., it grows slower than  $\sqrt{N}$ .

The previous two conditions are conflicting and the LASSO estimator cannot comply with the two oracle conditions simultaneously. The proofs of the previous two points are somewhat technical and are not given here. The interested reader can obtain them from the previously given references. However, before we proceed, it is instructive to see why the regularization parameter has to grow slower than  $N$ , in any case. Without being too rigorous mathematically, recall that the LASSO solution comes from Eq. (23.13). This can be written as

$$\mathbf{0} \in -\frac{2}{N} \sum_{n=1}^N \mathbf{x}_n y_n + \frac{2}{N} \left( \sum_{n=1}^N \mathbf{x}_n \mathbf{x}_n^T \right) \boldsymbol{\theta} + \frac{\lambda_N}{N} \partial \|\boldsymbol{\theta}\|_1, \quad (23.66)$$

where we have divided by  $N$  both sides. Taking the limit as  $N \rightarrow \infty$ , if  $\lambda_N/N \rightarrow 0$ , then we are left with the first two terms; this is exactly what we would have if the unregularized LS had been chosen as the cost function. In this case, the solution asymptotically converges<sup>4</sup> (under some general assumptions, which are assumed to hold true, here) to the true parameter vector; that is, we have strong consistency, e.g., [150].

### 1.23.13.2 The adaptive norm-weighted LASSO

There are two ways to get out of the previously stated conflict. One is to replace the  $\ell_1$  norm with a nonconvex function and this can lead to an estimator that satisfies the oracle properties simultaneously [153]. The other is to modify the  $\ell_1$  norm by replacing it with a weighted version. Recall that the weighted  $\ell_1$  norm was discussed in Section 1.23.12, as a means to assist the optimization procedure to unveil the sparse solution. Here the notion of weighted  $\ell_1$  norm comes as a necessity imposed by our willingness to satisfy the oracle properties. This gives rise to the *adaptive time-and-norm-weighted LASSO* (TNWL) cost estimator defined as<sup>5</sup>

$$\hat{\boldsymbol{\theta}} = \arg \min_{\boldsymbol{\theta} \in \mathcal{R}^l} \left\{ \sum_{j=1}^n \beta^{n-j} \left( y_j - \mathbf{x}_j^T \boldsymbol{\theta} \right)^2 + \lambda_n \sum_{i=1}^l w_i(n) |\theta_i| \right\}, \quad (23.67)$$

---

<sup>4</sup>Recall that this convergence is with probability 1.

<sup>5</sup>To emphasize that the number of training points is now increasing, we have used  $n$  in place of  $N$ . Capital  $N$  was previously used to denote a fixed number of points.

where  $\beta \leq 1$  is used as the forgetting factor to allow for tracking slow variations. The time varying weighting sequences is denoted as  $w_i(n)$ . There are different options. In [154] and under a stationary environment with  $\beta = 1$ , it is shown that if

$$w_i(n) = \frac{1}{|\theta_i^{\text{est}}|^\gamma},$$

where  $\theta_i^{\text{est}}$  is the estimate of the  $i$ th component obtained by *any*  $\sqrt{n}$ -consistent estimator, such as the unregularized LS, then for specific choices of  $\lambda_n$  and  $\gamma$  the estimator satisfies the oracle properties simultaneously. The main reasoning behind the weighted  $\ell_1$  norm is that as time goes by, and the  $\sqrt{n}$ -consistent estimator provides better and better estimates, then the weights corresponding to indices outside the true support (zero values) are inflated and those corresponding to the true support converge to a finite value. This helps the algorithm, simultaneously, to locate the support and obtain unbiased (asymptotically) estimates of the large coefficients.

Another choice for the weighing sequence is related to the so called *Smoothly Clipped Absolute Deviation* (SCAD) [153, 155]. This is defined as

$$w_i(n) = \chi_{(0, \mu_n)}(|\theta_i^{\text{est}}|) + \frac{(\alpha \mu_n - |\theta_i^{\text{est}}|)_+}{(\alpha - 1)\mu_n} \chi_{(\mu_n, \infty)}(|\theta_i^{\text{est}}|),$$

where  $\chi(\cdot)$  stands for the characteristic function,  $\mu_n = \lambda_n/n$ , and  $\alpha > 2$ . Basically, this corresponds to a quadratic spline function. It turns out, [155], that if  $\lambda_n$  is chosen to grow faster than  $\sqrt{n}$  and slower than  $n$ , the adaptive LASSO, with  $\beta = 1$  satisfies both oracle conditions, simultaneously.

A time adaptive scheme for solving the TNWL LASSO was presented in [156]. The cost function of the adaptive LASSO in (23.67) can be written as

$$J(\boldsymbol{\theta}) = \boldsymbol{\theta}^T R_n \boldsymbol{\theta} - \mathbf{r}_n^T \boldsymbol{\theta} + \lambda_n \|\boldsymbol{\theta}\|_{1,w(n)},$$

where

$$R_n := \sum_{j=1}^n \beta^{n-j} \mathbf{x}_j \mathbf{x}_j^T, \quad \mathbf{r}_n := \sum_{j=1}^n \beta^{n-j} y_j \mathbf{x}_j,$$

and  $\|\boldsymbol{\theta}\|_{1,w(n)}$  is the weighted  $\ell_1$  norm. It is straightforward to see, that

$$\mathbf{R}_n = \beta \mathbf{R}_{n-1} + \mathbf{x}_n \mathbf{x}_n^T, \quad \mathbf{r}_n = \beta \mathbf{r}_{n-1} + y_n \mathbf{x}_n.$$

The complexity for both of the previous updates, for matrices of a general structure, amounts to  $\mathcal{O}(l^2)$  multiply/add operations. One alternative is to update  $R_n$  and  $\mathbf{r}_n$  and then solve a convex optimization task for each time instant,  $n$ , using any standard algorithm. However, this is not appropriate for real time applications, due to its excessive computational cost. In [156], a time recursive version of a coordinate descent algorithm has been developed. As we have seen in Section 1.23.11.2, coordinate descent algorithms update one component at each recursive step. In [156], recursive steps are associated with time updates, as it is always the case with the time-recursive algorithms. As each new training pair  $(y_n, \mathbf{x}_n)$  is received, a single component of the unknown vector is updated. Hence, at each time instant,

a scalar optimization task has to be solved and its solution is given in closed form, which results in a simple soft thresholding operation. One of the drawbacks of the coordinate techniques is that each coefficient is updated every  $l$  time instants, which, for large values of  $l$ , can slow down convergence. Variants of the basic scheme that cope with this drawback are also addressed in [156], referred to as online cyclic coordinate descent time weighted Lasso (OCCD-TWL). If the weighted norm is to be used in place of the  $\ell_1$ , a RLS is run in parallel to provide the necessary weights; the resulting scheme is referred as (OCCD-TNWL). The complexity of the scheme is of the order of  $\mathcal{O}(l^2)$ . Computational savings are possible, if the input sequence is a time series and fast schemes for the updates of  $R_n$  and the RLS can then be exploited. However, if an RLS-type algorithm is used in parallel, the convergence of the overall scheme may be slowed down, since the RLS-type algorithm has to converge first, in order to provide reliable estimates for the weights, as pointed out before.

### 1.23.13.3 Adaptive CoSaMP algorithm (AdCoSaMP)

In [157], an adaptive version of the CoSaMP algorithm, which was presented in Section 1.23.11.1.3, was proposed. Iteration steps,  $i$ , now coincide with time updates,  $n$ , and the LS solver in Step 3c of the general CSMP scheme is replaced by an LMS one.

Let us focus first on the quantity  $X^T e^{(i-1)}$  in Step 3a of the CSMP scheme, which is used to compute the support at iteration  $i$ . In the adaptive setting and at (iteration) time  $n$ , this quantity is now “rephrased” as

$$X^T e(n-1) = \sum_{j=1}^{n-1} x_j e(j).$$

In order to make the algorithm flexible to adapt to variations of the environment, as the time index,  $n$ , increases, the previous correlation sum is modified to

$$p(n) := \sum_{j=1}^{n-1} \beta^{n-1-j} x_j e(j) = \beta p(n-1) + x_{n-1} e(n-1).$$

The LS task, constrained on the active columns that correspond to the indices in the support  $S$  in Step 3c, is performed in an adaptive rationale by involving the basic LMS recursions, i.e.,

$$\begin{aligned} \tilde{e}(n) &:= y_n - x_{n|S}^T \tilde{\theta}_{|S}(n-1), \\ \tilde{\theta}_{|S}(n) &:= \tilde{\theta}_{|S}(n-1) + \mu x_{n|S} \tilde{e}(n), \end{aligned}$$

where  $\tilde{\theta}_{|S}(\cdot)$  and  $x_{n|S}$  denote the respective subvectors corresponding to the indices in the support  $S$ . The resulting algorithm is given as follows:

#### Algorithm 4 (The AdCoSaMP Scheme).

1. Select the value of  $t = 2k$ .
2. Initialize the algorithm:  $\theta(1) = \mathbf{0}, \tilde{\theta}(1) = \mathbf{0}, p(1) = \mathbf{0}, e(1) = y_1$ .
3. Choose  $\mu$  and  $\beta$ .

4. For  $n = 2, 3, \dots$ , execute the following steps:

- a.  $\mathbf{p}(n) = \beta\mathbf{p}(n-1) + \mathbf{x}_{n-1}e(n-1)$ .
- b. Obtain the current support:

$$S = \text{supp}\{\boldsymbol{\theta}(n-1)\} \cup \left\{ \begin{array}{l} \text{indices of the } t \text{ largest} \\ \text{in magnitude components of } \mathbf{p}(n) \end{array} \right\}.$$

- c. Perform the LMS update:

$$\begin{aligned} \tilde{e}(n) &= y_n - \mathbf{x}_{n|S}^T \tilde{\boldsymbol{\theta}}_{|S}(n-1), \\ \tilde{\boldsymbol{\theta}}_{|S}(n) &= \tilde{\boldsymbol{\theta}}_{|S}(n-1) + \mu \mathbf{x}_{n|S} \tilde{e}(n). \end{aligned}$$

- d. Obtain the set  $S_k$  of the indices of the  $k$  largest components of  $\tilde{\boldsymbol{\theta}}_{|S}(n)$ .
- e. Obtain  $\boldsymbol{\theta}(n)$  such that:

$$\boldsymbol{\theta}_{|S_k}(n) = \tilde{\boldsymbol{\theta}}_{|S_k}, \quad \text{and} \quad \boldsymbol{\theta}_{|S_k^c}(n) = \mathbf{0},$$

where  $S_k^c$  is the complement set of  $S_k$ .

- f. Update the error:  $e(n) = y_n - \mathbf{x}_n^T \boldsymbol{\theta}(n)$ .

In place of the standard LMS, its normalized version can alternatively be adopted. Note that Step 4e is directly related to the hard thresholding operation.

In [157], it is shown that if the sensing matrix, which is now time dependent and keeps increasing in size, satisfies a condition similar to RIP, for each time instant, called *Exponentially Weighted Isometry Property* (ERIP), which depends on  $\beta$ , then the algorithm asymptotically satisfies an error bound, which is similar to the one that has been derived for CoSaMP in [89], plus an extra term that is due to the excess Mean Square Error, which is the price paid by replacing the LS solver by the LMS.

#### 1.23.13.4 Sparse adaptive parallel projection onto convex sets method (SpAPSM)

The APSM family of algorithms is one among the most powerful techniques for adaptive learning [149]. A major advantage of this algorithmic family is that one can readily incorporate convex constraints. The rationale behind APSM is that since our data are known to be generated by a regression model, then the unknown vector could be estimated by finding a point in the intersection of a sequence of hyperslabs, that are defined by the data points, i.e.,  $S_n[\epsilon] := \{\boldsymbol{\theta} \in \mathcal{R}^l : |y_n - \mathbf{x}_n^T \boldsymbol{\theta}| \leq \epsilon\}$ . Such a model is most natural when the noise is bounded, (which, after all, it is the case in any practical application). In case the noise is assumed unbounded, a choice of  $\epsilon$  of the order say,  $\sigma$ , can guarantee, with high probability, that the unknown solution lies inside these hyperslabs.

The APSM family builds upon the elegant philosophy that runs across the classical projections onto convex sets (POCS) theory. Recall that the basic rationale behind POCS is that starting from an arbitrary point in the space and sequentially projecting onto a *finite number* of convex sets then the sequence of projections converges, in some sense, into the intersection of all these sets, assuming this is not empty. The theory was extended to embrace the online processing setting in [158–160]. In contrast to

the classical POCS theory, here the number of the involved convex sets is *infinite*. It turns out that, under certain general conditions, a sequence of projections over all these sets also converges to a point in their intersection.

To fit the theory into our needs, the place of the aforementioned convex sets is taken by the hyperslabs, which are formed by the received training data, as mentioned before. Thus, the resulting algorithms involves (metric) projections onto these hyperslabs (see Appendix). However, when dealing with sparse vectors, there is an extra projection associated with the convex set formed by the  $\ell_1$  ball; that is,  $\|\boldsymbol{\theta}\|_1 \leq \rho$  (see, also, the LASSO formulation (23.14)). Hence, this task fits nicely in the APSM rationale and the basic recursion can be readily written, without much thought or derivation, as follows; for any arbitrarily chosen initial point  $\boldsymbol{\theta}(0)$ , define  $\forall n$ ,

$$\boldsymbol{\theta}(n) := P_{B_{\ell_1}[\delta]} \left( \boldsymbol{\theta}(n-1) + \mu_n \left( \frac{1}{q} \sum_{i=n-q+1}^n P_{S_i[\epsilon]}(\boldsymbol{\theta}(n-1)) - \boldsymbol{\theta}(n-1) \right) \right),$$

where  $P_{S_i[\epsilon]}$  is the metric projection onto the hyperslab  $S_i[\epsilon]$  (see Appendix). Note, that in the previous recursion we have used  $q$ , instead of one, hyperslabs whose metric projections are averaged out at time  $n$ . It turns out that such an averaging improves convergence significantly. Parameter  $\mu_n$  is an extrapolation parameter, which takes values in the interval  $(0, 2\mathcal{M}_n)$ , where

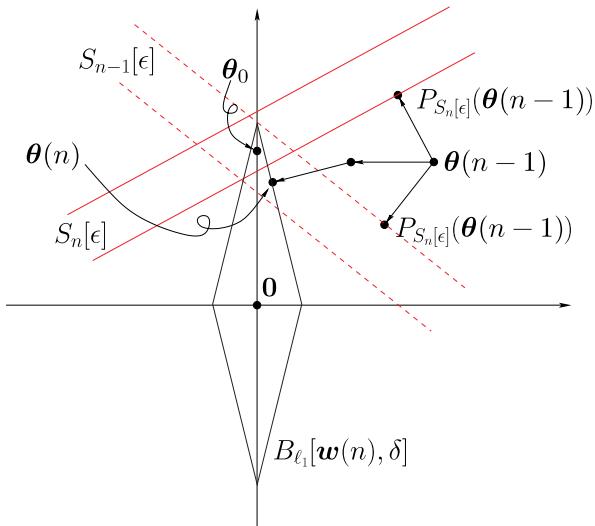

$$\mathcal{M}_n := \begin{cases} \frac{\sum_{i=n-q+1}^n \omega_i^{(n)} \|P_{S_i[\epsilon]}(\boldsymbol{\theta}(n-1)) - \boldsymbol{\theta}(n-1)\|^2}{\left\| \sum_{i=n-q+1}^n \omega_i^{(n)} P_{S_i[\epsilon]}(\boldsymbol{\theta}(n-1)) - \boldsymbol{\theta}(n-1) \right\|^2}, \\ \quad \text{if } \left\| \sum_{i=n-q+1}^n \omega_i^{(n)} P_{S_i[\epsilon]}(\boldsymbol{\theta}(n-1)) - \boldsymbol{\theta}(n-1) \right\| \neq 0, \\ 1, \quad \text{otherwise,} \end{cases} \quad (23.68)$$

and  $P_{B_{\ell_1}[\rho]}(\cdot)$  is the projection operator onto the  $\ell_1$  ball  $B_{\ell_1}[\rho] := \{\boldsymbol{\theta} \in \mathcal{R}^l : \|\boldsymbol{\theta}\|_1 \leq \rho\}$ , since the solution is constrained to live within this ball. Note, that the previous recursion is analogous to the iterative soft thresholding shrinkage algorithm in the batch processing case, (23.53). There, we saw that the only difference that the sparsity imposes on an iteration, with respect to its unconstrained counterpart, is an extra soft thresholding. This is exactly the case here. The term in the parenthesis is the iteration for the unconstrained task. Moreover, as it has been shown in [161], projection on the  $\ell_1$  ball is equivalent to a soft thresholding operation. It can be shown that the previous iteration converges arbitrarily close to a point in the intersection

$$B_{\ell_1}[\delta] \cap \bigcap_{n \geq n_0} S_n[\epsilon],$$

for some finite value of  $n_0$  [149, 158–160]. In [162, 163] the weighted  $\ell_1$  ball has been used to improve convergence as well as the tracking speed of the algorithm, when the environment is time varying. The weights were adopted in accordance to what was discussed in Section 1.23.12, i.e.,

$$w_i(n) := \frac{1}{|\theta_i(n-1)| + \epsilon_n}, \quad \forall i \in \{1, 2, \dots, l\},$$

**FIGURE 23.22**

Geometric illustration of the update steps involved in the SpAPSM algorithm, for the case of  $q = 2$ . The update at time  $n + 1$  is obtained by first convexly combining the projections onto the current and previously formed hyperslabs,  $S_n[\epsilon]$ ,  $S_{n-1}[\epsilon]$  and then projecting onto the weighted  $\ell_1$  ball. This brings the update closer to the target solution  $\theta_*$ .

where  $(\epsilon_n)_{n \geq 0}$  is a sequence (can be also constant) of small numbers to avoid division by zero. The basic time iteration becomes as follows; for any arbitrarily chosen initial point  $\theta(0)$ , define  $\forall n$ ,

$$\theta(n) := P_{B_{\ell_1}[\mathbf{w}(n), \rho]} \left( \theta(n-1) + \mu_n \left( \sum_{i=n-q+1}^n \omega_i^{(n)} P_{S_i[\epsilon]}(\theta(n-1)) - \theta(n-1) \right) \right), \quad (23.69)$$

where  $\mu_n \in (0, 2\mathcal{M}_n)$  and  $\mathcal{M}_n$  is given in (23.68). Figure 23.22 illustrates the associated geometry of the basic iteration in  $\mathbb{R}^2$  and for the case of  $q = 2$ . It comprises two parallel projections on the hyperslabs followed by one projection onto the weighted  $\ell_1$  ball. In [162], it is shown that a good bound for the weighted  $\ell_1$  norm is the sparsity level  $k$  of the target vector, which is assumed to be known and it is a user-defined parameter. In [162], it is shown that asymptotically, and under some general assumptions, this algorithmic scheme converges arbitrarily close to the intersection of the hyperslabs with the weighted  $\ell_1$  balls, i.e.,

$$\bigcap_{n \geq n_0} \left( P_{B_{\ell_1}[\mathbf{w}(n), \rho]} \cap S_j[\epsilon] \right),$$

for some non-negative integer  $n_0$ . It has to be pointed out that, in the case of weighted  $\ell_1$  norms, the constraint is *time varying* and the convergence analysis is not covered by the standard analysis used for APSM, and had to be extended to this more general case. The complexity of the algorithm amounts to  $\mathcal{O}(ql)$ . The larger the  $q$  the faster the convergence rate, at the expense of higher complexity. In [163],

in order to reduce the dependence of the complexity on  $q$ , the notion of the *sub-dimensional* projection is introduced, where projections onto the  $q$  hyperslabs could be restricted along the directions of the most significant coefficients, of the currently available estimates. The dependence on  $q$  now becomes  $\mathcal{O}(qk_n)$  where  $k_n$  is the sparsity level of the currently available estimate, which, after a few steps of the algorithm, gets much lower than  $l$ . The total complexity amounts to  $\mathcal{O}(l) + \mathcal{O}(qk_n)$ , per iteration step. This allows the use of large values of  $q$ , which drives the algorithm to a performance close to that of the adaptive weighted LASSO, at only a small extra computational cost.

#### 1.23.13.4.1 Projection onto the weighted $\ell_1$ ball

Projecting onto an  $\ell_1$  ball is equivalent to a soft thresholding operation. Projection onto the weighted  $\ell_1$  norm results to a slight variation of the soft thresholding, with different threshold values per component. In the sequel, we give the iteration steps for the more general case of the weighted  $\ell_1$  ball. The proof is a bit technical and lengthy and it will not be given here. It was derived, for the first time, via purely geometric arguments, and without the use of the classical Lagrange multipliers, in [162]. Lagrange multipliers have been used instead in [161], for the case of the  $\ell_1$  ball.

Given a point outside the ball,  $\boldsymbol{\theta} \in \mathcal{R}^l \setminus B_{\ell_1}[\mathbf{w}, \rho]$ , then its projection onto the weighted  $\ell_1$  ball is the point  $P_{B_{\ell_1}[\mathbf{w}, \rho]}(\boldsymbol{\theta}) \in B_{\ell_1}[\mathbf{w}, \rho] := \{z \in \mathcal{R}^l : \sum_{i=1}^l w_i |z_i| \leq \rho\}$ , that lies closest to  $\boldsymbol{\theta}$  in the Euclidean sense. If  $\boldsymbol{\theta}$  lies within the ball then it coincides with its projection. Given the weights and the value of  $\rho$ , the following iterations provide the projection.

**Algorithm 5 (Projection onto the weighted  $\ell_1$  ball  $B_{\ell_1}[\mathbf{w}, \rho]$ ).**

1. Form the vector  $[|\theta_1|/w_1, \dots, |\theta_l|/w_l]^T \in \mathcal{R}^l$ .
2. Sort the previous vector in a non-ascending order, so that  $|\theta_{\tau(1)}|/w_{\tau(1)} \geq \dots \geq |\theta_{\tau(l)}|/w_{\tau(l)}$ . The notation  $\tau$  stands for the permutation, which is implicitly defined by the sorting operation. Keep in memory the inverse  $\tau^{-1}$ , which is the index of the position of the element in the original vector.
3.  $r_1 := l$ .
4. Let  $m = 1$ . While  $m \leq l$ , do:
  - a.  $m_* := m$ .
  - b. Find the maximum  $j_*$  among those  $j \in \{1, 2, \dots, r_m\}$  such that  $\frac{|\theta_{\tau(j)}|}{w_{\tau(j)}} > \frac{\sum_{i=1}^{r_m} w_{\tau(i)} |\theta_{\tau(i)}| - \rho}{\sum_{i=1}^{r_m} w_{\tau(i)}^2}$ .
  - c. If  $j_* = r_m$  then break the loop.
  - d. Otherwise set  $r_{m+1} := j_*$ .
  - e. Increase  $m$  by 1 and go back to Step 4a.
5. Form the vector  $\hat{\mathbf{p}} \in \mathcal{R}^{r_{m_*}}$  whose  $j$ th component,  $j = 1, \dots, r_{m_*}$ , is given by

$$\hat{p}_j := |\theta_{\tau(j)}| - \frac{\sum_{i=1}^{r_{m_*}} w_{\tau(i)} |\theta_{\tau(i)}| - \rho}{\sum_{i=1}^{r_{m_*}} w_{\tau(i)}^2} w_{\tau(j)}.$$

6. Use the inverse mapping  $\tau^{-1}$  to insert the element  $\hat{p}_j$  into the  $\tau^{-1}(j)$  position of the  $l$ -dimensional vector  $\mathbf{p}$ ,  $\forall j \in \{1, 2, \dots, r_{m_*}\}$ , and fill in the rest with zeros.
7. The desired projection is  $P_{B_{\ell_1}[\mathbf{w}, \rho]}(\boldsymbol{\theta}) = [\text{sgn}(\theta_1) p_1, \dots, \text{sgn}(\theta_l) p_l]^T$ .

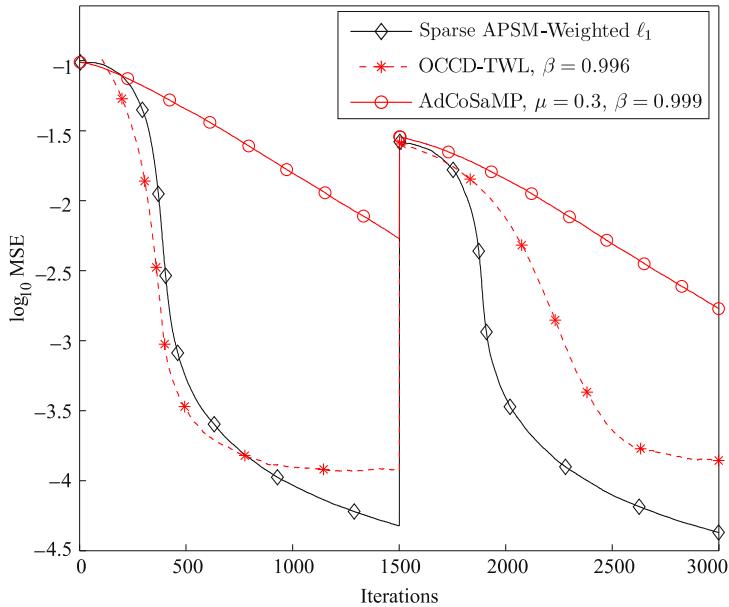

**Remarks 12.** Projections onto both  $\ell_1$  and weighted  $\ell_1$  balls impose convex sparsity inducing constraints via properly performed soft thresholding operations. More recent advances within the SpAPSM framework [164], allow the substitution of  $P_{B_{\ell_1}[\rho]}$  and  $P_{B_{\ell_1}[w, \rho]}$  with a *generalized thresholding*, built around the notions of SCAD, non-negative garrote, as well as a number of thresholding functions corresponding to the non-convex,  $\ell_p$ ,  $p < 1$  penalties. Moreover, it is shown that such generalized thresholding operators (GT) are nonlinear mappings with their fixed point set being a union of subspaces, i.e., the non-convex object which lies at the heart of any sparsity-promoting technique. Such schemes are very useful for low values of  $q$ , where one can improve upon the performance obtained by the LMS-based AdCoSAMP, at comparable complexity levels.

**Example 7 (Time varying signal).** In this example, the performance curves of the most typical online algorithms, mentioned before, are studied in the context of a time varying environment. A typical simulation setup, which is commonly adopted by the adaptive filtering community, in order to study the tracking agility of an algorithm, is that of an unknown vector which undergoes an abrupt change after a number of observations. Here, we consider a signal,  $s$ , with a sparse wavelet representation, i.e.,  $s = \Phi\theta$ , where  $\Phi$  is the corresponding transformation matrix. In particular, we set  $l = 1024$  with 100 nonzero wavelet coefficients. After 1500 measurements (observations), ten arbitrarily picked wavelet coefficients change their values to new ones selected uniformly at random from the interval  $[-11]$ . Note that this may affect the sparsity level of the signal, and we can now end with up to 110 nonzero coefficients. A total of  $N = 3000$  sensing vectors are used, which result from the wavelet transform of the input vectors  $x_n \in \mathcal{R}^l$ ,  $n = 1, 2, \dots, 3000$ , having elements drawn from  $\mathcal{N}(0, 1)$ . In this way, the adaptive algorithms do not estimate the signal itself, but its sparse wavelet representation,  $\theta$ . The observations are corrupted by additive white Gaussian noise of variance  $\sigma_n^2 = 0.1$ . Regarding SpAPSM, the extrapolation parameter  $\mu_n$  is set equal to  $1.8 \times \mathcal{M}_n$ , the hyperslabs parameter  $\epsilon$  was set equal to  $1.3\sigma_n$  and  $q = 390$ . The parameters for all algorithms were selected in order to optimize their performance. Since the sparsity level of the signal may change (from  $k = 100$  up to  $k = 110$ ) and since in practice it is not possible to know in advance the exact value of  $k$ , we feed the algorithms with an overestimate,  $\hat{k}$ , of the true sparsity value and in particular we used  $\hat{k} = 150$  (i.e., 50% overestimation up to the 1500th iteration).

The results are shown in Figure 23.23. Note the enhanced performance obtained via the SpAPSM algorithm. However, it has to be pointed out that the complexity of the AdCoSAMP is much lower compared to the other two algorithms, for the choice of  $q = 390$  for the SpAPSM. The interesting observation is that SpAPSM achieves a better performance compared to OCCD-TWL, albeit at significantly lower complexity. If on the other hand complexity is of major concern, as it has already been pointed out in 12, use of SpAPSM offers the flexibility to use GT operators, which lead to improved performance for small values of  $q$  at complexity comparable to that of LMS-based sparsity promoting algorithms [165].

### 1.23.14 Learning sparse analysis models

All our discussion, so far, has been exhausted in the terrain of signals which are either sparse themselves or they can be sparsely represented in terms of the atoms of a dictionary in a synthesis model, as

**FIGURE 23.23**

MSE learning curves for AdCoSAMP, SpAPSM and OCCD-TWL for the simulation example discussed in 7. The vertical axis shows the  $\log_{10}$  of the Mean Squares Error, i.e.,  $\log_{10} \left( \frac{1}{2} \|\mathbf{s} - \Phi\theta(n)\|_2^2 \right)$  and the horizontal shows the time index. At time  $n = 1500$ , the system undergoes a sudden change.

introduced in (23.23), i.e.,

$$\mathbf{s} = \sum_{i \in \mathcal{I}} \theta_i \psi_i.$$

As a matter of fact, most of the research activity over the last decade or so has been focused on the synthesis model. This may be partly due to the fact that the synthesis modeling path may provide a more intuitively appealing structure to describe the generation of the signal in terms of the elements (atoms) of a dictionary. Recall from Section 1.23.10 that the sparsity assumption was imposed on  $\theta$  in the synthesis model and the corresponding optimization task was formulated in (23.45) and (23.46) for the exact and noisy cases, respectively.

However, this is not the only way to attack the task of sparsity modeling. Very early in this paper, in Section 1.23.5, we referred to the analysis model,

$$\mathbf{S} = \Phi^H \mathbf{s}$$

and pointed out that in a number of real life applications the resulting transform  $\mathbf{S}$  is sparse. To be fair, for such an experimental evidence, the most orthodox way to deal with the underlying model sparsity would be to consider  $\|\Phi^H \mathbf{s}\|_0$ . Thus, if one wants to estimate  $\mathbf{s}$ , a very natural way would be to cast the

related optimization task as

$$\begin{aligned} \min_s \quad & \left\| \Phi^H s \right\|_0, \\ \text{s.t. } & y = Xs, \quad \text{or} \quad \|y - Xs\|_2^2 \leq \epsilon, \end{aligned} \quad (23.70)$$

depending on whether the measurements via a sensing matrix,  $X$ , are exact or noisy. Strictly speaking, the total variation minimization approach, which was used in Example 6, falls under this analysis model formulation umbrella, since what is minimized is the  $\ell_1$  norm of the gradient transform of the image.

The optimization tasks in either of the two formulations given in (23.70) build around the assumption that the signal of interest has *sparse analysis representation*. The obvious question that is now raised is whether the optimization tasks in (23.70) and their counterparts in (23.45) or (23.46) are any different. One of the first efforts to shed light in this problem was in [166]. There, it was pointed out that the two tasks, although related, yet they are in general different. Moreover, their comparative performance depends on the specific problem at hand. However, it is fair to say that this is a new field of research and more definite conclusions are currently being shaped. An easy answer can be obtained for the case where the involved dictionary corresponds to an orthonormal transformation matrix, e.g., DFT. In this case, we already know that the analysis and synthesis matrices are related as

$$\Phi = \Psi = \Psi^{-H},$$

which leads to an equivalence between the two previously stated formulations. Indeed, for such a transform we have

$$\underbrace{S = \Phi^H s}_{\text{Analysis}} \Leftrightarrow \underbrace{s = \Phi S}_{\text{Synthesis}}.$$

Using the last formula into the (23.70), the tasks in (23.45) or (23.46) are readily obtained by replacing  $\theta$  by  $s$ . However, this reasoning cannot be carried out to the case of overcomplete dictionaries; it is for these cases, where the two optimization tasks may lead to different solutions.

The previous discussion, concerning the comparative performance between the synthesis or analysis-based sparse representations, is not only of a “philosophical” value. It turns out that, often in practice, the nature of certain overcomplete dictionaries does not permit the use of the synthesis based formulation. These are the cases where the columns of the overcomplete dictionary exhibit high degree of dependence; that is, the coherence of the matrix, as defined in Section 1.23.7.1, has large values. Typical examples of such overcomplete dictionaries are the Gabor frames, the curvelet frames and the oversampled DFT. The use of such dictionaries lead to enhanced performance in a number of applications, e.g., [167, 168]. Take as an example the case of our familiar DFT transform. This transform provides a representation of our signal samples in terms of sampled exponential sinusoids, whose frequencies are multiples of  $\frac{2\pi}{lT}$ , where  $T$  is the sampling frequency and  $lT$  is the length of our signal segment  $s$ ; that is,

$$s := \begin{bmatrix} s(0) \\ s(T) \\ \vdots \\ s((l-1)T) \end{bmatrix} = \sum_{i=0}^{l-1} S_i \psi_i, \quad (23.71)$$

where  $S_i$  are the DFT coefficients and  $\psi_i$  is the sampled sinusoid with frequency equal to  $\frac{2\pi}{T}i$ , i.e.,

$$\psi_i = \begin{bmatrix} 1 \\ \exp(-j\frac{2\pi}{T}iT) \\ \vdots \\ \exp(-j\frac{2\pi}{T}i(l-1)T) \end{bmatrix}. \quad (23.72)$$

However, this is not necessarily the most efficient representation. For example, it is highly unlikely that a signal comprises only frequencies which are multiples of the basic one; only such signals can result in a sparse representation using the DFT basis. Most probably, in general, there will be frequencies lying in between the frequency samples of the DFT basis, which result in non-sparse representations. Using these extra frequencies, a much better representation of the frequency content of the signal can be obtained. However, in such a dictionary the atoms are no more linearly independent and the coherence of the respective (dictionary) matrix increases.

Once a dictionary exhibits high coherence, then there is no way of finding a sensing matrix,  $X$ , so that  $X\Psi$  to obey the RIP. Recall that at the heart of the sparsity-aware learning lies the concept of stable embedding, that allows the recovery of a vector/signal after projecting it in a lower dimensional space; this is what all the available conditions, e.g., RIP, guarantee. However, no stable embedding is possible with highly coherent dictionaries. Take as an extreme example the case where the first and second atoms are identical. Then no sensing matrix  $X$  can achieve a signal recovery that distinguishes the vector  $[1, 0, \dots, 0]^T$  from  $[0, 1, 0, \dots, 0]^T$ . Can then one conclude that for highly coherent overcomplete dictionaries compressed sensing techniques are not possible? Fortunately, the answer to this is negative. After all, our goal in compressed sensing has always been the recovery of the signal  $s = \Psi\theta$  and not the identification of the sparse vector  $\theta$  in the synthesis model representation. The latter was just a means to an end. While the unique recovery of  $\theta$  cannot be guaranteed for highly coherent dictionaries, this does not necessarily cause any problems for the recovery of  $s$ , using a small set of measurement samples. The escape route will come by considering the analysis model formulation. However, prior to this treatment, it will be of no harm to refresh our basics concerning the theory of *frames* and recall some key definitions.

### 1.23.14.1 Some hints from the theory of frames

In order to remain in the same framework as the one already adopted for this paper and comply with the notation previously used, we will adhere to the real data case, although everything we are going to say is readily extended to the complex case, by replacing transposition with its Hermitian counterpart.

A frame in a vector space<sup>6</sup>  $V \subseteq \mathcal{R}^l$  is a generalization of the notion of a basis. Recall from our linear algebra basics that a *basis* is a set of vectors  $\psi_i, i \in \mathcal{I}$ , with the following two properties: (a)  $V = \text{span}\{\psi_i : i \in \mathcal{I}\}$ , where the cardinality  $\text{card}(\mathcal{I}) = l$  and (b)  $\psi_i, i \in \mathcal{I}$ , are mutually independent. If, in addition,  $\langle \psi_i, \psi_j \rangle = \delta_{i,j}$  then the basis is known as orthonormal. If we now relax the second condition and allow  $l < \text{card}(\mathcal{I}) := p$ , we introduce redundancy in the signal representations,

---

<sup>6</sup>We constrain our discussion in this section to finite dimensional Euclidean spaces. The theory of frames has been developed for general Hilbert spaces.

which, as it has already been mentioned, can offer a number of advantages in a wide range of applications. However, once redundancy is introduced we lose uniqueness in the signal representation

$$\mathbf{s} = \sum_{i \in \mathcal{I}} \theta_i \boldsymbol{\psi}_i, \quad (23.73)$$

due to the dependency among the vectors  $\boldsymbol{\psi}_i$ . The question that is now raised is whether there is a simple and systematic way to compute the coefficients  $\theta_i$  in the previous expansion.

**Definition 4.** The set  $\boldsymbol{\psi}_i, i \in \mathcal{I}$ , which spans a vector space,  $V$ , is called a *frame* if there exist positive real numbers,  $A$  and  $B$ , such that for any nonzero  $\mathbf{s} \in V$ ,

$$0 < A \|\mathbf{s}\|_2^2 \leq \sum_{i \in \mathcal{I}} |\langle \boldsymbol{\psi}_i, \mathbf{s} \rangle|^2 \leq B \|\mathbf{s}\|_2^2, \quad (23.74)$$

where  $A$  and  $B$  are known as the bounds of the frame.

Note that if  $\boldsymbol{\psi}_i, i \in \mathcal{I}$ , comprise an orthonormal basis, then  $A = B = 1$  and (23.74) is the celebrated Parseval's theorem. Thus, (23.74) can be considered as a generalization of Parseval's theorem. Looking at it more carefully, we notice that this is a stability condition that closely resembles our familiar RIP condition in (23.36). Indeed, the upper bound guarantees that the expansion never diverges (this applies to infinite dimensional spaces) and the lower bound guarantees that no nonzero vector,  $\|\mathbf{s}\| \neq 0$ , will ever become zero after projecting it along the atoms of the frame. To look at it from a slightly different perspective, form the dictionary matrix

$$\Psi = [\boldsymbol{\psi}_1, \boldsymbol{\psi}_2, \dots, \boldsymbol{\psi}_p],$$

where we used  $p$  to denote the cardinality of  $\mathcal{I}$ . Then, the lower bound in (23.74) guarantees that  $\mathbf{s}$  can be reconstructed from its transform samples  $\Psi^T \mathbf{s}$ ; note that in such a case, if  $s_1 \neq s_2$ , then their respective transform values will be different.

It can be shown that if condition (23.74) is valid, then there exists another set of vectors,  $\tilde{\boldsymbol{\psi}}_i, i \in \mathcal{I}$ , known as the *dual frame*, with the following elegant property

$$\mathbf{s} = \sum_{i \in \mathcal{I}} \langle \tilde{\boldsymbol{\psi}}_i, \mathbf{s} \rangle \boldsymbol{\psi}_i = \sum_{i \in \mathcal{I}} \langle \boldsymbol{\psi}_i, \mathbf{s} \rangle \tilde{\boldsymbol{\psi}}_i, \quad \forall \mathbf{s} \in V. \quad (23.75)$$

Once a dual frame is available, the coefficients in the expansion of a vector in terms of the atoms of a frame are easily obtained. If we form the matrix  $\tilde{\Psi}$  of the dual frame vectors, then it is easily checked out that since condition (23.75) is true for any  $\mathbf{s}$ , it implies that

$$\tilde{\Psi} \Psi^T = \Psi \tilde{\Psi}^T = I, \quad (23.76)$$

where  $I$  is the  $l \times l$  identity matrix. Note that all of us have used the property in (23.75), possibly in a disguised form, many times in our professional life. Indeed, consider the simple case of two independent vectors in the two-dimensional space (in order to make things simple). Then, (23.73) becomes

$$\mathbf{s} = \theta_1 \boldsymbol{\psi}_1 + \theta_2 \boldsymbol{\psi}_2 = \Psi \boldsymbol{\theta}.$$

Solving for the unknown  $\theta$  is nothing but the solution of a linear set of equations; note that the involved matrix  $\Psi$  is invertible. Let us rephrase a bit our familiar solution

$$\theta = \Psi^{-1}s := \tilde{\Psi}s := \begin{bmatrix} \tilde{\psi}_1^T \\ \tilde{\psi}_2^T \end{bmatrix} s, \quad (23.77)$$

where  $\tilde{\psi}_i^T$ ,  $i = 1, 2$ , are the rows of the inverse matrix. Using now the previous notation, it is readily seen that

$$s = \langle \tilde{\psi}_1, s \rangle \psi_1 + \langle \tilde{\psi}_2, s \rangle \psi_2.$$

Moreover, note that in this special case of independent vectors, the respective definitions imply

$$\begin{bmatrix} \tilde{\psi}_1^T \\ \tilde{\psi}_2^T \end{bmatrix} [\psi_1, \psi_2] = I,$$

and the dual frame is not only unique but it also fulfills the *biorthogonality* condition, i.e.,

$$\langle \tilde{\psi}_i, \psi_j \rangle = \delta_{i,j}. \quad (23.78)$$

In the case of a general frame, the dual frames are neither biorthogonal nor uniquely defined. The latter can also be verified by the condition (23.76) that defines the respective matrices.  $\Psi^T$  is a rectangular tall matrix and its left inverse is not unique. There is, however, a uniquely defined dual frame, known as the *canonical* dual frame, given as

$$\tilde{\psi}_i := (\Psi\Psi^T)^{-1}\psi_i, \quad \text{or} \quad \tilde{\Psi} := (\Psi\Psi^T)^{-1}\Psi. \quad (23.79)$$

Another family of frames of special type are the so-called *tight frames*. For tight frames, the two bounds in (23.74) are equal, i.e.,  $A = B$ . Thus, once a tight frame is available, we can normalize each vector in the frame as

$$\psi_i \mapsto \frac{1}{\sqrt{A}}\psi_i,$$

which then results to the so-called *Parseval tight frame*; the condition (23.74) now becomes similar in appearance with our familiar Parseval's theorem for orthonormal bases

$$\sum_{i \in \mathcal{I}} |\langle \psi_i, s \rangle|^2 = \|s\|_2^2. \quad (23.80)$$

Moreover, it can be shown that a Parseval tight frame coincides with its canonical dual frame (that is, it is self dual) and we can write

$$s = \sum_{i \in \mathcal{I}} \langle \psi_i, s \rangle \psi_i,$$

or in matrix form

$$\tilde{\Psi} = \Psi, \quad (23.81)$$

which is similar with what we know for orthonormal bases; however in this case, orthogonality does not hold.

We will conclude this subsection with a simple example of a Parseval (tight) frame, known as the *Mercedes Benz (MB)*,

$$\Psi = \begin{bmatrix} 0 & -\frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \\ \sqrt{\frac{2}{3}} & -\frac{1}{\sqrt{6}} & -\frac{1}{\sqrt{6}} \end{bmatrix}.$$

One can easily check that all the properties of a Parseval tight frame are fulfilled. If constructing a frame, especially in high dimensional spaces, may sound a bit difficult, the following theorem (due to Naimark, see, e.g., [169]) offers a systematic way for such constructions.

**Theorem 6.** *A set  $\{\psi_i\}_{i \in \mathcal{I}}$  in a Hilbert space  $\mathcal{H}_s$  is a Parseval tight frame, if and only if it can be obtained via orthogonal projection,  $P_{\mathcal{H}_s} : \mathcal{H} \rightarrow \mathcal{H}_s$ , of an orthonormal basis  $\{e_i\}_{i \in \mathcal{I}}$  in a larger Hilbert space  $\mathcal{H}$ , such that  $\mathcal{H}_s \subset \mathcal{H}$ .*

To verify the theorem, check that the MB frame is obtained by orthogonally projecting the three-dimensional orthonormal basis

$$e_1 = \begin{bmatrix} 0 \\ -\frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} \end{bmatrix}, \quad e_2 = \begin{bmatrix} \sqrt{\frac{2}{3}} \\ -\frac{1}{\sqrt{6}} \\ -\frac{1}{\sqrt{6}} \end{bmatrix}, \quad e_3 = \begin{bmatrix} \frac{1}{\sqrt{3}} \\ \frac{1}{\sqrt{3}} \\ \frac{1}{\sqrt{3}} \end{bmatrix},$$

using the projection matrix

$$P_{\mathcal{H}_s} := \begin{bmatrix} \frac{2}{3} & -\frac{1}{3} & -\frac{1}{3} \\ \frac{1}{3} & \frac{2}{3} & -\frac{1}{3} \\ -\frac{1}{3} & \frac{1}{3} & \frac{2}{3} \\ -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} \end{bmatrix}.$$

Observe that the effect of the projection

$$P_{\mathcal{H}_s}[e_1, e_2, e_3] = \Psi^T,$$

is to set  $e_3$  to the zero vector.

Frames were introduced by Duffin and Schaeffer in their study on nonharmonic Fourier series in 1952 [170] and they remained rather obscured till they were used in the context of wavelet theory, e.g., [171]. The interested reader can obtain the proofs of what has been said in this section from these references. An introductory review with a lot of engineering flavor can be found in [172], where the major references in the field are given.

### 1.23.14.2 Compressed sensing for signals sparse in coherent dictionaries

Our goal in this subsection is to establish conditions that guarantee recovery of a signal vector, which accepts a sparse representation in a redundant and coherent dictionary, using a small number of signal-related measurements. Let the dictionary at hand be a tight frame,  $\Psi$ . Then, our signal vector is written as

$$\mathbf{s} = \Psi\boldsymbol{\theta}, \quad (23.82)$$

where  $\boldsymbol{\theta}$  is assumed to be  $k$ -sparse. Recalling the properties of a tight frame, as they were summarized in the previous subsection, the coefficients in the expansion (23.82) can be written as  $\langle \psi_i, \mathbf{s} \rangle$ , and the respective vector as

$$\boldsymbol{\theta} = \Psi^T \mathbf{s},$$

since a tight frame is self dual. Then, the analysis counterpart of the synthesis formulation in (23.46) can be cast as

$$\begin{aligned} \min_{\mathbf{s}} \quad & \left\| \Psi^T \mathbf{s} \right\|_1, \\ \text{s.t.} \quad & \|\mathbf{y} - X\mathbf{s}\|_2^2 \leq \epsilon. \end{aligned} \quad (23.83)$$

The goal now is to investigate the accuracy of the recovered solution to this convex optimization task. It turns out that similar strong theorems are also valid for this problem as with the case of the synthesis formulation, which was studied earlier.

**Definition 5.** Let  $\Sigma_k$  be the union of all subspaces spanned by all subsets of  $k$  columns of  $\Psi$ . A sensing matrix,  $X$ , obeys the restricted isometry property adapted to  $\Psi$ , ( $\Psi$ -RIP) with  $\delta_k$ , if

$$(1 - \delta_k) \|\mathbf{s}\|_2^2 \leq \|X\mathbf{s}\|_2^2 \leq (1 + \delta_k) \|\mathbf{s}\|_2^2, \quad (23.84)$$

for all  $\mathbf{s} \in \Sigma_k$ .

The union of subspaces,  $\Sigma_k$ , is the image under  $\Psi$  of all  $k$ -sparse vectors. This is the difference with the RIP definition given in Section 1.23.8.2. All the random matrices discussed earlier in this paper can be shown to satisfy this form of RIP, with overwhelming probability, provided the number of measurements,  $N$ , is at least of the order of  $k \ln(p/k)$ . We are now ready to establish the main theorem concerning our  $\ell_1$  minimization task.

**Theorem 7.** Let  $\Psi$  be an arbitrary tight frame and  $X$  a sensing matrix that satisfies the  $\Psi$ -RIP with  $\delta_{2k} \leq 0.08$ , for some positive  $k$ . Then the solution,  $\mathbf{s}_*$ , of the minimization task in (23.83) satisfies the following property

$$\|\mathbf{s} - \mathbf{s}_*\|_2 \leq C_0 k^{-\frac{1}{2}} \left\| \Psi^T \mathbf{s} - (\Psi^T \mathbf{s})_k \right\|_1 + C_1 \sqrt{\epsilon}, \quad (23.85)$$

where  $C_0, C_1$  are constants depending on  $\delta_{2k}$ ,  $(\Psi^T \mathbf{s})_k$  denotes the best  $k$ -sparse approximation of  $\Psi^T \mathbf{s}$ ; i.e., it results by setting all but the  $k$  largest in magnitude components of  $\Psi^T \mathbf{s}$  equal to zero.

The bound in (23.85) is the counterpart of that given in (23.43). In other words, the previous theorem states that if  $\Psi^T \mathbf{s}$  decays rapidly, then  $\mathbf{s}$  can be reconstructed from just a few (compared to the signal length  $l$ ) measurements. The theorem was first given in [173] and it is the first time that such a theorem provides results for the sparse analysis model formulation in a general context.

### 1.23.14.3 Cosparsity

In [174], the task of sparse analysis modeling was approached via an alternative route, employing the tools which were developed in [137, 175] for treating general union-of-subspaces models. This complementary point of view will also unveil different aspects of the problem by contributing to its deeper understanding. We have done it before, where the notions of spark, coherence and RIP were all mobilized to shed light from different corners to the sparse synthesis modeling task.

In the sparse synthesis formulation, one searches for a solution in a union of subspaces, which are formed by all possible combinations of  $k$  columns of the dictionary,  $\Psi$ . Our signal vector lies in one of these subspaces; the one which is spanned by the columns of  $\Psi$  whose indices lie in the support set (Section 1.23.11.1). In the sparse analysis approach things get different. The kick off point is the sparsity of the transform  $S := \Phi^T s$ , where  $\Phi$  defines the transformation matrix or analysis operator. Since  $S$  is assumed to be sparse, there exists an index set  $\mathcal{I}$  such that  $\forall i \in \mathcal{I}, S_i = 0$ . In other words,  $\forall i \in \mathcal{I}, \langle \phi_i^T s \rangle := \langle \phi_i, s \rangle = 0$ , where  $\phi_i$  stands for the  $i$ th column of  $\Phi$ . Hence, the subspace in which  $s$  lives is the orthogonal complement of the subspace formed by those columns of  $\Phi$ , which correspond to a zero in the transform vector  $S$ . Assume, now, that  $\text{card}(\mathcal{I}) = C_o$ . The signal,  $s$ , can be identified by searching on the *orthogonal complements* of the subspaces formed by all possible combinations of  $C_o$  columns of  $\Phi$ , i.e.,

$$\langle \phi_i, s \rangle = 0, \quad \forall i \in \mathcal{I}.$$

The difference between the synthesis and analysis problems is illustrated in Figure 23.24. To facilitate the theoretical treatment of this new setting, the notion of *cosparsity* was introduced in [174].

**Definition 6.** The cosparsity of a signal  $s \in \mathbb{R}^l$  with respect to a  $p \times l$  matrix  $\Phi^T$  is defined as

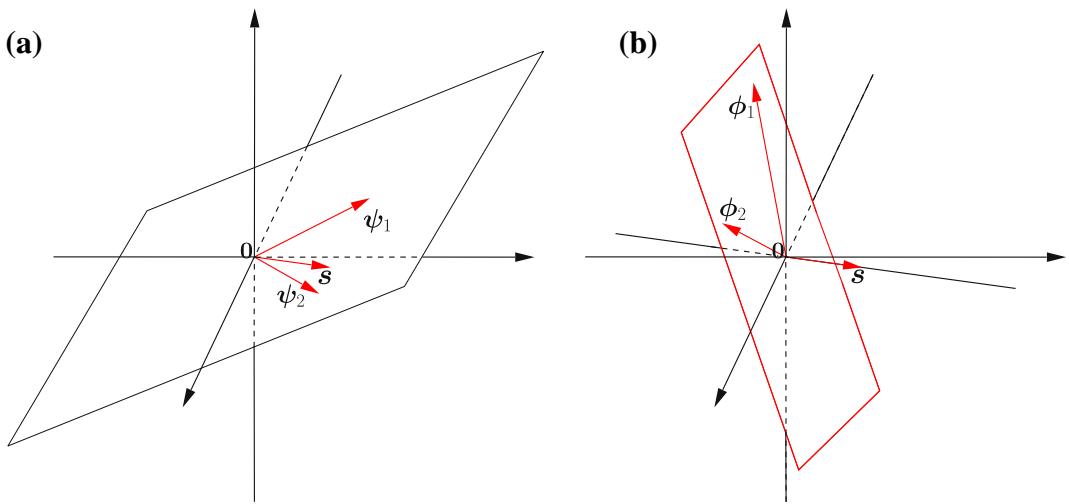

$$C_o := p - \left\| \Phi^T s \right\|_0. \quad (23.86)$$

In words, the cosparsity is the number of zeros in the obtained transform vector  $S = \Phi^T s$ ; in contrast, the sparsity measures the number of the nonzero elements of the respective sparse vector. If one assumes that  $\Phi$  has “full spark,”<sup>7</sup> i.e.,  $l + 1$ , then any  $l$  of the columns of  $\Phi$ , and thus any  $l$  rows of  $\Phi^T$  are guaranteed to be independent. This indicates that for such matrices, the maximum value that cosparsity can take is equal to  $C_o = l - 1$ . Otherwise, the existence of  $l$  zeros will necessarily correspond to a zero signal vector. Higher cosparsity levels are possible, by relaxing the full spark requirement.

Let now the cosparsity of our signal with respect to a matrix  $\Phi^T$  be  $C_o$ . Then, in order to dig out the signal from the subspace in which is hidden, one must form all possible combinations of  $C_o$  columns of  $\Phi$  and search in their orthogonal complements. In case that  $\Phi$  is full rank, we have seen previously that  $C_o < l$ , and hence any set of  $C_o$  columns of  $\Phi$  are linearly independent. In other words, the dimension of the span of those columns is  $C_o$ . As a result, the dimensionality of the orthogonal complement, into which we search for  $s$ , is  $l - C_o$ .

We have by now accumulated enough information to elaborate a bit more on the statement made before, concerning the different nature of the synthesis and analysis tasks. Let us consider a synthesis task using an  $l \times p$  dictionary and let  $k$  be the sparsity level in the corresponding expansion of a signal in terms of this dictionary. The dimensionality of the subspaces in which the solution is sought is  $k$

<sup>7</sup>Recall by Definition 2 that  $\text{spark}(\Phi)$  is defined for an  $l \times p$  matrix  $\Phi$  with  $p \geq l$  and of full rank.

**FIGURE 23.24**

Searching for a sparse vector  $s$ . (a) In the synthesis model, the sparse vector lies in subspaces formed by combinations of  $k$  (in this case  $k = 2$ ) columns of the dictionary  $\Psi$ . (b) In the analysis model, the sparse vector lies in the orthogonal compliment of the subspace formed by  $C_o$  (in this case  $C_o = 2$ ) columns of the transformation matrix  $\Phi$ .

( $k$  is assumed to be less than the spark of the respective matrix). Let us keep the same dimensionality for the subspaces in which we are going to search for a solution in an analysis task. Hence, in this case  $C_o = l - k$  (assuming a full spark matrix). Also, for the sake of comparison, assume that the analysis matrix is  $p \times l$ . Solving the synthesis task, one has to search  $\binom{p}{k}$  subspaces, while solving the analysis

task one has to search for  $\binom{p}{C_o = l - k}$  subspaces. These are two different numbers; assuming that  $k \ll l$  and also that  $l < p/2$ , which are natural assumptions for overcomplete dictionaries, then the latter of the two numbers is much larger than the former one (use your computer to play with some typical values). In other words, there are much more analysis than synthesis low-dimensional subspaces to be searched for. The large number of low-dimensional subspaces makes the algorithmic recovery of a solution from the analysis model a tougher task, [174]. However, it might reveal a much stronger descriptive power of the analysis model compared to the synthesis one.

Another interesting aspect that highlights the difference between the two approaches is the following. Assume that the synthesis and analysis matrices are related as  $\Phi = \Psi$ , as it was the case for tight frames. Under this assumption,  $\Phi^T s$  provides a set of coefficients for the synthesis expansion in terms of the atoms of  $\Phi = \Psi$ . Moreover, if  $\|\Phi^T s\|_0 = k$ , then the  $\Phi^T s$  is a possible  $k$ -sparse solution for the synthesis model. However, there is no guarantee that this is the sparsest one.

It is now the time to investigate whether conditions that guarantee uniqueness of the solution for the sparse analysis formulation can be derived. The answer is affirmative and it has been established in [174], for the case of exact measurements.

**Lemma 5.** Let  $\Phi$  be a transformation matrix of full spark. Then, for almost all  $N \times l$  sensing matrices and for  $N > 2(l - C_o)$ , the equation

$$\mathbf{y} = \mathbf{X}\mathbf{s},$$

has at most one solution with cosparcity at least  $C_o$ .

The above lemma guarantees the uniqueness of the solution, if one exists, of the following optimization

$$\begin{aligned} \min_{\mathbf{s}} \quad & \|\Phi^T \mathbf{s}\|_0 \\ \text{s.t. } & \mathbf{y} = \mathbf{X}\mathbf{s}. \end{aligned} \tag{23.87}$$

However, solving the previous  $\ell_0$  minimization task is a difficult one and we know that its synthesis counterpart has been shown to be NP-hard, in general. Its relaxed convex relative is the  $\ell_1$  minimization

$$\begin{aligned} \min_{\mathbf{s}} \quad & \|\Phi^T \mathbf{s}\|_1 \\ \text{s.t. } & \mathbf{y} = \mathbf{X}\mathbf{s}. \end{aligned} \tag{23.88}$$

In [174], conditions are derived that guarantee the equivalence of the  $\ell_0$  and  $\ell_1$  tasks, in (23.87) and (23.88), respectively; this is done in a way similar to that for the sparse synthesis modeling. Also, in [174], a greedy algorithm inspired by the Orthogonal Matching Pursuit, discussed in Section 1.23.11.1, has been derived. Other algorithms that solve the  $\ell_1$  optimization in the analysis modeling framework can be found in, e.g., [176–178]. NESTA can also be used for the analysis formulation.

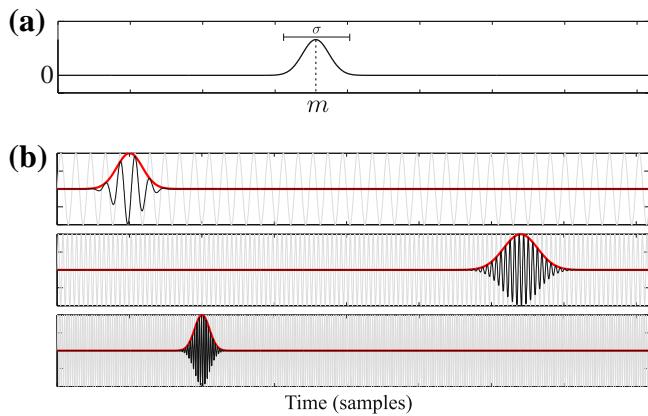

## 1.23.15 A case study: time-frequency analysis

The goal of this section is to demonstrate how all the previously stated theoretical findings can be exploited in the context of a real application. Sparse modeling has been applied to almost everything. So, picking up a typical application would not be easy. We preferred to focus on a less “publicized” application; that of analyzing echolocation signals emitted by bats. However, the analysis will take place within the framework of time-frequency representation, which is one of the research areas that significantly inspired the evolution of compressed sensing theory. Time-Frequency analysis of signals has been the field of intense research for a number of decades, and it is one of the most powerful signal processing tools. Typical applications include speech processing, sonar sounding, communications, biological signals, EEG processing, to name but a few, see, e.g., [179, 180].

### 1.23.15.1 Gabor transform and frames

It is not our intention to present the theory behind the Gabor transform. Our goal is to outline some basic related notions and use it as a vehicle for the less familiar reader so that (a) to better understand how redundant dictionaries are used and (b) get more acquainted with their potential performance benefits.

The Gabor transform was introduced in the middle 1940s by Dennis Gabor (1900–1979), who was a Hungarian-British engineer. His most notable scientific achievement was the invention of holography, for which he won the Nobel prize for Physics in 1971. The discrete version of the Gabor transform can

**FIGURE 23.25**

(a) The Gaussian window with spreading factor  $\sigma$  centered at time instant  $m$ . (b) Pulses obtained by windowing three different sinusoids with Gaussian windows of different spread and applied at different time instants.

be seen as a special case of the Short Time Fourier Transform (STFT), e.g., [180, 181]. In the standard DFT transform, the full length of a time sequence, comprising  $l$  samples, is used all in “one-go” in order to compute the corresponding frequency content. However, the latter can be time varying, so the DFT will provide an average information, which cannot be of much use. The Gabor transform (and the STFT in general) introduces time localization via the use of a window function, which slides along the signal segment in time, and at each time instant focusses on a different part of the signal; this is a way that allows one to follow the slow time variations, which take place in the frequency domain. The time localization in the context of the Gabor transform is achieved via a Gaussian window function, i.e.,

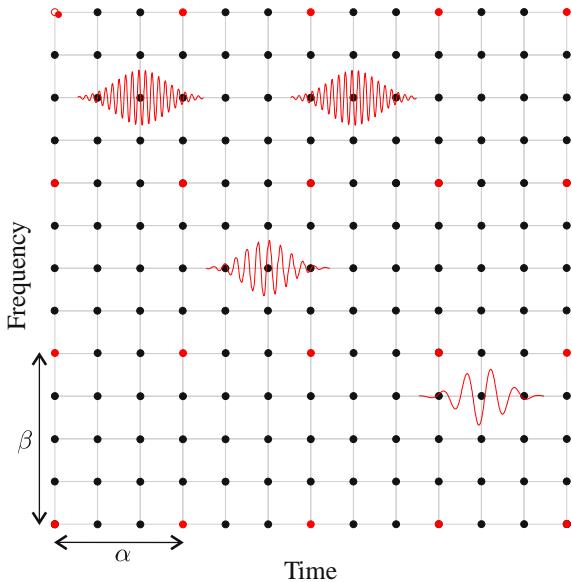

$$g(n) := \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{n^2}{2\sigma^2}\right). \quad (23.89)$$

Figure 23.25a shows the Gaussian window,  $g(n - m)$ , centered at time instant  $m$ . The choice of the window spreading factor,  $\sigma$ , will be discussed later on.

Let us now construct the atoms of the Gabor dictionary. Recall that in the case of the signal representation in terms of the DFT in (23.71), each frequency is represented only once, by the corresponding sampled sinusoid, (23.72). In the Gabor transform, each frequency appears  $l$  times; the corresponding sampled sinusoid is multiplied by the Gaussian window sequence, each time shifted by one sample. Thus, at the  $i$ th frequency bin, we have  $l$  atoms,  $g^{(m,i)}$ ,  $m = 0, 1, \dots, l - 1$ , with elements given by

$$g^{(m,i)}(n) = g(n - m)\psi_i(n), \quad n, m, i = 0, 1, \dots, l - 1, \quad (23.90)$$

where  $\psi_i(n)$  is the  $n$ th element of the vector  $\psi_i$  in (23.72). This results to an overcomplete dictionary comprising  $l^2$  atoms in the  $l$ -dimensional space. Figure 23.25b illustrates the effect of multiplying different sinusoids with Gaussian pulses of different spread and at different time delays. Figure 23.26

**FIGURE 23.26**

Each atom of the Gabor dictionary corresponds to a node in the time-frequency grid. That is, it is a sampled windowed sinusoid whose frequency and location in time are given by the coordinates of the respective node. In practice, this grid may be subsampled by factors  $\alpha$  and  $\beta$  for the two axes respectively, in order to reduce the number of the involved atoms.

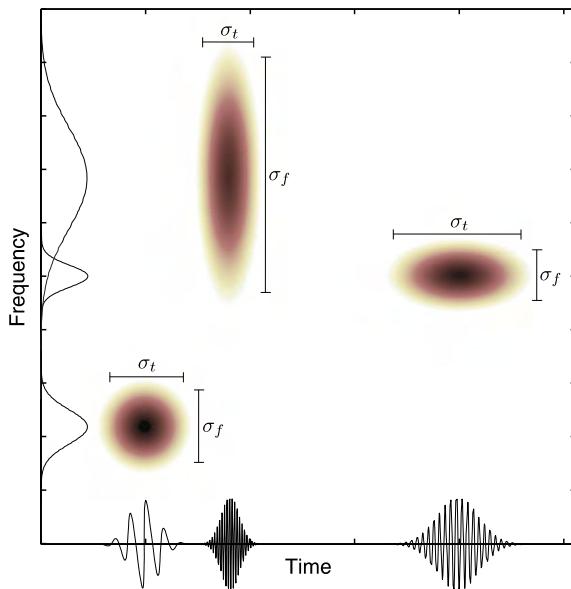

is a graphical interpretation of the atoms involved in the Gabor dictionary. Each node,  $(m, i)$ , in this time-frequency plot, corresponds to an atom of frequency equal to  $\frac{2\pi}{lT} i$  and delay equal to  $m$ .

Note that the windowing of a signal of finite duration inevitably introduces boundary effects, especially when the delay  $m$  gets close to the time segment edges, 0 and  $l - 1$ . A solution to it, that facilitates the theoretical analysis, is to use a modulo  $l$  arithmetic to wrap around at the edge points (this is equivalent with extending the signal periodically), see, e.g., [182].

Once the atoms have been defined, they can be stacked one next to the other to form the columns of the  $l \times l^2$  Gabor dictionary,  $G$ . It can be shown that the Gabor dictionary is a tight frame, [183].

### 1.23.15.2 Time-frequency resolution

By the definition of the Gabor dictionary, it is readily understood that the choice of the window spread, as measured by  $\sigma$ , must be a critical factor, since it controls the localization in time. As it is known from our Fourier transform basics, when the pulse becomes short, in order to increase the time resolution, its corresponding frequency content spreads out, and vice versa. From Heisenberg's principle, we know that we can never achieve high time and frequency resolution, simultaneously; one is gained at the expense of the other. It is here where the Gaussian shape in the Gabor transform is justified. It can be shown that the Gaussian window gives the optimal trade-off between time and frequency resolution, [180, 181].

**FIGURE 23.27**

The shorter the width of the pulsed (windowed) sinusoid is in time the wider the spread of its frequency content around the frequency of the sinusoid. The Gaussian-like curves along the frequency axis indicate the energy spread in frequency of the respective pulses. The values of  $\sigma_t$  and  $\sigma_f$  indicate the spread in time and frequency, respectively.

The time-frequency resolution trade-off is demonstrated in Figure 23.27, where three sinusoids are shown windowed with different pulse durations. The diagram shows the corresponding spread in the time-frequency plot. The value of  $\sigma_t$  indicates the time spread and  $\sigma_f$  the spread of the respective frequency content around the basic frequency of each sinusoid.

### 1.23.15.3 Gabor frames

In practice,  $l^2$  can take large values and it is desirable to see whether one can reduce the number of the involved atoms, without sacrificing the frame-related properties. This can be achieved by an appropriate subsampling, as this is illustrated in Figure 23.26. We only keep the atoms that correspond to the red nodes. That is, we subsample by keeping every  $\alpha$  nodes in time and every  $\beta$  nodes in frequency in order to form the dictionary, i.e.,

$$G_{(\alpha,\beta)} = \{\mathbf{g}^{(m\alpha,i\beta)}\}, \quad m = 0, 1, \dots, \frac{l}{\alpha} - 1, \quad i = 0, 1, \dots, \frac{l}{\beta} - 1,$$

where  $\alpha$  and  $\beta$  are divisors of  $l$ . Then, it can be shown, e.g., ([180]), that if  $\alpha\beta < l$  the resulting dictionary retains its frame properties. Once  $G_{(\alpha,\beta)}$  is obtained, the canonical dual frame is readily available via (23.79) (adjusted for complex data), from which the corresponding set of expansion coefficients,  $\theta$ , results.

### 1.23.15.4 Time-frequency analysis of echolocation signals emitted by bats

Bats are using echolocation for navigation (flying around at night), for prey detection (small insects) and for prey approaching and catching; each bat adaptively changes the shape and frequency content of its calls in order to better serve the previous tasks. Echolocation is used in a similar way for sonars. Bats emit calls as they fly, and “listen” to the returning echoes in order to build up a sonic map of their surroundings. In this way, bats can infer on the distance, the size of obstacles as well as of other flying creatures/insects. Moreover, all bats emit special types of calls, called social calls, which are used for socializing, flirting, etc. The fundamental characteristics of the echolocation calls, as for example, the frequency range and the average time duration, differ from species to species since, thanks to evolution, bats have adapted their calls in order to get best suited to the environment in which a species operates.

Time-Frequency analysis of echolocation calls provides information about the species (species identification) as well as of the specific task and behavior of the bats in certain environments. Moreover, the bat-biosonar system is studied in order humans to learn more about nature and be inspired for subsequent advances in applications such as sonar navigation systems, radars, medical ultrasonic devices, etc.

Figure 23.28a shows a case of a recorded echolocation signal from bats. Zooming at two different parts of the signal, we can observe that the frequency is changing with time. In Figure 23.28b, the DFT of the signal is shown, but there is no much information that can be drawn from it, except that the signal is compressible in the frequency domain; most of the activity takes place within a short range of frequencies.

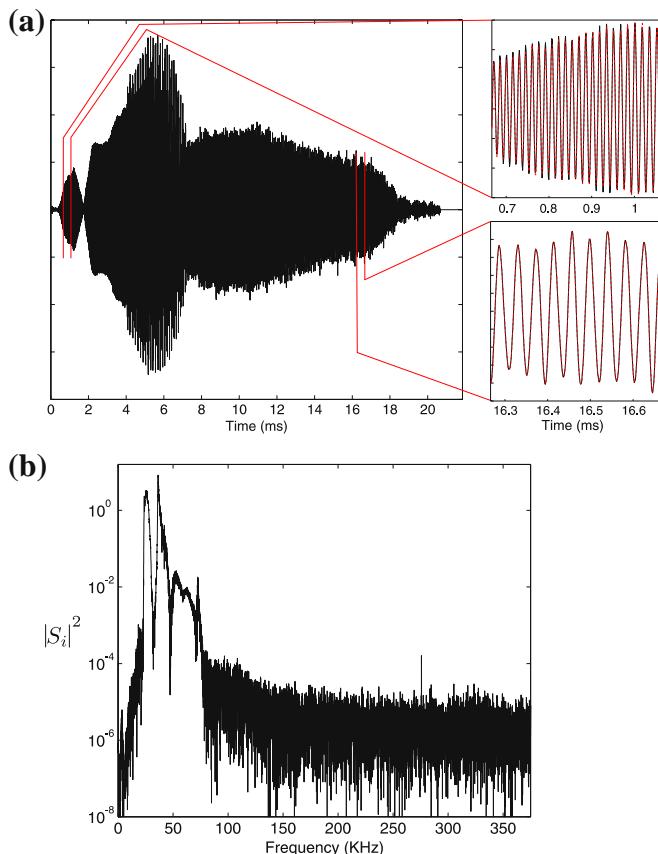

Our echolocation signal was a recording of total length  $T = 21.845$  ms, [184]. Samples were taken at the sampling frequency  $f_s = 750$  kHz, which results in a total of  $l = 16384$  samples. Although the signal itself is not sparse in the time domain, we will take advantage of the fact that it is sparse in a transformed domain. We will assume that the signal is sparse in its expansion in terms of the Gabor dictionary.

Our goal in this example is to demonstrate that one does not really need all 16384 samples to perform time-frequency analysis; all the processing can be carried out by using a reduced number of measurements, by exploiting the theory of compressed sensing. To form the measurements vector,  $\mathbf{y}$ , the number of measurements was chosen to be  $N = 2048$ . This amounts to a reduction of eight times with respect to the number of available samples. The measurements vector was formed as

$$\mathbf{y} = \mathbf{X}\mathbf{s},$$

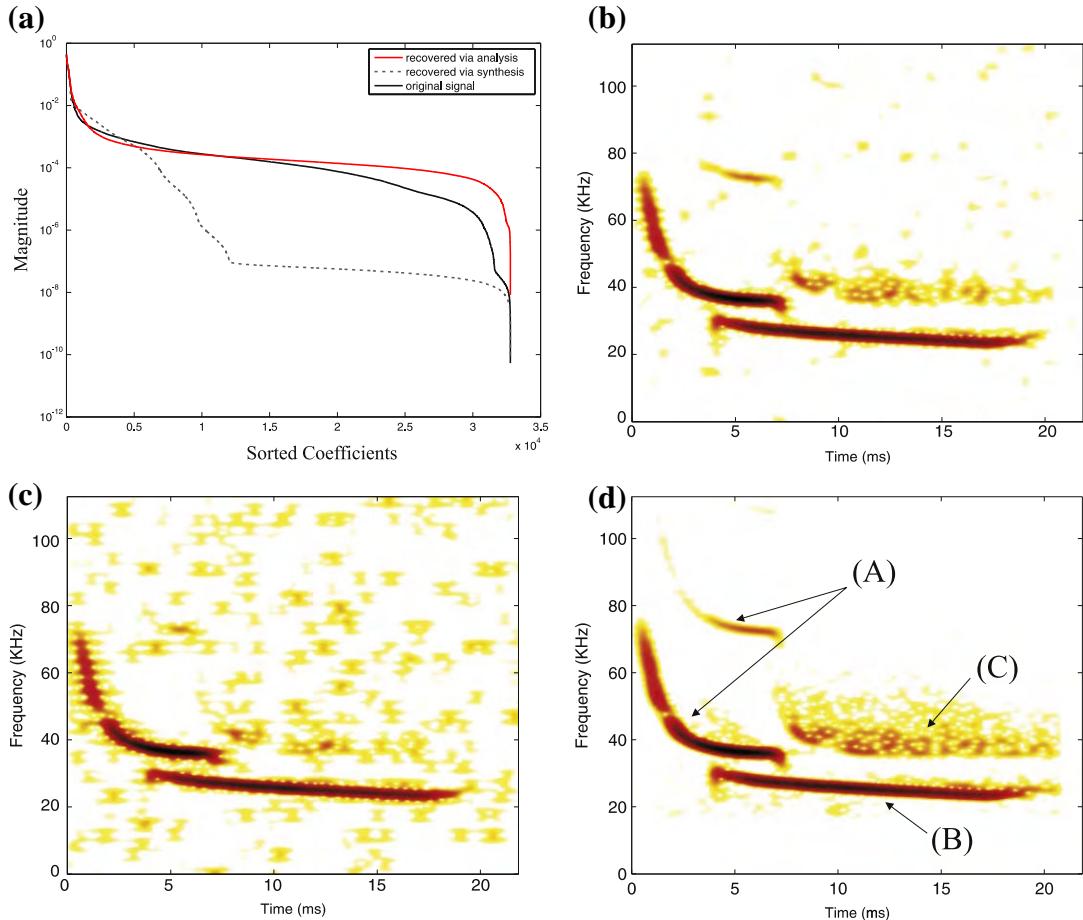

where  $\mathbf{X}$  is a  $N \times l$  sensing matrix comprising  $\pm 1$  generated in a random way. This means that once we obtain  $\mathbf{y}$ , one does not need to store the original samples any more, leading to a saving in memory. Ideally, one could have obtained the reduced number of measurements by sampling directly the analog signal at sub-Nyquist rates, as it has already been discussed at the end of Section 1.23.10. Another goal is to use both the analysis and synthesis models and demonstrate their difference.

Three different spectrograms were computed. Two of them, shown in Figures 23.29b and 23.29c, correspond to the reconstructed signals obtained by the analysis, (23.88), and the synthesis, (23.44), formulations, respectively. In both cases, the NESTA algorithm was used and the  $G_{(128,64)}$  frame was employed. Note that the latter dictionary is redundant by a factor of 2. The spectrograms are

**FIGURE 23.28**

(a) The recorded echolocation signal. The frequency of the signal is time varying and this is indicated by focussing on two different parts of the signal. (b) Plot of the energy of the DFT transform coefficients,  $S_i$ . Observe that most of the frequency activity takes place within a short frequency range.

the result of plotting the time-frequency grid and coloring each node  $(t, i)$  according to the energy  $|\theta|^2$  of the coefficient associated with the respective atom in the Gabor dictionary. The full Gabor transform applied on the reconstructed signals to obtain the spectrograms, in order to get a better coverage of the time-frequency grid. The scale is logarithmic and the darker areas correspond to larger values. The spectrogram of the original signal obtained via the full Gabor transform is shown in Figure 23.29d. It is evident, that the analysis model resulted in a more clear spectrogram, which resembles the original one better. When the frame  $G_{(64,32)}$  is employed, which is a highly redundant Gabor dictionary comprising  $8l$  atoms, then the analysis model results in a recovered signal whose spectrogram is visually indistinguishable from the original one in Figure 23.29d.

**FIGURE 23.29**

(a) Plot of the magnitude of the coefficients, sorted in decreasing order, in the expansion in terms of the  $G_{(128,64)}$  Gabor frame. The results correspond to the analysis and synthesis model formulations. The third curve corresponds to the case of analyzing the original vector signal directly, by projecting it on the dual frame.  
 (b) The spectrogram from the analysis. (c) The spectrogram from the synthesis formulations, respectively.  
 (d) The spectrogram corresponding to  $G_{(64,32)}$  frame using the analysis formulation. For all cases, the number of measurements used was one eighth of the total number of signal samples. A, B, and C indicate different parts of the signal, as explained in the text.

Figure 23.29a is the plot of the magnitude of the corresponding Gabor transform coefficients, sorted in decreasing values. The synthesis model provides a sparser representation, in the sense that the coefficients decrease much faster. The third curve is the one that results if we multiply the dual frame matrix  $\tilde{G}_{(128,64)}$  directly with the vector of the original signal samples and it is shown for comparison reasons.

To conclude, the curious reader may wonder what do these curves in Figure 23.29d mean after all. The call denoted by (A) belongs to a Pipistrellus pipistrellus (!) and the call denoted by (B) is either a social call or belongs to a different species. The (C) is the return echo from the signal (A). The large spread in time of (C) indicates a highly reflective environment, [184].

## 1.23.16 From sparse vectors to low rank matrices: a highlight

In this section, we move beyond sparse vectors and our goal is to investigate if and how notions related to sparsity can be generalized to matrices. We will see that such a generalization builds upon linear algebra tools and notions related to SVD decomposition, low rank approximation and dimensionality reduction. Our goal is to simply highlight the basic concepts and definitions without delving into a deeper treatment. Our aim is to make the reader alert of the problems and their potential for applications.

### 1.23.16.1 Matrix completion

Consider a signal vector  $s \in \mathcal{R}^l$ , where only  $N$  of its components are observed and the rest are unknown. This is equivalent with sensing  $s$  via a sensing matrix  $X$  having its  $N$  rows picked uniformly at random from the standard (canonical) basis  $\Phi = I$ , where  $I$  is the  $l \times l$  identity matrix. The question which is now posed is whether it is possible to recover the missing components of  $s$  based on these  $N$  components. From the theory presented, so far, we know that one can recover all the components of  $s$ , provided that  $s$  is sparse in some basis or dictionary,  $\Psi$ , which exhibits low mutual coherence with  $\Phi = I$ , and  $N$  is large enough, as it has been pointed out in Section 1.23.10.

Inspired by the theoretical advances in Compressed Sensing, a question similar in flavor and with a prominent impact regarding practical applications was posed in [185]. Given a  $l_1 \times l_2$  matrix  $M$ , assume that only  $N << l_1 l_2$  among its entries are known. The question now is whether one is able to recover the exact full matrix. This problem is widely known as *matrix completion* [185]. The answer, although it might come as a surprise, is “yes” with high probability, provided that (a) the matrix is *well structured*, (b) it has a *low rank*,  $r << l$ , where  $l = \min(l_1, l_2)$ , and (c) that  $N$  is large enough. Intuitively, this is plausible because a low rank matrix is fully described in terms of a number of parameters (degrees of freedom), which is much smaller than its total number of entries. These parameters are revealed via its Singular Value Decomposition (SVD)

$$M = \sum_{i=1}^r \sigma_i \mathbf{u}_i \mathbf{v}_i^T = U \begin{bmatrix} \sigma_1 & & 0 \\ & \ddots & \\ 0 & & \sigma_r \end{bmatrix} V^T, \quad (23.91)$$

where  $r$  is the rank of the matrix,  $\mathbf{u}_i \in \mathcal{R}^{l_1}$  and  $\mathbf{v}_i \in \mathcal{R}^{l_2}$ ,  $i = 1, 2, \dots, r$ , are the left and right orthonormal singular vectors, spanning the column and row spaces of  $M$  respectively,  $\sigma_i$ ,  $i = 1, 2, \dots, r$ , are the corresponding singular values and  $U = [\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_r]$ ,  $V = [\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_r]$ .

Let  $\sigma_M$  denote the vector containing all the singular values of  $M$ , i.e.,  $\sigma_M = [\sigma_1, \sigma_2, \dots, \sigma_l]^T$ , then  $\text{rank}(M) := \|\sigma_M\|_0$ . Counting the parameters associated with the singular values and vectors in (23.91)

turns out that the number of degrees of freedom of a rank  $r$  matrix is equal to  $d_M = r(l_1 + l_2) - r^2$  [186]. When  $r$  is small,  $d_M$  is much smaller than  $l$ .

Let us denote with  $\Omega$  the set of  $N$  pairs of indexes,  $(i, j)$ ,  $i = 1, 2, \dots, l_1$ ,  $j = 1, 2, \dots, l_2$ , of the locations of the known entries of  $M$ , which have been sampled uniformly at random. Adopting the main reasoning followed so far, one would attempt to recover  $M$  based on the following rank minimization problem

$$\begin{aligned} & \min_{\hat{M} \in \mathcal{R}^{l_1 \times l_2}} \|\sigma_{\hat{M}}\|_0 \\ & \text{s.t. } \hat{M}_{i,j} = M_{i,j}, \quad (i, j) \in \Omega. \end{aligned} \quad (23.92)$$

It turns out that, assuming that there exist a unique low-rank matrix having the specific known entries, then (23.92) leads to the exact solution [185]. However, compared to the case of sparse vectors, in the matrix completion problem the uniqueness issue gets much more involved. The following issues play a crucial part concerning the uniqueness of the task in (23.92).

1. If the number of known entries is lower than the degrees of freedom, i.e.,  $N < d_M$ , then there is no way to recover the missing entries whatsoever, since there is an infinite number of low rank matrices consistent with the  $N$  observed entries.
2. Even if  $N \geq d_M$ , uniqueness is still not guaranteed. It is required that the  $N$  elements with indices in  $\Omega$  are such that at least one entry per column and one entry per row is observed. Otherwise, even a rank-1 matrix, i.e.,  $M = \sigma_1 \mathbf{u}_1 \mathbf{v}_1^T$ , is not possible to be recovered. This becomes clear with a simple example. Assume that  $M$  is a rank-1 matrix and that no entry in the first column as well as in the last row is observed. Then, since for this case  $M(i, j) = \sigma_1 u_{1i} v_{1j}$ , it is clear that no information concerning the first component of  $\mathbf{v}_1$  as well as the last component of  $\mathbf{u}_1$  is available; hence these singular vector components are impossible to be recovered, regardless which method is used. As a consequence, the matrix can not be completed. On the other hand, if the elements of  $\Omega$  are picked at random and  $N$  is large enough, one can only hope that  $\Omega$  is such that to comply with the previous requirement; i.e., at least one entry per row and column is observed, with high probability. It turns out that this problem resembles the famous in probability theory theorem known as the *coupon collector's* problem. According to this, at least  $N = C_0 l \ln l$  entries are needed, where  $C_0$  is a constant [187]. This is the information theoretic limit for exact matrix completion [186] of any low-rank matrix.
3. Even if points (1) and (2) before are fulfilled, still uniqueness is not guaranteed. In fact, not every low rank matrix is liable to exact completion, regardless of the number and the positions of the observed entries. We will demonstrate that with the aid of an example. Let one of the singular vectors be sparse. Assume, without loss of generality, that the third left singular vector,  $\mathbf{u}_3$ , is sparse with sparsity level  $k = 1$  and also that its nonzero component is the first one, i.e.,  $u_{31} \neq 0$ . The rest of  $\mathbf{u}_i$  and all  $\mathbf{v}_i$  are assumed to be dense. Let us return to the SVD for a while, and specifically to the leftmost formula given in (23.91). Observe that the matrix  $M$  is written as the sum of  $r, l_1 \times l_2$  matrices  $\sigma_i \mathbf{u}_i \mathbf{v}_i^T, i = 1, \dots, r$ . Thus, in this specific case where  $\mathbf{u}_3$  is  $k = 1$  sparse, the matrix  $\sigma_3 \mathbf{u}_3 \mathbf{v}_3^T$  has zeros everywhere except from its first row. In other words, the information that  $\sigma_3 \mathbf{u}_3 \mathbf{v}_3^T$  brings to the formation of  $M$  is concentrated to its first row only. This argument can also be viewed from another perspective; the entries of  $M$  obtained from any row but the first one, do not provide

any useful information with respect to the values of the free parameters  $\sigma_3, \mathbf{u}_3, \mathbf{v}_3$ . As a result, in this case, unless if one incorporates extra information about the sparse nature of the singular vector, the entries from the first row that are missed are not recoverable, since the number of parameters concerning this row is larger than the available number of data.

Intuitively, when a matrix has dense singular vectors is better rendered for exact completion, since each one among the observed entries carries information associated with all the  $d_M$  parameters that fully describe it. To this end, a number of conditions, which evaluate the suitability of the singular vectors, have been established. The simplest one is given next [185]:

$$\|\mathbf{u}_i\|_\infty \leq \sqrt{\frac{\mu_B}{l_1}}, \quad \|\mathbf{v}_i\|_\infty \leq \sqrt{\frac{\mu_B}{l_2}}, \quad i = 1, \dots, r, \quad (23.93)$$

where  $\mu_B$  is a bound parameter. In fact,  $\mu_B$  is a measure of the coherence<sup>8</sup> of matrix  $U$  (and similarly of  $V$ ), (vis-à-vis the standard basis), defined as follows:

$$\mu(U) := \frac{l_1}{r} \max_{1 \leq i \leq l_1} \|\mathbf{P}_U \mathbf{e}_i\|^2, \quad (23.94)$$

where  $\mathbf{P}_U$  defines the orthogonal projection to subspace  $U$  and  $\mathbf{e}_i$  is the  $i$ th vector of the canonical basis. It is easy to show that  $\|\mathbf{P}_U \mathbf{e}_i\|^2 = \|U^T \mathbf{e}_i\|^2$ . In essence, coherence is an index quantifying the extent to which the singular vectors are correlated with the standard basis,  $\mathbf{e}_i, i = 1, 2, \dots, l$ . The smaller the  $\mu_B$  is the less “spiky” the singular vectors are likely to be, and the corresponding matrix is better suited for exact completion. Indeed, assuming for simplicity a square matrix  $M$ , i.e.,  $l_1 = l_2 = l$ , then if *any one* among the singular vectors is sparse having a single nonzero component only, then, taking into account that  $\mathbf{u}_i^T \mathbf{u}_i = \mathbf{v}_i^T \mathbf{v}_i = 1$ , this value will have magnitude equal to one and the bound parameter will take its largest value possible, i.e.,  $\mu_B = l$ . On the other hand, the smaller value that  $\mu_B$  can get is 1, something that occurs when the components of *all* the singular vectors assume the same value (in magnitude). Note that in this case, due to the normalization, this common component value has magnitude  $\frac{1}{l}$ . Tighter bounds to the matrix coherence result via the more elaborate incoherence property [185, 188] and the strong incoherence property [186]. In all cases, the larger the bound parameter is the larger the number of known entries, which is required in order to guarantee uniqueness, becomes.

In Section 1.23.16.3, the aspects of uniqueness will be discussed in the context of a real life application.

The problem described in (23.92) is of limited practical interest since it is an NP-hard task. Thus, following the Compressed Sensing paradigm, it is replaced by a *convexly* relaxed counterpart of it, i.e.,

$$\begin{aligned} & \min_{\hat{M} \in \mathcal{R}^{l_1 \times l_2}} \|\boldsymbol{\sigma}_{\hat{M}}\|_1 \\ & \text{s.t. } \hat{M}_{i,j} = M_{i,j}, \quad (i, j) \in \Omega, \end{aligned} \quad (23.95)$$

---

<sup>8</sup>This is a quantity different than the mutual-coherence already discussed in Section 1.23.7.1.

where  $\|\sigma_{\hat{M}}\|_1$ , i.e., the sum of the singular values, is referred to as *nuclear norm* of the matrix  $\hat{M}$ , often denoted as  $\|\hat{M}\|_*$ . The nuclear norm minimization was proposed in [189] as a convex approximation of rank minimization, which can be cast as a semidefinite program.

**Theorem 8 ([186], Corollary 1.5).** *Let  $M$  be a  $l_1 \times l_2$  matrix of rank  $r$ , which is a constant much smaller than  $l = \max(l_1, l_2)$ , obeying (23.93). Suppose that we observe  $N$  entries of  $M$  with locations sampled uniformly at random. Then there is a positive constant  $C$  such that if*

$$N \geq C\mu_B^4 l \ln^2 l, \quad (23.96)$$

*then  $\hat{M}$  is the unique solution to (23.95) with probability at least  $1 - l^{-3}$ .*

There might be an ambiguity on how small the rank should be in order for the corresponding matrix to be characterized as “low rank.” More rigorously, a matrix is said to be of low rank if  $r = \mathcal{O}(1)$ , which means that  $r$  is a constant with no dependence (not even logarithmic), on  $l$ . Matrix completion is also possible for more general rank cases where instead of the mild coherence property of (23.93), the incoherence and the strong incoherence properties [185, 186, 188, 190] are mobilized in order to get similar theoretical guarantees. The detailed exposition of these alternatives is out of the scope of this paper. In fact, Theorem 8 embodies the essence of the matrix completion task: with high probability, nuclear-norm minimization recovers all the entries of a low rank matrix  $M$  with no error. More importantly, the number of entries  $N$ , which the convexly relaxed problem requires, is only by a logarithmic factor larger than the information theoretic limit; recall that the latter is equal to  $C_0 l \ln l$ . Moreover, similarly to Compressed Sensing, robust matrix completion in the present of noise is also possible as long as the request  $\hat{M}_{i,j} = M_{i,j}$  in (23.92) and (23.95) is replaced by  $\|\hat{M}_{i,j} - M_{i,j}\|_2 \leq \epsilon$  [191]. Furthermore, the notion of matrix completion has also been extended to tensors [192, 193].

### 1.23.16.2 Robust PCA

The developments on matrix completion theory led, more recently, to the formulation and solution of another problem of high significance. To this end, the notation  $\|M\|_1$ , i.e., the  $\ell_1$  norm of a matrix, is introduced and it is defined as the sum of the absolute values of its entries, i.e.,  $\|M\|_1 = \sum_{i=1}^{l_1} \sum_{j=1}^{l_2} |M_{i,j}|$ . In other words, it acts on the matrix as if this were a long vector. Assume that  $M$  is expressed as the sum of a low rank matrix,  $L$ , and a sparse matrix,  $S$ , i.e.,  $M = L + S$ . The following convex minimization problem [194–196], usually referred to as *principal component pursuit* (PCP),

$$\begin{aligned} \min_{\hat{L} \in \mathcal{R}^{l_1 \times l_2}, \hat{S} \in \mathcal{R}^{l_1 \times l_2}} \quad & \|\sigma_{\hat{L}}\|_1 + \lambda \|\hat{S}\|_1 \\ \text{s.t. } \hat{L} + \hat{S} = M, \end{aligned} \quad (23.97)$$

is shown to recover both  $L$  and  $S$  according to the following theorem [194]:

**Theorem 9.** *The PCP recovers both  $L$  and  $S$  with probability at least  $1 - cl_1^{-10}$ , where  $c$  is a constant, provided that:*

1. the support set  $\Omega$  of  $S$  is uniformly distributed among all sets of cardinality  $N$ ,
2. the number,  $k$ , of nonzero entries of  $S$  is relatively small, [197], i.e.,  $k \leq \rho l_1 l_2$ , where  $\rho$  is a sufficiently small positive constant,
3.  $L$  obeys the incoherence property, with bound  $\mu_c$ , which is simultaneously larger than  $\mu(U)$ ,  $\mu(V)$  and  $\frac{l_1 l_2}{r} \|U V^T\|_\infty^2$
4. the regularization parameter,  $\lambda$ , is constant with value  $\lambda = \frac{1}{\sqrt{l_2}}$ ,
5.  $\text{rank}(L) \leq C \frac{l_2}{\mu_c \ln^2 l_1}$ , with  $C$  being a constant.

In other words, based on *all* the entries of a matrix  $M$ , which is known that is the sum of two unknown matrices  $L$  and  $S$ , with the first one being of low rank matrix and the second being sparse, then PCP recovers exactly, with probability almost 1, both  $L$  and  $S$ , irrespective of how large the magnitude of the entries of  $S$  are, provided that *both  $r$  and  $k$  are sufficiently small*.

The applicability of the previous task is very broad. For example, PCP can be employed in order to find a low rank approximation of  $M$ . It is well known that the task of low rank approximation is closely related to the dimensionality reduction task, where the columns of  $M$  are expressed in terms of the  $r$  (principal components) columns of  $U$ , e.g., Chapter 6, [1]. However, in contrast to the standard SVD or PCA approach, PCP is robust and insensitive to the presence of outliers, since these are naturally modeled, via the presence of  $S$ . For this reason, the above task is widely known as *robust PCA via nuclear norm minimization*. (More classical PCA techniques are known to be sensitive to outliers and a number of alternative approaches have in the past been proposed towards its robustification, e.g., [198–202]).

When PCP serves as a robust PCA approach, the matrix of interest is  $L$  and  $S$  accounts for the outliers. However, PCP provides estimates for both  $L$  and  $S$ . As it will be discussed in the next subsection, state-of-the-art applications are well accommodated when the focus of interest is turned into the sparse matrix  $S$  itself.

### Remarks 13.

- Just as  $\ell_1$ -minimization is the tightest convex relaxation of the combinatorial  $\ell_0$ -minimization problem in compressed sensing, the nuclear-norm minimization is the tightest convex relaxation of the NP-hard rank minimization problem; i.e., the nuclear ball  $\{M \in \mathcal{R}^{l_1 \times l_2} : \|M\|_* \leq 1\}$  is the convex hull of the set of rank-one matrices with spectral norm bounded by one. Besides the Nuclear norm, other heuristics have also been proposed, such as the log-det heuristic [203] and the max-norm [204].
- The nuclear norm, as a rank minimization approach, is the generalization of the trace-related cost, which is often used in the control community for the rank minimization of positive semidefinite matrices [205]. Indeed, when the matrix is symmetric and positive semidefinite, the nuclear norm of  $M$  is the sum of the eigenvalues and thus it is equal to the trace of  $M$ . Such problems arise when, for example, the rank minimization task refers to covariance matrices and positive semidefinite Toeplitz or Hankel matrices (see, e.g., [203]).
- Both matrix completion (23.95) and PCP (23.97) can be formulated as semidefinite programs and are solved via mobilizing interior-point methods. However, whenever the size of a matrix becomes large (e.g.,  $100 \times 100$ ), these methods are deemed to fail in practice due to excessive power and memory requirements. As a result, there is an increasing interest, which has propelled intensive research efforts, for the development of efficient methods to solve (23.95), (23.97) or related approximations,

which scale well with large matrices. Many of these methods revolve around the philosophy of the iterative soft and hard thresholding techniques, as discussed in previous sections. However, in the current low rank approximation setting, it is the singular values of the estimated matrix which are thresholded. As a result, in each iteration, the estimated matrix, after thresholding its singular values, tends to be of lower rank. The thresholding of the singular values is either imposed, such as in the case of the singular value thresholding (SVT) algorithm [206] or it results as a solution of the regularized versions of (23.95) and (23.97) (see, e.g., [207–211]). Moreover, algorithms inspired by greedy methods such as CoSaMP, have also been proposed [212, 213].

- Further developments on PCP led to improved versions [197] allowing for exact recovery even though the number of nonzero entries of  $S$  approaches  $l_1 l_2$  arbitrarily close, provided that the sign pattern of  $S$  is random. Furthermore, even full columns are allowed to be corrupted [214, 215]. Moreover, fusions of PCP with matrix completion and Compressed Sensing are possible, in the sense that only a subset of the entries of  $M$  is available and/or linear measurements of the matrix in a Compressed Sensing fashion can be used instead of matrix entries (see, e.g., [213, 216]). Moreover, stable versions of PCP dealing with noise have also been investigated (see, e.g., [217]).

### 1.23.16.3 Applications of matrix completion and PCP

The number of applications in which these techniques are involved is ever increasing and their extensive presentation is out of the scope of this paper. Next, some key applications will be selectively discussed since they reveal the potential of these methods and at the same time will assist the reader for a better understanding of the underline notions.

#### 1.23.16.3.1 Matrix completion

A typical application, where the matrix completion problem arises, is in the collaborative filtering task [218], which is essential for building up successful recommender systems. Let us consider that a group of individuals provide their ratings concerning products, which they have enjoyed. Then a matrix with ratings can be filled where each row indexes a different individual and the columns index the products. As a popular example take the case where the products are different movies. Inevitably, the associated matrix will be partially filled, since it is not common that all customers have watched all the movies and submit ratings for all of them. Matrix completion comes to provide an answer, potentially in the affirmative, to the following question. Can we predict the ratings that the users would give to films that they have not seen yet? This is the task of a recommender system in order to encourage users to watch movies, which are likely to be of their preference. The exact objective of competition for the famous Netflix prize (<http://www.netflixprize.com/>) was the development of such a recommender system.

The aforementioned problem provides a good opportunity to build up our intuition about the matrix completion task. First, an individual's preferences or taste on movies are typically governed by a small number of factors, such as the gender, the actors they play in it, the continent of origin, etc. As a result, a matrix fully filled with ratings is expected to be low rank. Moreover, it is clear that each user need to have at least one movie rated in order to have any hope to fill out his/her ratings across all movies. The same is true for each movie. This requirement complies with the second requirement in Section 1.23.16.1, concerning uniqueness, i.e., one needs to know at least one entry per row and column. Finally, imagine a single user who rates movies with criteria that are completely different to those used by the

rest of the users. He/She could, for example, provide ratings at random or depending on, let us say, the first letter of the movie title. Such a scenario complies with the third point concerning the uniqueness in the matrix completion problem, as previously discussed. Unless all the ratings of the specific user are known, the matrix cannot get fully completed.

In the previous application, the matrix of interest can be characterized as approximately low rank. In other cases, such as in sensor network localization [219], the rank of the matrix assumes an exact value. The goal of localization is to assign geographic coordinates to each node in the sensor network based on a square matrix, which contains the pairwise distances between the nodes [220, 221]. It turns out that this matrix is of very low rank, e.g., two or three, depending on whether the sensors are placed in the 2D or 3D space. As a result, matrix completion is possible using a limited number of distance measurements. The number of distance measurements is reduced either intentionally, in order to save power and/or due to the presence of irregularities and obstacles in the deployment area, which renders the communication among nodes impossible. Other applications of matrix completion includes system identification [222], recovering structure from motion [223] and multi-task learning [224].

### 1.23.16.3.2 Robust PCA/PCP

In the collaborative filtering task, robust PCA offers an extra attribute compared to matrix completion, which can be proved very crucial in practice. The users are allowed to even tamper with some of the ratings without affecting the estimation of the low rank matrix. This seems to be the case whenever the rating process involves many individuals in an environment, which is not strictly controlled, since some of them occasionally are expected to provide ratings in an ad hoc, or even malicious manner.

One of the first applications of PCP was in video surveillance systems [194] and the main idea behind it appeared to be popular and extendable to a number of computer vision applications. Take the example of a camera recording a sequence of frames consisting of a merely static background and a foreground with few moving objects, e.g., vehicles and/or individuals. A common task in surveillance video is to extract from the background the foreground, in order, for example, to detect any activity or to proceed with further processing such as face recognition. Suppose the successive frames are converted to vectors in lexicographic order and then are placed as columns in a matrix  $M$ . Due to the background, even though this may slightly vary due to changes in illumination, successive columns are expected to be highly correlated. As a result, the background can be modeled as an approximately low rank matrix  $L$ . On the other hand, the objects on the foreground, appear as “anomalies” concerning a fraction of pixels of each frame, i.e., a limited number of entries in each column of  $M$ . Moreover, due to the motion of the foreground objects, the positions of these anomalies are likely to change from one column of  $M$  to the next. Therefore, they can be modeled as a sparse matrix  $S$ . Note that in this application, the matrix of interest is the sparse matrix rather than the low rank one.

---

## 1.23.17 Conclusions

In this paper, we provided an overview of the major theoretical advances as well as the main trends in algorithmic developments in the area of sparsity-aware learning and compressed sensing. Both batch processing and online processing techniques were considered. A case study in the context of time-frequency analysis of signals was also presented. Our intent is to update the review from time to time, since this is a very hot research area with a momentum and speed that is sometimes difficult to follow up.

## Appendix

The stage of our discussion in this Appendix is the real Euclidean space  $\mathcal{R}^l$ , where  $l$  is a positive integer. Although all of the following arguments hold true even in the case where the  $\mathcal{R}^l$  is substituted by the much more general Hilbert space setting, we confine ourselves here, for the sake of simplicity, to the Euclidean space. Henceforth, the space  $\mathcal{R}^l$  is considered to be equipped with an inner product, which, in the present context, is denoted by  $\langle \theta_1, \theta_2 \rangle, \forall \theta_1, \theta_2 \in \mathcal{R}^l$ . A standard example of such an inner product is the classical vector/dot one, defined by  $\langle \theta_1, \theta_2 \rangle := \theta_1^T \theta_2, \forall \theta_1, \theta_2 \in \mathcal{R}^l$ , where the superscript  $(\cdot)^T$  stands for vector transposition. Another example of an inner product for the space  $\mathcal{R}^l$  is the following *weighted* one;  $\langle \theta_1, \theta_2 \rangle := \theta_1^T W \theta_2, \forall \theta_1, \theta_2 \in \mathcal{R}^l$ , where  $W \in \mathcal{R}^{l \times l}$  is any user-defined positive definite matrix. In order not to spare the generality of the following discussion, we let  $\langle \cdot, \cdot \rangle$  stand for any user-defined inner product on the linear space  $\mathcal{R}^l$ . Given such an inner product, the associated norm is induced according to the following rule:  $\|\cdot\| := \sqrt{\langle \cdot, \cdot \rangle}$ . Excellent resources for a deeper study on the extremely rich subject of convex analysis are [225–228].

We start, now, with few notions of fundamental importance to convex analysis.

### A.1 Closed convex sets and metric projection mappings

**Definition 7 (Convex set, convex function).** A non-empty subset  $C$  of  $\mathcal{R}^l$  is called *convex* if  $\forall \theta_1, \theta_2 \in \mathcal{R}^l$ , and  $\forall \lambda \in [0, 1]$ , the following holds true:  $\lambda \theta_1 + (1 - \lambda) \theta_2 \in C$ . Moreover, a function  $\mathcal{L} : \mathcal{R}^l \rightarrow \mathcal{R}$  is called *convex* if  $\forall \theta_1, \theta_2 \in \mathcal{R}^l$ , and  $\forall \lambda \in [0, 1]$ ,  $\mathcal{L}(\lambda \theta_1 + (1 - \lambda) \theta_2) \leq \lambda \mathcal{L}(\theta_1) + (1 - \lambda) \mathcal{L}(\theta_2)$ . The function  $\mathcal{L}$  is called *strictly convex* if  $\forall \lambda \in (0, 1)$  and  $\forall \theta_1, \theta_2 \in \mathcal{R}^l$ , such that  $\theta_1 \neq \theta_2$ , we have  $\mathcal{L}(\lambda \theta_1 + (1 - \lambda) \theta_2) < \lambda \mathcal{L}(\theta_1) + (1 - \lambda) \mathcal{L}(\theta_2)$ .

The *epigraph* of a function  $\mathcal{L}$  is defined as the set

$$\text{epi}(\mathcal{L}) := \{(\theta, r) \in \mathcal{R}^l \times \mathcal{R} : \mathcal{L}(\theta) \leq r\}.$$

In other words, the epigraph of  $\mathcal{L}$  is the set of all points of  $\mathcal{R}^l \times \mathcal{R}$  which belong to and lie above the graph of  $\mathcal{L}$ . Notice, also, by the definition of convexity, that  $\mathcal{L}$  is convex if and only if  $\text{epi}(\mathcal{L})$  is convex.

Given a real number  $\xi$ , the *lower level set* of  $\mathcal{L}$  at height  $\xi$  is defined as the set

$$\text{lev}_{\leq \xi}(\mathcal{L}) := \{\theta \in \mathcal{R}^l : \mathcal{L}(\theta) \leq \xi\}.$$

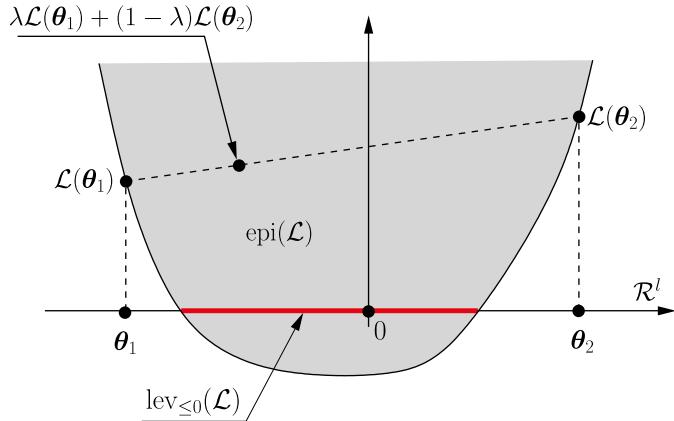

For the geometry behind the previous definitions, see Figure 23.30.

**Definition 8 (The metric projection mapping).** Given a non-empty *closed* convex set  $C \subset \mathcal{R}^l$ , the *metric projection mapping onto*  $C$  is defined as the operator that maps to each  $\theta \in \mathcal{R}^l$  the *unique*  $P_C(\theta) \in C$  such that

$$\|\theta - P_C(\theta)\| = d(\theta, C).$$

In other words, the point  $P_C(\theta)$  is the unique minimizer of the function  $\|\theta - x\|, x \in C$ . Obviously, in the case where  $\theta \in C$ , then  $P_C(\theta) = \theta$ .

As an example, the metric projection mapping onto the *hyperslab* is given next.

**FIGURE 23.30**

A convex function  $\mathcal{L}$ , its epigraph, and the lower level set of  $\mathcal{L}$  at height 0.

**Example 8 (Hyperslab).** A hyperslab  $S[\epsilon]$  is the closed convex subset of  $\mathcal{R}^l$  which is defined as

$$S[\epsilon] := \{x \in \mathcal{R}^l : |\langle a, x \rangle - c| \leq \epsilon\},$$

for some nonzero  $a \in \mathcal{R}^l$  and some  $c \in \mathcal{R}$ . The projection mapping  $P_{S[\epsilon]}$  onto  $S[\epsilon]$  is given as follows:

$$P_{S[\epsilon]}(\theta) = \theta - \begin{cases} \frac{\langle a, \theta \rangle - c - \epsilon}{\|a\|^2} a, & \text{if } \langle a, \theta \rangle > c + \epsilon, \\ 0, & \text{if } |\langle a, \theta \rangle - c| \leq \epsilon, \\ \frac{\langle a, \theta \rangle - c + \epsilon}{\|a\|^2} a, & \text{if } \langle a, \theta \rangle < c - \epsilon. \end{cases} \quad (23.98)$$

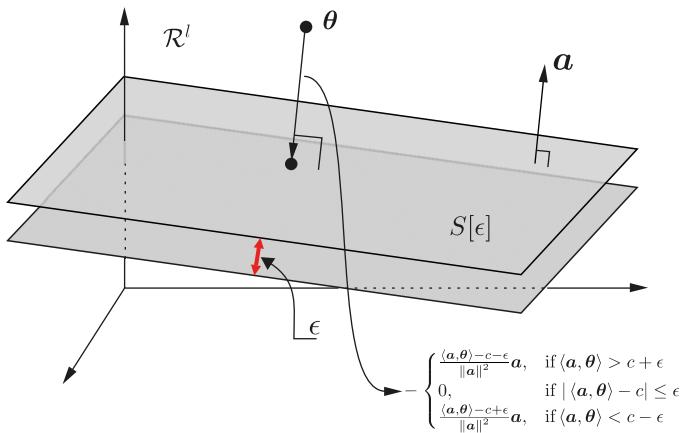

For the related geometry, see Figure 23.31. Notice that  $a$  stands for the *normal vector* defining the hyperplanes associated with the hyperslab.

## A.2 The subgradient

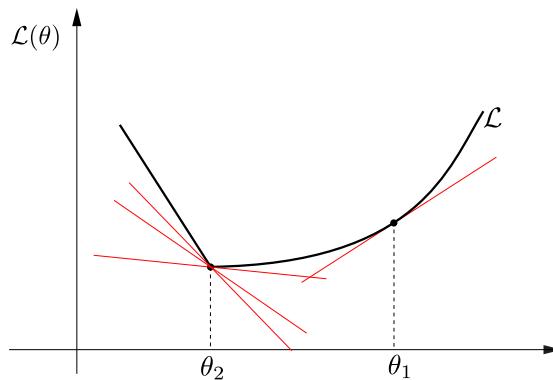

**Definition 9 (Subgradient, Subdifferential).** Given a convex function  $\mathcal{L}$ , defined on  $\mathcal{R}^l$ , and a point  $\theta \in \mathcal{R}^l$ , the subgradient of  $\mathcal{L}$  at  $\theta$  is defined as any vector,  $h$ , such that

$$\langle h, x - \theta \rangle + \mathcal{L}(\theta) \leq \mathcal{L}(x), \quad \forall x \in \mathcal{R}^l. \quad (23.99)$$

If the function  $\mathcal{L}$  is differentiable at  $\theta$  then the subgradient coincides with the (unique) gradient. As it is the case for the gradient, a subgradient defines a hyperplane. This hyperplane “supports” the epigraph of  $\mathcal{L}$ ; that is, the epigraph is on the one side of this hyperplane (see Figure 23.32). At  $\theta_1$ , the convex function is differentiable and there is only one subgradient, which coincides with the gradient. Thus at this point, there is a simple hyperplane that supports the epigraph. At  $\theta_2$ , the function is not differentiable.

**FIGURE 23.31**

A hyperslab and its associated projection mapping.

**FIGURE 23.32**

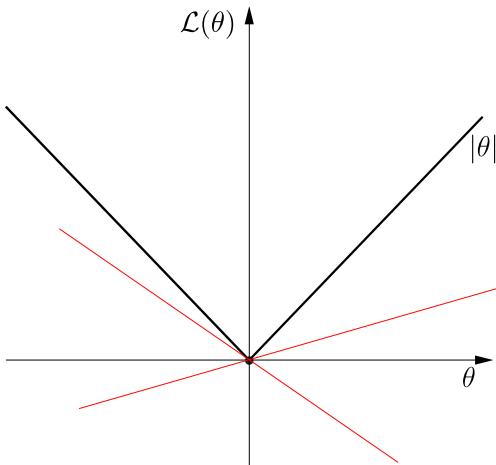

The graph of  $\mathcal{L}$  and supporting hyperplanes generated by the subgradients at points,  $\theta_1, \theta_2$ , where the function is differentiable and non-differentiable, respectively.

Hence there is an infinity of subgradients that define hyperplanes that support the epigraph. The set of all subgradients at a point  $\theta$  is known as the subdifferential and is denoted as  $\partial\mathcal{L}$ , i.e.,

$$\partial\mathcal{L}(\theta) := \{\mathbf{h} \in \mathbb{R}^l : \langle \mathbf{h}, \mathbf{x} - \theta \rangle + \mathcal{L}(\mathbf{x}) \leq \mathcal{L}(\theta), \quad \forall \mathbf{x} \in \mathbb{R}^l\}.$$

Next, the subdifferential of  $\mathcal{L}(\theta) := |\theta|$ ,  $\theta \in \mathbb{R}$  is given:

$$\partial\mathcal{L}(\theta) = \begin{cases} [-1, 1], & \text{if } \theta = 0, \\ \text{sgn}(\theta), & \text{if } \theta \neq 0, \end{cases}$$

**FIGURE 23.33**

The graph of the function  $|\cdot|$ , and the supporting hyperplanes generated by the subgradients of  $|\cdot|$  at  $\theta = 0$ .

where  $\text{sgn}(\cdot)$  stands for the sign of a real number. For the geometry associated to this cost function see Figure 23.33.

Traditional methods in machine learning and adaptive signal processing mainly exploit second order signal statistics (covariance,  $L_2$  distance, correlation functions, etc.). The emphasis on second order statistics as the choice of optimality criterion is due to the computational simplicity and the optimality under linear and Gaussian assumptions. Although second order statistics are still prevalent today in machine learning community and provide successful engineering solutions to most practical problems, it has become evident that this approach can be improved, especially when data possess non-Gaussian distributions (either fat tails or finite range). Recent studies suggest that machine learning problems that cannot be successfully solved using second order statistics benefit greatly from the use of the information theoretic performance measures. This information based learning has been named information theoretic learning (ITL), and it utilizes information concepts or descriptors from information theory to adapt the learning machines (linear or nonlinear) in both supervised and unsupervised paradigms. In this chapter, we present a brief but comprehensive introduction on general ITL methods to implement learning algorithms with information theoretic criteria. Some basic information theoretic descriptors (or information measures) are introduced, and a unifying learning framework based on these descriptors is presented. We also provide nonparametric kernel estimators for information measures and express them in reproducing kernel Hilbert space (RKHS). The information particle interaction model for learning is also presented. Finally, several application examples are provided, including TDNN training, classification, clustering, image retrieval, and independent component analysis (ICA).

---

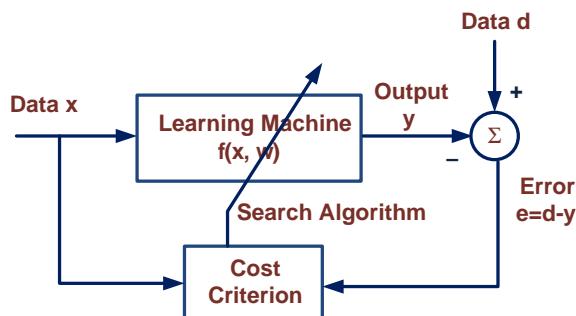

## 1.24.1 Introduction

The concept of learning was first applied to biological organisms and describes the process of revising behavior or understanding through acquisition of new experience from the environment. In the areas of machine learning, learning means to build a model from data with the goal of extracting useful structure contained in the data. The learning process is in essence a procedure of information processing, decreasing data redundancy in the presence of uncertainty and encoding the data into a model. Therefore, learning theory is intrinsically related to information theory, which was first conceptualized by Claude Shannon in the mathematical design of optimal communication systems [1,2]. A general statistical description of learning processes was given in [3], where learning is defined as a process in which the system's subjective entropy or, equivalently, its missing information decreases in time. In [4],

the mathematical concept of information was brought to biologically plausible information processing. The principle of maximum information preservation (Infomax) was applied in self-organization [5]. Further, a unifying framework for learning based on information theoretic criteria has been presented in [6,7].

To extract information from data, we have to build a model, which basically summarizes the process of data generation. In the framework of statistical machine learning, the learning machine goal can be thought of as approximating the a posteriori distribution of the targets given a set of examples (training data). If the joint or conditional probability density functions (PDFs) of the data source can be obtained, the data modeling can be directly implemented, by Bayesian reasoning. Examples of this approach include Bayesian filtering, hidden Markov modeling, and so on. Another approach for statistical learning, which is much simpler computationally, deals with the construction of scalar descriptors of the PDFs, the so called Bayes risks [8]. These descriptors, combined with a parametric data model, can be used to measure the similarity or dependency between the model output and the data. They are often used as cost functions for optimizing the learning systems' parameters. Figure 24.1 shows a general scheme of supervised machine learning. In this figure the cost criterion is, in general, an evaluator of the error's PDF. The goal of the learning is to search the parameter  $\omega$  of the model (learning machine)  $f(x, \omega)$ , such that the discrepancy (measured by the cost criterion) between the model output  $y$  and the desired (teacher) signal  $d$  is minimized. In this scenario, the process of finding parameters from the data is called learning.

The most widely used descriptors of the PDFs are the statistical moments. The combination of the second order moments (variance, correlation, etc.) and the Gaussian assumption in general leads to mathematically convenient and analytically tractable optimal solutions. Familiar examples are the mean square error (MSE) in least-squares linear regression and output variance in principal components analysis (PCA). The second order statistics as a cost criterion, however, may be a poor descriptor of optimality especially in nonlinear and non-Gaussian (e.g., heavy-tail or finite range distributions) situations. Thus selecting a new criterion beyond second order statistics is attractive in both signal processing and machine learning domains. Recent studies indicate that the information theoretic descriptors of entropy and dissimilarity (divergence and mutual information) do not suffer from the limitation of Gaussian assumption, and can improve performance in many realistic scenarios. Combined with nonparametric estimators of entropy and divergence, one can easily develop a variety of new learning algorithms.

**FIGURE 24.1**

Model building through supervised machine learning.

In this chapter, we will provide a brief but comprehensive picture of *information theoretic learning* (ITL), which describes machine learning under a general framework of information theory, and designs new learning costs based on information theoretic descriptors like entropy and mutual information.

## 1.24.2 Information theoretic descriptors

Let's start with a brief introduction of some basic information theoretic descriptors. The concept of information is so rich that a single information measure (or information descriptors) may never be able to quantify information properly. Here we focus mainly on Claude Shannon and Alfred Renyi's definitions of entropy, divergence and mutual information (a special case of divergence).

### 1.24.2.1 Entropy

Given a discrete random variable  $X$  with probability mass function  $P\{X = x_k\} = p_k, k = 1, \dots, n$ , Shannon's entropy is defined by [1, 2]

$$H_S(X) = \sum_{k=1}^n p_k I(p_k), \quad (24.1)$$

where  $I(p_k) = -\log p_k$  is Hartley's amount of information associated with the discrete event  $x_k$  with probability  $p_k$ . This information measure was originally devised by Claude Shannon in 1948 to study the amount of information in a transmitted message. Since learning systems deal, in general, with continuous random variables, we are more interested in information measure of a continuous random variable. Given a continuous random variable  $X$  with PDF  $p(x), x \in C$ , Shannon's differential entropy is defined as

$$H_S(X) = - \int_C p(x) \log p(x) dx. \quad (24.2)$$

Shannon entropy measures the average information (or uncertainty) contained in the probability distribution, and can also be used to measure many other concepts such as diversity, similarity, disorder, randomness, and so on.

A well-known generalization of Shannon entropy is Renyi entropy named after Alfred Renyi [9]. For a continuous random variable  $X$ , order-  $\alpha$  Renyi entropy is defined by ( $\alpha > 0, \alpha \neq 1$ )

$$H_\alpha(X) = \frac{1}{1-\alpha} \log V_\alpha(X), \quad (24.3)$$

where  $V_\alpha(X)$  is the order-  $\alpha$  information potential (IP) [7, 10, 11], given by

$$V_\alpha(X) = \int_C p^\alpha(x) dx = E[p^{\alpha-1}(X)]. \quad (24.4)$$

When  $\alpha = 2$ , we have  $H_2(X) = -\log V_2(X)$ . By L'Hoptital's rule one can easily show that as  $\alpha \rightarrow 1$ , Renyi entropy converges to Shannon entropy. The information potential  $V_\alpha(X)$  can be interpreted as the  $\alpha$ -power of the  $\alpha$ -norm in the PDF space. It was proposed as an optimality criterion for learning

systems (adaptive filters, neural networks, etc.) in [11]. The main reasons are: (1) due to the monotonic property of the logarithm function, optimizing the information potential will be equivalent to optimizing Renyi entropy; (2) the information potential, especially the quadratic information potential ( $\alpha = 2$ ), can easily be estimated from sample data by kernel density estimation method (also referred to as Parzen windowing approach [12, 13]); (3) in general the learning seeks extrema (either minimum or maximum) of the cost function, independently to its actual value, so the dependence on estimation error is decreased.

There is an important optimization principle of entropy, i.e., the maximum entropy (MaxEnt) principle enunciated by Jaynes [14, 15]. According to MaxEnt, among all the distributions that satisfy certain constraints, one should choose the distribution that maximizes the entropy. MaxEnt is a powerful and widely accepted method for statistical inference with incomplete knowledge of the probability distribution.

### 1.24.2.2 Divergence

Information divergence measures the discrepancy between two distributions. The Kullback-Leibler (KL) divergence (or Shannon's relative entropy) between two PDFs  $p_1(x)$  and  $p_2(x)$  is

$$D_{\text{KL}}(p_1 \| p_2) = \int_C p_1(x) \log \frac{p_1(x)}{p_2(x)} dx. \quad (24.5)$$

In statistics, the KL divergence  $D_{\text{KL}}(p_1 \| p_2)$  is a measure of the equivocation of assuming that the distribution is  $p_2$  when the true distribution is  $p_1$ . One can easily show  $D_{\text{KL}}(p_1 \| p_2) \geq 0$ , with equality if and only if  $p_1(x)$  and  $p_2(x)$  are identical almost everywhere. Note that the KL divergence is a measure of the “distance” between the two PDFs, but in general we have  $D_{\text{KL}}(p_1 \| p_2) \neq D_{\text{KL}}(p_2 \| p_1)$ , so it does not obey all the properties of a distance.

Renyi's order-  $\alpha$  divergence between  $p_1(x)$  and  $p_2(x)$  is defined by [16]

$$D_\alpha(p_1 \| p_2) = \frac{1}{\alpha - 1} \log \int_C p_1(x) \left( \frac{p_1(x)}{p_2(x)} \right)^{\alpha-1} dx. \quad (24.6)$$

When  $\alpha \rightarrow 1$ , we have  $\lim_{\alpha \rightarrow 1} D_\alpha(p_1 \| p_2) = D_{\text{KL}}(p_1 \| p_2)$ . In [17], a new Renyi's divergence, called the relative  $\alpha$ -Renyi entropy between  $p_1(x)$  and  $p_2(x)$  is defined as

$$D_{R_\alpha}(p_1 \| p_2) = \log \frac{\left( \int p_2^{\alpha-1}(x) p_1(x) dx \right)^{\frac{1}{(1-\alpha)}} \left( \int p_2^\alpha(x) dx \right)^{\frac{1}{\alpha}}}{\left( \int p_1^\alpha(x) dx \right)^{\frac{1}{\alpha(1-\alpha)}}}. \quad (24.7)$$

Note that this definition is more robust than Renyi's original definition in (24.6) since the denominator in the argument of the log contains an integral.

In machine learning, to simplify the computation of the above divergences, some quadratic divergences are frequently used. These quadratic divergences involve only a simple quadratic form of PDFs. The Euclidean distance (ED) in probability spaces and Cauchy-Schwarz (CS) divergence are popular,

which are defined respectively as [7]

$$D_{\text{ED}}(p_1 \| p_2) = \int_C (p_1(x) - p_2(x))^2 dx, \quad (24.8)$$

$$D_{\text{CS}}(p_1 \| p_2) = -\log \frac{\left(\int_C p_1(x)p_2(x)dx\right)^2}{\int_C p_1^2(x)dx \int_C p_2^2(x)dx}. \quad (24.9)$$

It is worth noting that  $D_{\text{ED}}$  can be expressed in terms of quadratic information potential (QIP):

$$D_{\text{ED}}(p_1 \| p_2) = V_2(p_1) + V_2(p_2) - 2V_2(p_1; p_2) \quad (24.10)$$

where  $V_2(p_1; p_2) \triangleq \int p_1(x)p_2(x)dx$  is the cross information potential (CIP). Further,  $D_{\text{CS}}$  can be rewritten in terms of Renyi's quadratic entropy:

$$D_{\text{CS}}(p_1 \| p_2) = 2H_2(p_1; p_2) - H_2(p_1) - H_2(p_2), \quad (24.11)$$

where  $H_2(p_1; p_2) \triangleq -\log \int p_1(x)p_2(x)dx$  is Renyi's quadratic cross-entropy.

### 1.24.2.3 Mutual information

Mutual information measures the degree of dependence between two random variables, and it is actually a special case of divergence. Let  $X_1$  and  $X_2$  be two random variables with joint PDF  $p_{X_1 X_2}(x_1, x_2)$  and marginal PDFs  $p_{X_1}(x_1)$  and  $p_{X_2}(x_2)$ , the mutual information between  $X_1$  and  $X_2$  is defined as the KL divergence between  $p_{X_1 X_2}(x_1, x_2)$  and  $p_{X_1}(x_1)p_{X_2}(x_2)$ , that is

$$\begin{aligned} I(X_1, X_2) &= D_{\text{KL}}(p_{X_1 X_2} \| p_{X_1} p_{X_2}) \\ &= \int_C p_{X_1 X_2}(x_1, x_2) \log \frac{p_{X_1 X_2}(x_1, x_2)}{p_{X_1}(x_1)p_{X_2}(x_2)} dx_1 dx_2. \end{aligned} \quad (24.12)$$

Clearly, mutual information  $I(X_1, X_2)$  is symmetric and always greater than zero, which vanishes if and only if  $X_1$  and  $X_2$  are statistically independent.

Mutual information (24.12) can alternatively be expressed as

$$I(X_1, X_2) = H_S(X_1) - H_S(X_1|X_2), \quad (24.13)$$

where  $H_S(X_1|X_2)$  is the conditional Shannon entropy of  $X_1$  given  $X_2$ , defined as

$$H_S(X_1|X_2) = - \int_C p_{X_1 X_2}(x_1, x_2) \log p_{X_1|X_2}(x_1|x_2) dx_1 dx_2, \quad (24.14)$$

where  $p_{X_1|X_2}(x_1|x_2)$  denotes the conditional PDF of  $X_1$  given  $X_2$ . As one can see from (24.13), mutual information quantifies the reduction of uncertainty in  $X_1$  after observing  $X_2$ .

In a similar way one can also define Renyi's order-  $\alpha$  mutual information  $I_\alpha(X_1, X_2)$ , Euclidean distance mutual information  $I_{\text{ED}}(X_1, X_2)$ , and Cauchy-Schwartz mutual information  $I_{\text{CS}}(X_1, X_2)$ , that is

$$\begin{cases} I_\alpha(X_1, X_2) = D_\alpha(p_{X_1 X_2} \| p_{X_1} p_{X_2}), \\ I_{\text{ED}}(X_1, X_2) = D_{\text{ED}}(p_{X_1 X_2} \| p_{X_1} p_{X_2}), \\ I_{\text{CS}}(X_1, X_2) = D_{\text{CS}}(p_{X_1 X_2} \| p_{X_1} p_{X_2}). \end{cases} \quad (24.15)$$

The previous information measures are all defined based on PDFs (for continuous random variables). Some researchers also propose to define information measures using distribution functions or survival functions. For example, the cumulative residual entropy (CRE) of random variable  $X$  is defined by [18]

$$\mathcal{E}(X) = - \int_{\mathbb{R}_+} \bar{F}_{|X|}(x) \log \bar{F}_{|X|}(x) dx, \quad (24.16)$$

where  $\bar{F}_{|X|}(x) = P(|X| > x)$  is the survival function of  $|X|$ . In a recent paper [19], we define the order  $\alpha$  survival information potential (SIP) as ( $\alpha > 0$ )

$$S_\alpha(X) = \int_{\mathbb{R}_+} \bar{F}_{|X|}^\alpha(x) dx. \quad (24.17)$$

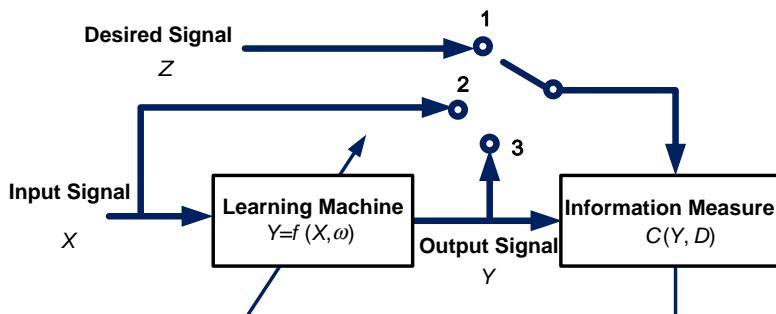

The survival information potential (24.16) is just defined by replacing the PDF with the survival function (of an absolute value transformation of  $X$ ) in the original information potential (24.4). This new definition seems more natural and reasonable, because the survival function is more regular and general than the PDF.

### 1.24.3 Unifying information theoretic framework for machine learning

Information theoretic methodology provides a unifying framework for both supervised and unsupervised machine learning [7]. Figure 24.2 shows a unifying view of learning based on information theoretic cost criteria. In Figure 24.2, the cost  $C(Y, D)$  denotes generally the information measure (divergence or mutual information) between  $Y$  and  $D$ , where  $Y$  is the output signal of the model (learning machine), and  $D$  depends on which position the switch is in. Information theoretic learning (ITL) is then to adjust the parameters  $\omega$  such that the cost  $C(Y, D)$  is optimized (minimized or maximized).

#### 1.24.3.1 Switch in position 1

When the switch is in position 1, the cost includes the model output  $Y$  and an external desired signal  $Z$ . Then the learning is supervised, and the goal is to make the output signal and the desired signal

**FIGURE 24.2**

Information theoretic learning framework.

as “close” as possible. In this case the learning can be categorized into two categories: (1) filtering (or regression) and classification; (2) feature extraction.

#### 1.24.3.1.1 Filtering and classification

In tradition filtering and classification, the cost function is in general the mean square error (the squares error loss) or misclassification error rate (the 0–1 loss). In ITL framework, the problem can be formulated as minimizing the divergence or maximizing the mutual information between output  $Y$  and the desired response  $Z$ , that is

$$\min_{\omega} D_{\text{KL}}(Y \| Z) = \int p_Y(x) \log \frac{p_Y(x)}{p_Z(x)} dx, \quad (24.18)$$

$$\max_{\omega} I(Y, Z) = \max_{\omega} \{H_S(Y) - H_S(Y|Z)\}. \quad (24.19)$$

The above optimization criteria are based purely on PDFs of the output and the desired signal; therefore we don't require the same number of desired and output data to calculate the errors.

For filtering and classification problems, another important ITL criterion is the *Minimum Error Entropy* (MEE) criterion [20–23], which aims at minimizing the entropy of the error between the output and the desired responses:

$$\min_{\omega} H_S(e) = \min_{\omega} \left\{ - \int p(e) \log p(e) de \right\}, \quad (24.20)$$

where  $e = Z - Y$  is the error. As entropy measures the average uncertainty or dispersion of a random variable, its minimization makes the error concentrated. Different from conventional Bayesian risks, like MSE, the “loss function” in MEE is  $-\log p(\cdot)$ , which is directly related to the error's PDF, transforming nonlinearly the error by its own PDF. If using Renyi's entropy as the cost, the optimization problem in (24.20) becomes

$$\begin{aligned} \min_{\omega} H_{\alpha}(e) &= \min_{\omega} \left\{ \frac{1}{1-\alpha} \log V_{\alpha}(e) \right\} \\ &\Leftrightarrow \begin{cases} \min_{\omega} V_{\alpha}(e) & \text{if } \alpha < 1, \\ \max_{\omega} V_{\alpha}(e) & \text{if } \alpha > 1, \end{cases} \end{aligned} \quad (24.21)$$

where  $V_{\alpha}(e)$  denotes error's information potential,  $V_{\alpha}(e) = \int p^{\alpha}(e) de$ .

#### 1.24.3.1.2 Feature extraction

In machine learning, when the input data are too large and the dimensionality is very high, it is necessary to transform nonlinearly the input data into a reduced representation set of features. Feature extraction (or feature selection) involves reducing the amount of resources required to describe a large set of data accurately. The feature set will extract the relevant information from the input in order to perform the desired task using the reduced representation instead of the full size input. Suppose the desired signal is the class label, then an intuitive cost for feature extraction should be some measure of “relevance” between the projection outputs (features) and the labels. In ITL, this problem can be solved

by maximizing the mutual information between the output  $Y$  and the label  $C$ :

$$\max_{\omega} I(Y, C) = \max_{\omega} \{H_S(Y) - H_S(Y|C)\}. \quad (24.22)$$

There are many other mutual information based criteria for feature extraction. A summary of these criteria can be found in [24], where a unifying framework for information theoretic feature selection has been presented. The use of mutual information criterion for feature extraction can be justified using Fano's inequality, according to which one should maximize the mutual information to improve the lower bound on the achievable probability of error [25].

### 1.24.3.2 Switch in position 2

When the switch is in position 2, the learning is in essence unsupervised because there is no external signal besides the input and output signals. In this situation, the well-known optimization principle is the *Maximum Information Transfer*, which aims to maximize the mutual information between the original input data and the output of the system:

$$\max_{\omega} I(Y, X) = \max_{\omega} \int p_{XY}(y, x) \log \frac{p_{XY}(y, x)}{p_Y(y)p_X(x)} dy dx. \quad (24.23)$$

This principle is also known as the principle of maximum information preservation (Infomax) described by Linsker, which is a widely accepted optimization principle for neural networks, self-organization, and other information processing systems [5]. Infomax is also related to an algorithm for independent component analysis (ICA) described by Bell and Sejnowski in 1995 [26].

Another information optimization principle for unsupervised learning (clustering, principal curves, vector quantization, etc.) is the *Principle of Relevant Information* (PRI), which can be formulated as [27–29]

$$\min_{\omega} \{H_S(Y) + \lambda D_{KL}(Y||X)\}, \quad (24.24)$$

where  $X$  denotes the original data set,  $Y$  is the compressed version of the original data, and  $\lambda$  is the trade-off parameter. The basic idea of PRI is to minimize the data redundancy (entropy term) while preserving the similarity to the original data (divergence term). Using Renyi's definition of entropy and divergence, (24.24) can be reformulated as

$$\min_{\omega} \{H_{\alpha}(Y) + \lambda D_{\alpha}(Y||X)\}. \quad (24.25)$$

To simplify the computation, one often uses Renyi's quadratic entropy to measure the redundancy, and Cauchy-Schwarz divergence to measure the distortion, which yields

$$\min_{\omega} \{H_2(Y) + \lambda D_{CS}(Y||X)\}. \quad (24.26)$$

### 1.24.3.3 Switch in position 3

When the switch is in position 3, the only source of data is the model output, which in this case is in general assumed multidimensional. Typical examples of this case include independent component analysis (ICA), clustering, output entropy optimization, and so on:

*Independent component analysis:* ICA is an unsupervised technique aiming to reduce the redundancy between components of the system output [30]. Given a nonlinear multiple-input-multiple-output (MIMO) system  $\mathbf{y} = f(\mathbf{x}, \boldsymbol{\omega})$ , the nonlinear ICA usually optimizes the parameter vector  $\boldsymbol{\omega}$  such that the mutual information between the components of  $\mathbf{y}$  is minimized:

$$\min_{\boldsymbol{\omega}} I(\mathbf{y}) = \int p(y_1 \cdots y_m) \log \frac{p(y_1 \cdots y_m)}{\prod_{d=1}^m p(y_d)} dy. \quad (24.27)$$

*Clustering:* Clustering (or clustering analysis) is a common technique for statistical data analysis used in machine learning, pattern recognition, bioinformatics, etc. The goal of clustering is to divide the input data into groups (called clusters) so that the objects in the same cluster are more “similar” to each other than to those in other clusters, and different clusters are defined as compactly and distinctly as possible. Information theoretic measures like entropy and divergence are frequently used as an optimization criterion for clustering. For example, in the case of two clusters, one can use the symmetrized KL divergence as the cost:

$$\max_{\boldsymbol{\omega}} D_{\text{KL}}(p_1(\mathbf{y}) \| p_2(\mathbf{y})) + D_{\text{KL}}(p_2(\mathbf{y}) \| p_1(\mathbf{y})). \quad (24.28)$$

*Output entropy optimization:* If the switch is in position 3, one can also optimize (minimize or maximize) the entropy at system output (usually subject to some constraint on the weight norm or nonlinear topology) so as to capture the underlying structure in high dimensional data:

$$\begin{cases} \min_{\boldsymbol{\omega}} \text{ or } \max_{\boldsymbol{\omega}} H(\mathbf{y}) = - \int p(\mathbf{y}) \log p(\mathbf{y}) d\mathbf{y}, \\ \text{s.t. } E[h_i(\mathbf{y})] = \alpha_i, \quad i = 1, \dots, d. \end{cases} \quad (24.29)$$

This optimization formulation is useful in blind equalization, nonlinear PCA, ICA and novelty filtering [30,31].

#### 1.24.3.4 Switch simultaneously in position 1 and 2

In Figure 24.2 the switch can be simultaneously in position 1 and 2. In this case, the cost has access to input data  $X$ , output data  $Y$ , and the desired or reference data  $Z$ . A well-known example is the *Information Bottleneck* (IB) method, introduced by Naftali Tishby et al. [32,33]. Given a random variable  $X$  and an observed relevant variable  $Z$ , and assuming that the joint distribution between  $X$  and  $Z$  is known, the IB method aims to compress  $X$  and try to find the best tradeoff between: (1) the minimization of mutual information between  $X$  and its compressed version  $Y$ ; and (2) the maximization of mutual information between  $Y$  and the relevant variable  $Z$ . Then the IB method minimizes the following cost:

$$\min_{\boldsymbol{\omega}} I(X, Y) - \beta I(Y, Z), \quad (24.30)$$

where  $\beta$  is the trade-off parameter. The basic idea in IB is to find a reduced representation of  $X$  while preserving the information of  $X$  with respect to another variable  $Z$ .

### 1.24.4 Nonparametric information estimators

To implement the previous ITL learning methods, one should evaluate the information theoretic costs, such as entropy and divergence. In practice, the data distributions are usually unknown, and the analytical evaluation of these measures is not possible. Thus we have to estimate ITL costs using sample data. There are two simple ways: (1) one way is to estimate the underlying distributions based on available samples, and plug the estimated distributions directly into the cost functions to obtain the information estimators (the so called “*plug-in estimators*”); and (2) another way is to substitute the estimated distributions into the *sample mean approximation* of the information measures (approximating the expected values by their sample mean). In the literature there are three possible techniques for estimating the PDF of a random variable based on its sample data: parametric, semi-parametric, and nonparametric. Accordingly, there are also parametric, semi-parametric, and nonparametric approaches for estimating information theoretic quantities. We refer the reader to [34] for a review of entropy estimation methods.

In the following, we focus only on the nonparametric kernel approach (Parzen windowing approach) that has been widely and successfully applied in ITL learning. Further, we mainly discuss entropy estimators. The estimation of other information measures is similar.

Given a set of independent and identically distributed (i.i.d.) samples  $\{x_1, \dots, x_N\}$  drawn from  $p(x)$ , the kernel density estimation (KDE) for  $p(x)$ , assuming a fixed-size kernel function  $\kappa_\sigma(\cdot)$  for simplicity, is given by [12, 13]

$$\hat{p}(x) = \frac{1}{N} \sum_{i=1}^N \kappa_\sigma(x - x_i). \quad (24.31)$$

In general the kernel function satisfies  $\kappa_\sigma(x) \geq 0$ , and  $\int \kappa_\sigma(x) dx = 1$ , and hence  $\hat{p}(x)$  is still a PDF. Further, to make the estimator smooth, the kernel function is usually continuous and differentiable (and preferably symmetric and unimodal). The most widely used kernel function is the Gaussian function:

$$\kappa_\sigma(x) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{\|x\|^2}{2\sigma^2}\right). \quad (24.32)$$

The kernel size (or bandwidth) for the Gaussian kernel can be optimized using maximum likelihood (ML) principle, or selected according to rules-of-thumb, such as Silverman’s rule [13].

For fixed kernel size  $\sigma$ , we have  $\lim_{N \rightarrow \infty} \hat{p}(x) = p(x) * \kappa_\sigma(x)$  (here, “ $*$ ” denotes the convolution operator). Using a suitable annealing rate for the kernel size, the KDE can be asymptotically unbiased and consistent. Specifically, if  $\lim_{N \rightarrow \infty} \sigma(N) = 0$ , and  $\lim_{N \rightarrow \infty} N\sigma(N) = \infty$ , then  $\lim_{N \rightarrow \infty} \hat{p}(x) = p(x)$  in probability [35].

Substitute (24.31) in Shannon’s entropy expression (24.2), we get the following plug-in estimator:

$$\widehat{H}_S(X) = -\frac{1}{N} \int \sum_{i=1}^N \kappa_\sigma(x - x_i) \log \left( \frac{1}{N} \sum_{i=1}^N \kappa_\sigma(x - x_i) \right) dx. \quad (24.33)$$

To avoid the evaluation of integral, one can alternatively substitute (24.31) in the sample mean estimator of Shannon entropy and obtain

$$\hat{H}_S(X) = -\frac{1}{N} \sum_{j=1}^N \log \left( \frac{1}{N} \sum_{i=1}^N \kappa_\sigma(x_j - x_i) \right). \quad (24.34)$$

Similarly, substituting (24.31) in Renyi's entropy expression, we have

$$\hat{H}_\alpha(X) = \frac{1}{1-\alpha} \log \int \left( \frac{1}{N} \sum_{i=1}^N \kappa_\sigma(x - x_i) \right)^\alpha dx. \quad (24.35)$$

Further, the sample mean estimator of Renyi's entropy will be

$$\begin{aligned} \hat{H}_\alpha(X) &= \frac{1}{1-\alpha} \log \frac{1}{N} \sum_{j=1}^N \left( \frac{1}{N} \sum_{i=1}^N \kappa_\sigma(x_j - x_i) \right)^{\alpha-1} \\ &= \frac{1}{1-\alpha} \log \frac{1}{N^\alpha} \sum_{j=1}^N \left( \sum_{i=1}^N \kappa_\sigma(x_j - x_i) \right)^{\alpha-1}. \end{aligned} \quad (24.36)$$

In (24.35), if  $\alpha = 2$  and the kernel function is Gaussian function, we can derive

$$\begin{aligned} \hat{H}_2(X) &= -\log \int_{-\infty}^{\infty} \left( \frac{1}{N} \sum_{i=1}^N \kappa_\sigma(x - x_i) \right)^2 dx \\ &= -\log \frac{1}{N^2} \int_{-\infty}^{\infty} \left( \sum_{i=1}^N \sum_{j=1}^N \kappa_\sigma(x - x_j) \kappa_\sigma(x - x_i) \right)^2 dx \\ &= -\log \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N \int_{-\infty}^{\infty} \kappa_\sigma(x - x_j) \kappa_\sigma(x - x_i) dx \\ &= -\log \left( \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N \kappa_{\sqrt{2}\sigma}(x_j - x_i) \right). \end{aligned} \quad (24.37)$$

This result comes from the fact that the integral of the product of two Gaussian functions can be exactly evaluated as the value of the Gaussian function computed at the difference of the arguments and whose variance is the sum of the variances of the two original Gaussian functions. As one can see, the plug-in estimator (24.37) is identical to the sample mean estimator of quadratic Renyi's entropy but with kernel size  $\sqrt{2}\sigma$  instead of  $\sigma$ . The argument of the logarithm in (24.37) is the estimator of quadratic information potential (QIP):

$$\hat{V}_2(X) = \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N \kappa_{\sqrt{2}\sigma}(x_j - x_i). \quad (24.38)$$

Based on the estimator of QIP, one can easily estimate other quadratic information measures ( $D_{ED}$ ,  $D_{CS}$ ,  $I_{ED}$ ,  $I_{CS}$ ). For example, the Cauchy-Schwarz divergence (24.9) can be estimated as

$$\widehat{D}_{CS}(p_1 \| p_2) = \log \frac{\widehat{V}_{p_1} \widehat{V}_{p_2}}{\widehat{V}_c^2}, \quad (24.39)$$

where

$$\widehat{V}_{p_1} = \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N \kappa_{\sqrt{2}\sigma}(x_1(j) - x_1(i)), \quad (24.40)$$

$$\widehat{V}_{p_2} = \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N \kappa_{\sqrt{2}\sigma}(x_2(j) - x_2(i)), \quad (24.41)$$

$$\widehat{V}_c = \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N \kappa_{\sqrt{2}\sigma}(x_1(j) - x_2(i)), \quad (24.42)$$

where  $\{x_1(i)\}_{i=1}^N$  and  $\{x_2(i)\}_{i=1}^N$  are samples from  $p_1$  and  $p_2$ , respectively,  $\widehat{V}_c$  is the cross information potential estimator.

There are some nice properties of the nonparametric information estimators. For example, the entropy estimators possess the same location of the extremum (maximum or minimum) as the actual entropy [10]. The following theorem shows that under a certain condition, the minimum value of entropy estimators occurs when sample data are related to a  $\delta$  distribution.

**Theorem 1.** *If the kernel function  $\kappa_\sigma(\xi)$  achieves its maximum value at  $\xi = 0$ , then the minimum value of the entropy estimator in (24.36) is achieved when all sample data are equal to each other, that is  $x_1 = \dots = x_N = c$ .*

The above result can be easily proved. Actually, for  $\alpha > 1$ , we have

$$\sum_{j=1}^N \left( \sum_{i=1}^N \kappa_\sigma(x_j - x_i) \right)^{\alpha-1} \leq \sum_{j=1}^N \left( \sum_{i=1}^N \max_x \kappa_\sigma(x) \right)^{\alpha-1} = N^\alpha \kappa_\sigma^{\alpha-1}(0). \quad (24.43)$$

And hence

$$\widehat{H}_\alpha(X) = \frac{1}{1-\alpha} \log \frac{1}{N^\alpha} \sum_{j=1}^N \left( \sum_{i=1}^N \kappa_\sigma(x_j - x_i) \right)^{\alpha-1} \geq -\log \kappa_\sigma(0). \quad (24.44)$$

When  $x_1 = \dots = x_N = c$ , the equality will hold. The proof for the case  $\alpha < 1$  is similar.

One can further prove that if the kernel function is continuous, differentiable, symmetric, and unimodal, then the global minimum in the above theorem will be smooth, that is, it has a zero gradient and a positive semi-definite Hessian matrix [10]. In adaptive learning using numerical optimization techniques, it is crucial that the global optimum be a smooth point in the weight space with zero-gradient.

## 1.24.5 Reproducing kernel Hilbert space framework for ITL

ITL learning is closely related to kernel methods and Reproducing Kernel Hilbert Space (RKHS) [36–38]. In this section, we present a RKHS framework for ITL. In fact, we can uniquely determine a RKHS using the symmetric non-negative definite kernel function defined as the *cross information potential* (CIP).

### 1.24.5.1 RKHS for ITL

Let  $\mathcal{E}$  be the set of all square integrable one-dimensional PDFs over the real numbers; that is,  $p_i(x) \in \mathcal{E}, \forall i \in \mathcal{I}$ , where  $\int p_i(x)^2 dx < \infty$  and  $\mathcal{I}$  is an index set. Here, for simplicity, we focus on one dimensional PDFs, the extension to multi-dimensions is straightforward. Then one can form a linear manifold:  $\{\sum_{i \in \mathcal{K}} \alpha_i p_i(x)\}$  for any  $\mathcal{K} \subseteq \mathcal{I}$ , and  $\alpha_i \in \mathbb{R}$ . Let  $L_2(\mathcal{E})$  be the Hilbert space that consists of all linear combinations of PDFs and their limit points, and is equipped with inner product:

$$\langle f_i(x), f_j(x) \rangle_{L_2} = \int f_i(x) f_j(x) dx \quad \forall f_i, f_j \in \mathcal{E}. \quad (24.45)$$

Note that the above inner product is exactly the CIP between  $f_i$  and  $f_j$ . The Hilbert space  $L_2(\mathcal{E})$  is not a RKHS since the inner product is not reproducing in  $L_2(\mathcal{E})$ ; that is, the evaluation of any element in  $L_2(\mathcal{E})$  cannot be reproduced via the inner product between two functions in  $L_2(\mathcal{E})$ . However, one can use the inner product in (45) to induce a RKHS that is congruent with  $L_2(\mathcal{E})$ .

Let  $v(f_i, f_j)$  be a bivariate function on the set  $\mathcal{E}$ , defined as

$$v(f_i, f_j) = \int f_i(x) f_j(x) dx \quad \forall f_i, f_j \in \mathcal{E}. \quad (24.46)$$

It can be easily verified that the function  $v(f_i, f_j)$  is symmetric and non-negative definite, and is a Mercer kernel function. According to the Moore-Aronszajn theorem [39,40], there is a unique RKHS, denoted by  $\mathcal{H}_v$ , associated with  $v(f_i, f_j)$ . One can construct the RKHS  $\mathcal{H}_v$  bottom-up. By Mercer's theorem [41], function  $v(f_i, f_j)$  has eigen-decomposition:

$$v(f_i, f_j) = \sum_{k=1}^{\infty} \lambda_k \psi_k(f_i) \psi_k(f_j), \quad (24.47)$$

where  $\{\psi_k(f_i), k = 1, 2, \dots\}$  and  $\{\lambda_k, k = 1, 2, \dots\}$  are sequences of eigenfunctions and corresponding eigenvalues of  $v(f_i, f_j)$ , respectively. The above series converges absolutely and uniformly on  $\mathcal{E} \times \mathcal{E}$ . We then define a space  $\mathcal{H}_v$  consisting of all functionals  $G(\cdot)$  whose evaluation for any given PDF  $f_i \in \mathcal{E}$  is

$$G(f_i) = \sum_{k=1}^{\infty} \lambda_k a_k \psi_k(f_i), \quad (24.48)$$

where the sequence  $\{a_k, k = 1, 2, \dots\}$  satisfies  $\sum_{k=1}^{\infty} \lambda_k a_k^2 < \infty$ . The inner product of two functionals in  $\mathcal{H}_v$  is defined by

$$\langle G, F \rangle_{\mathcal{H}_v} = \sum_{k=1}^{\infty} \lambda_k a_k b_k, \quad (24.49)$$

where  $F(f_i) = \sum_{k=1}^{\infty} \lambda_k b_k \psi_k(f_i)$ ,  $\sum_{k=1}^{\infty} \lambda_k b_k^2 < \infty$ . Now it can be verified that the space  $\mathcal{H}_v$  induced by the kernel function  $v(f_i, f_j)$  is indeed a RKHS, and this kernel function is a reproducing kernel because it satisfies:

1.  $\forall f_i \in \mathcal{E}$ ,  $v(f_i, f_j)$  as a functional of  $f_j$  belongs to  $\mathcal{H}_v$ ,
2.  $\forall G \in \mathcal{H}_v$ ,  $\langle G, v(f_i, .) \rangle_{\mathcal{H}_v} = G(f_i)$  (the so called reproducing property).

By the reproducing property, one can rewrite the kernel function  $v(f_i, f_j)$  as the inner product:

$$v(f_i, f_j) = \langle v(f_i, .), v(f_j, .) \rangle_{\mathcal{H}_v}, \quad v(f_i, .) : f_i \mapsto \sqrt{\lambda_i} \psi_i(f_i), \quad k = 1, 2, \dots \quad (24.50)$$

The reproducing kernel nonlinearly maps the original PDF  $f_i$  into the RKHS  $\mathcal{H}_v$ .

It is worth noting that, although the RKHS  $\mathcal{H}_v$  and the Hilbert space  $L_2(\mathcal{E})$  are much different, they are congruent with each other. Actually one can prove that there exists a one-to-one congruence mapping  $\Psi$  from  $\mathcal{H}_v$  to  $L_2(\mathcal{E})$  such that  $\Psi(v(f_i, .)) = f_i$  [37].

### 1.24.5.2 ITL cost functions in RKHS

The ITL costs can be reformulated in RKHS  $\mathcal{H}_v$ . First of all, the cross information potential (CIP) can be expressed as the inner product in  $\mathcal{H}_v$ :

$$\int p_1(x) p_2(x) dx = \langle v(p_1, .), v(p_2, .) \rangle_{\mathcal{H}_v}. \quad (24.51)$$

The inner product quantifies similarity between two functionals and this agrees with the definition of cross information potential. Then the quadratic information potential (QIP) can also be specified as the inner product between a functional and itself:

$$\int p^2(x) dx = \langle v(p, .), v(p, .) \rangle_{\mathcal{H}_v} = \|v(p, .)\|_{\mathcal{H}_v}^2. \quad (24.52)$$

Therefore, maximizing QIP in ITL turns out to be maximization of the norm square in  $\mathcal{H}_v$ . Using (24.52), we can rewrite Renyi's quadratic entropy as

$$H_2(X) = -\log \|v(p, .)\|_{\mathcal{H}_v}^2. \quad (24.53)$$

Based on the reformulations of CIP (24.51) and QIP (24.52) one can easily rewrite other quadratic information measures in terms of operations on functional in  $\mathcal{H}_v$ . For example, the Cauchy-Schwarz divergence measure can be expressed as

$$D_{CS}(p_1 \| p_2) = -2 \log \left( \frac{\langle v(p_1, .), v(p_2, .) \rangle_{\mathcal{H}_v}}{\sqrt{\|v(p_1, .)\|_{\mathcal{H}_v}^2 \|v(p_2, .)\|_{\mathcal{H}_v}^2}} \right) = -2 \log (\cos \theta), \quad (24.54)$$

where  $\theta$  is the angle in  $\mathcal{H}_v$  between two functionals  $v(p_1, .)$  and  $v(p_2, .)$ . Therefore the RKHS  $\mathcal{H}_v$  provides an insightful geometric interpretation for CS-divergence; that is, the argument of the log of CS-divergence truly measures the separation (angle) between two functional vectors in  $\mathcal{H}_v$ .

### 1.24.5.3 Information estimator in RKHS

The estimators of information theoretic quantities can also be reinterpreted in RKHS (kernel space). Consider the nonparametric kernel estimator of quadratic information potential (QIP) in (24.38). The Gaussian kernel  $\kappa_{\sqrt{2}\sigma}(.)$  is a Mercer kernel and can be written as an inner product in a RKHS:

$$K_{\sqrt{2}\sigma}(x_i - x_j) = k(x_i - x_j) = \langle \varphi(x_i), \varphi(x_j) \rangle_{\mathcal{H}_\kappa}, \quad (24.55)$$

where  $\varphi(x) = \kappa(x, .)$  defines the nonlinear mapping between input space and kernel space  $\mathcal{H}_\kappa$ . Hence the estimated QIP in (38) can be expressed in terms of an inner product in kernel space:

$$\begin{aligned} \widehat{V}_2(x) &= \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N \kappa_{\sqrt{2}\sigma}(x_j - x_i) \\ &= \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N \langle \varphi(x_i), \varphi(x_j) \rangle_{\mathcal{H}_\kappa} \\ &= \left\langle \frac{1}{N} \sum_{j=1}^N \varphi(X_i), \frac{1}{N} \sum_{j=1}^N \varphi(X_i) \right\rangle_{\mathcal{H}_\kappa} \\ &= \mathbf{m}^T \mathbf{m} = \|\mathbf{m}\|^2. \end{aligned} \quad (24.56)$$

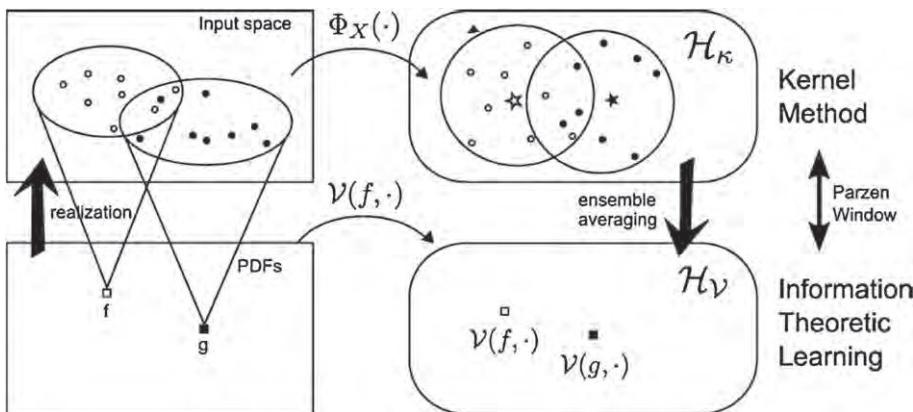

It turns out that the estimated QIP may be expressed as the squared norm of the mean vector of the data in kernel space. Other quadratic information estimators may also be expressed in terms of mean vectors in the kernel space. Actually one can express the estimated ED-divergence and CS-divergence as

$$\widehat{D}_{\text{ED}}(p_1 \| p_2) = \|\mathbf{m}_1\|^2 - 2\mathbf{m}_1^T \mathbf{m}_2 + \|\mathbf{m}_2\|^2 = \|\mathbf{m}_1 - \mathbf{m}_2\|^2, \quad (24.57)$$

$$\widehat{D}_{\text{ED}}(p_1 \| p_2) = -2 \log \left( \frac{\mathbf{m}_1^T \mathbf{m}_2}{\|\mathbf{m}_1\| \|\mathbf{m}_2\|} \right) = -2 \log (\cos(\langle \mathbf{m}_1, \mathbf{m}_2 \rangle)), \quad (24.58)$$

where  $\mathbf{m}_1$  and  $\mathbf{m}_2$  are kernel space mean vectors of the data points drawn from  $p_1(x)$  and  $p_2(x)$ , respectively. From (24.57) and (24.58), one can see the ED-divergence estimator measures the square of the norm of the difference vector between  $\mathbf{m}_1$  and  $\mathbf{m}_2$ , while the argument of the log of CS-divergence estimator measures the cosine of the angle between mean vectors.

Figure 24.3 illustrates the relationship between the two RKHS  $\mathcal{H}_v$  and  $\mathcal{H}_\kappa$ . The information quantities in  $\mathcal{H}_v$  can be estimated by the mean operator of the projected functionals in  $\mathcal{H}_\kappa$ , which was effectively derived with Parzen's nonparametric PDF estimator employed in ITL cost functions, and with a Mercer kernel (symmetric and non-negative definite kernel) as the Parzen window.

**FIGURE 24.3**

The relationship between  $\mathcal{H}_V$  and  $\mathcal{H}_\kappa$  (from [37]).

### 1.24.6 Information particle interaction for learning from samples

In training of a multilayer network such as multilayer perceptrons (MLPs), the output (or output error) is back-propagated through the layers to determine the gradient update rule for weight vector [42]. If the learning is supervised, the mean square error (MSE) is widely used as an adaptation cost. The simple LMS algorithm is a special case of back-propagation (BP) for single layer network with linear processing elements. The conventional BP algorithms can be readily extended to ITL costs. Under ITL costs (e.g., error entropy), the gradient of the weight vector can be calculated by the chain rule of partial derivatives as: (1) sensitivity of the output of the adaptive network with respective to its weights, and (2) sensitivity of the ITL cost on the values of the samples. With the kernel estimator in Renyi's entropy, the latter sensitivity has an interesting analogy with physical particles interacting on an *information potential field* [43,44]. This analogy has its roots in the link between Renyi's entropy and the norms of the PDF of the data. Actually, since the kernels in PDF estimation are positive functions that decay with the distance between samples, we can think that one kernel placed on a sample creates a potential field in the same place, just like physical particles create a gravity field in space. In our case, however, the law of interaction is dictated by the kernel shape. The potential field in the sample space is thus an approximation of the PDF that generates the data. In this context, samples can be named as *information particles* and they interact in the information potential field of the PDF through *information forces* [43].

The kernel estimator of quadratic information potential can alternatively be expressed as the average sum of interactions from each sample in the sample set, that is

$$\widehat{V}_2(X) = \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N \kappa_{\sqrt{2}\sigma}(x_j - x_i)$$

$$\begin{aligned}
&= \frac{1}{N} \sum_{j=1}^N \left( \frac{1}{N} \sum_{i=1}^N \kappa_{\sqrt{2}\sigma}(x_j - x_i) \right) \\
&= \frac{1}{N} \sum_{j=1}^N \left( \frac{1}{N} \sum_{i=1}^N \widehat{V}_2(x_j, x_i) \right) \\
&= \frac{1}{N} \sum_{j=1}^N \widehat{V}_2(x_j),
\end{aligned} \tag{24.59}$$

where  $\widehat{V}_2(x_j, x_i) = \kappa_{\sqrt{2}\sigma}(x_j - x_i)$ , and  $\widehat{V}_2(x_j) = \frac{1}{N} \sum_{i=1}^N \widehat{V}_2(x_j, x_i)$ . Here the term  $\widehat{V}_2(x_j, x_i)$  measures the contribution of sample  $x_i$  to the potential of  $x_j$ , and the quantity  $\widehat{V}_2(x_j)$  measures the potential field in the space location occupied by the sample  $x_j$  due to all the other samples. The information potential is thus just the average value of the information potential field of the sample set (hence the name).

The derivative of the information potential with respect to the position of sample  $x_j$  can be easily evaluated as

$$\frac{\partial}{\partial x_j} \widehat{V}_2(X) = \frac{1}{N} \sum_{j=1}^N \widehat{F}_2(x_j), \quad \widehat{F}_2(x_j) = \frac{1}{N} \sum_{i=1}^N \widehat{F}_2(x_j, x_i), \tag{24.60}$$

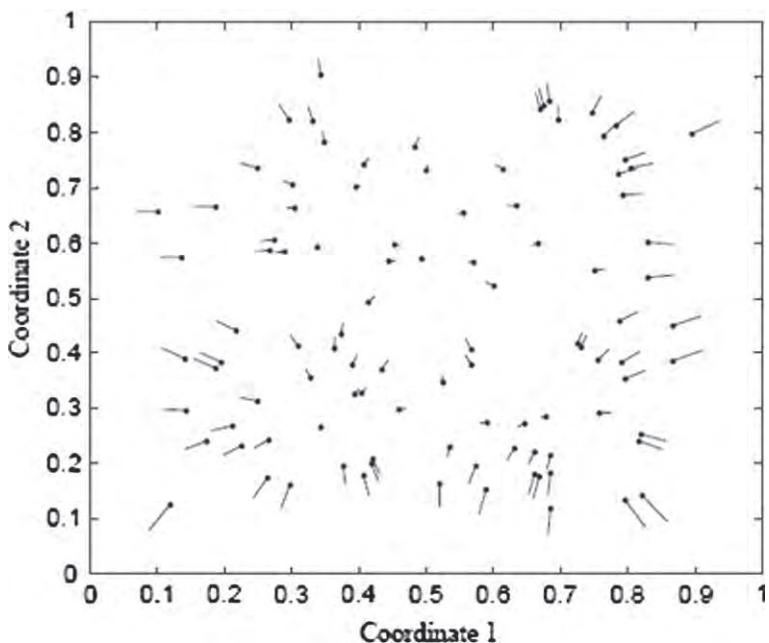

where  $\widehat{F}_2(x_j) = \frac{\partial}{\partial x_j} \widehat{V}_2(x_j)$ ,  $\widehat{F}_2(x_j, x_i) = \frac{\partial}{\partial x_j} \widehat{V}_2(x_j, x_i)$ . These two quantities are named the (*total*) *information force* acting on sample  $x_j$  and the *information force* on sample  $x_j$  due to sample  $x_i$ , respectively. Note that the concepts of information potential fields and information forces can be generalized to other information measures, such as quadratic divergence and quadratic mutual information [7].

In adaptive system training with ITL costs, the system parameters can be adapted by information forces created among the pair-wise interactions in the sample set. In supervised learning, if the error samples are generated by an MLP with weights  $\boldsymbol{\omega}$ , the gradient of the information potential with respect to these weights would be [45]

$$\frac{\partial}{\partial \boldsymbol{\omega}} \widehat{V}_2(e) = \frac{1}{N^2} \sum_{i=1}^N \sum_{j=1}^N \widehat{F}_2(x_j, x_i) \left( \frac{\partial x_i}{\partial \boldsymbol{\omega}} - \frac{\partial x_j}{\partial \boldsymbol{\omega}} \right). \tag{24.61}$$

Thus, for the adaptation of an MLP, the principle of error back-propagation can be extended to information force back-propagation by simply substituting the injected error of the MSE with the information force  $\widehat{F}_2(x_j, x_i)$ .

Figure 24.4 shows a snapshot of a two-dimensional entropy maximization scenario, where the particles are bounded to within a unit square and interact under the quadratic force definition with Gaussian kernel choice. The objective is to maximize the entropy of the sample ensemble, and hence the forces become repulsive. Given a set of randomly spaced samples in the unit square, when the forces acting on each sample are evaluated, it becomes clear that the information particles are pushed by the other particles in order to move along the direction of maximal entropy. In Figure 24.4, the lines attached to each sample are vectors that display intensity and point to the direction of change.

**FIGURE 24.4**

A snapshot of the locations of the information particles and the instantaneous quadratic information forces acting on them to maximize the joint entropy in the two-dimensional unit square (from [43]).

## 1.24.7 Illustrative examples

### 1.24.7.1 MEE based adaptive system training

*Back Propagation for MEE:* The entropy of the error can be employed as a robust cost function to learn the parameters of function approximation. Below, we derive a back propagation procedure to adjust the parameters of a feedforward network based on the error entropy. In particular, we want to minimize the Renyi's second order entropy of the prediction error in a time series using a time delay neural network as predictor. A sliding window of size  $L$  is utilized to compute the estimation of the error information potential. Suppose we have an upcoming example at time  $t$ , the estimate of the information potential is given by,

$$\widehat{V}_E(t) = \sum_{i,j=t-L+1}^t \kappa_\sigma(\|\mathbf{e}(i) - \mathbf{e}(j)\|). \quad (24.62)$$

Although, (24.62) is conceptually the right cost, the computation of the gradient for multiple output functions is rather cumbersome. Therefore a modified version of this cost is introduced,

$$\widehat{V}_E(t) = \sum_{i,j=t-L+1}^t \sum_{k=1}^{M_p} \kappa_\sigma(\mathbf{e}_k(i) - \mathbf{e}_k(j)). \quad (24.63)$$

The gradient equations with respect to the network parameters of the output layer  $p$  are:

$$\frac{\partial \widehat{V}_E(t)}{\partial \mathbf{w}_{(p)_k}} = \frac{1}{\sigma^2 L^2} \sum_{j=t-L+1}^t \kappa_\sigma(e_k(i) - e_k(j))(e_k(i) - e_k(j)) \begin{bmatrix} f'_p \left( \mathbf{w}_k^{(p)T} \delta^{(p-1)}(i) \right) \delta^{(p-1)}(i) + \\ -f'_p \left( \mathbf{w}_k^{(p)T} \delta^{(p-1)}(j) \right) \delta^{(p-1)}(j) \end{bmatrix} \quad (24.64)$$

and for the hidden layer  $p-1$ ,

$$\begin{aligned} \frac{\partial \widehat{V}_E(t)}{\partial \mathbf{w}_l^{(p-1)}} &= \frac{1}{\sigma^2 L^2} \sum_{k=1}^{M_p} \sum_{j=t-L+1}^t \kappa'_\sigma(e_k(i) - e_k(j)) \\ &\times \begin{bmatrix} f'_p \left( \mathbf{w}_k^{(p)T} \delta^{(p-1)}(i) \right) w_{kl}^{(p)} f'_{p-1} \left( \mathbf{w}_l^{(p-1)T} \delta^{(p-2)}(i) \right) \delta^{(p-2)}(i) + \\ -f'_p \left( \mathbf{w}_k^{(p)T} \delta^{(p-1)}(j) \right) w_{kl}^{(p)} f'_{p-1} \left( \mathbf{w}_l^{(p-1)T} \delta^{(p-2)}(j) \right) \delta^{(p-2)}(j) \end{bmatrix}, \end{aligned} \quad (24.65)$$

where the matrices  $\mathbf{w}^{(i)}$  and  $f_i$  are the weights and activation function of the  $i$ th layer and  $\delta^{(i)}(t) = f_i(\mathbf{w}^{(i)} \delta^{(i-1)}(t))$  the outputs of the units at the same layer.

*Experiments:* In the following a feedforward neural network is trained to perform prediction of a nonlinear time series. The Mackey-Glass system is a chaotic system defined by

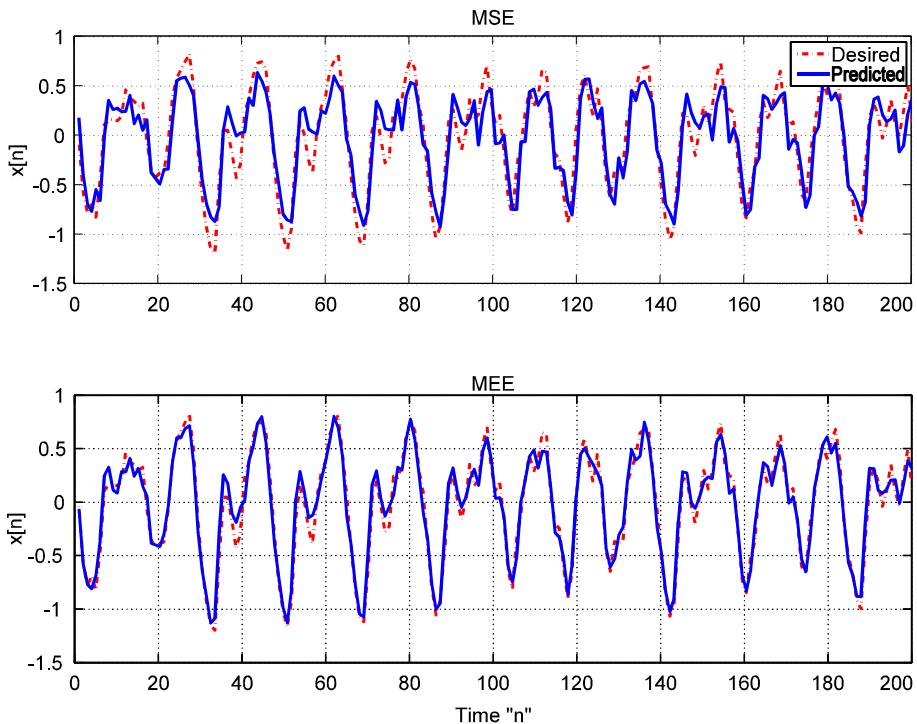

$$\dot{x}(t) = -0.1x(t) + \frac{0.2x(t-\tau)}{1+x(t-\tau)^{10}}. \quad (24.66)$$

In particular, we use  $\tau = 30$ , the number of delays for the time embedding of the series is 7, the generation of the samples follows [46]; a total of 5000 samples are generated. A TDNN with 10 units in the hidden layer and sigmoidal tangent activation function is trained using the first 500 samples from the series and in the case of MEE the sliding window has  $L = 50$ . The kernel size is kept fixed at  $\sigma = 0.2$ . The parameters are adjusted using momentum gradient with parameter  $\gamma = 0.5$  and the step size is  $\eta = 0.08$  for MSE and  $\eta = 0.02$  for MEE. Figure 24.5 shows the desired and predicted test signals for the two different cost functions.

The advantage of MEE can be observed from the distribution of the test error shown in Figure 24.6. Note that the test errors obtained from the network trained with MEE is more concentrated around zero than the one trained by MSE.

### 1.24.7.2 ED-divergence-based classification

In this case, we are given two or more distributions, for which, we are interested in basically 2 types of interactions: the particle interactions within a distribution, and the particle interactions among distributions. First, let us recall the definition of the so called Euclidean divergence between densities.

**FIGURE 24.5**

Predicted and desired outputs for TDNN trained with MSE and MEE.

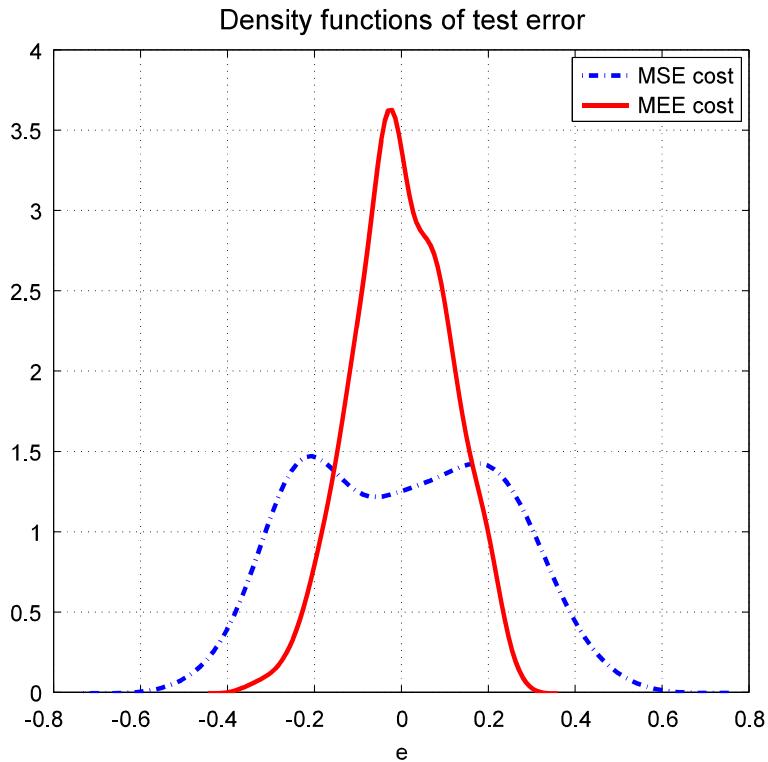

For random variables (vectors)  $X_1$  and  $X_2$  and their respective densities  $p(x)$  and  $q(x)$ . The Euclidean divergence is the overall squared difference between  $p$  and  $q$  along their common support  $X \subset \mathbb{R}^d$ , that is

$$D_{\text{ED}}(p\|q) = \int_X (p(x) - q(x))^2 dx. \quad (24.67)$$

The first condition that naturally arises from this definition is that  $p$  and  $q$  must be square integrable functions. Mutual information was originally conceived as a measure of common entropy associated with two variables. In Shannon's definition of mutual information leads to the more general concept of KL-divergence that can be utilized to compute mutual information as a dissimilarity between the joint and marginal densities (or probability mass functions). Extending this idea of dissimilarity we have the Quadratic mutual information based on the Euclidean divergence QMI<sub>ED</sub> for two random variables (or vectors)  $X_1$  and  $X_2$  with joint  $p(x_1, x_2)$  and marginals  $p_1(x)$  and  $p_2(x)$ , respectively:

$$\text{QMI}_{\text{ED}}(X_1; X_2) = D_{\text{ED}}(p(x_1, x_2)\|p_1(x_1)p_2(x_2)). \quad (24.68)$$

Notice this definition can be adapted for discrete random variables where densities are now probability mass functions and integrals become finite or countable summations.

**FIGURE 24.6**

Densities of the test errors for MSE and MEE after training.

The dataset is divided into two classes; therefore we have a second variable  $Y$  which is the class label. We can use the Euclidean divergence to compare the conditional density of  $X$  given the label  $Y$  that yields  $D_{ED}(p(x|Y=1)\|p(x|Y=2))$ . We will denote the data points that belong to class 1 as  $x_i^{(1)}$  and class 2 as  $x_i^{(2)}$ , the number of instances for class 1 is  $N_1$  and  $N_2$  for class 2. Let us construct a kernel matrix with all the data points available for the two classes in the following way:

$$\mathbf{K}_{\text{full}} = \begin{bmatrix} \mathbf{K}_1 & \mathbf{K}_{12} \\ \mathbf{K}_{21} & \mathbf{K}_2 \end{bmatrix}, \quad (24.69)$$

where  $\mathbf{K}_1$  corresponds to all pair-wise comparisons between points from class 1, likewise  $\mathbf{K}_2$  is defined for points in class 2 and the elements of  $\mathbf{K}_{12} = \mathbf{K}_{21}^T$  are given by  $K_{ij} = \kappa(x_i, x_j)$ . Having introduced this notation, let's compute the empirical estimate of the Euclidean divergence as:

$$\widehat{D}_{ED}(p(x|Y=1)\|p(x|Y=2)) = \frac{1}{N_1^2} \mathbf{1}^T \mathbf{K}_1 \mathbf{1} + \frac{1}{N_2^2} \mathbf{1}^T \mathbf{K}_2 \mathbf{1} - \frac{2}{N_1 N_2} \mathbf{1}^T \mathbf{K}_{12} \mathbf{1}. \quad (24.70)$$

The first two terms of the right-hand side are the information potential within class and the third term is the cross-information potential. Basically, we have two potential fields each one generated by the samples of the corresponding class. Figure 24.7 shows the information potential fields created by each one of the classes along with the forces experienced by each data point under that specific field.

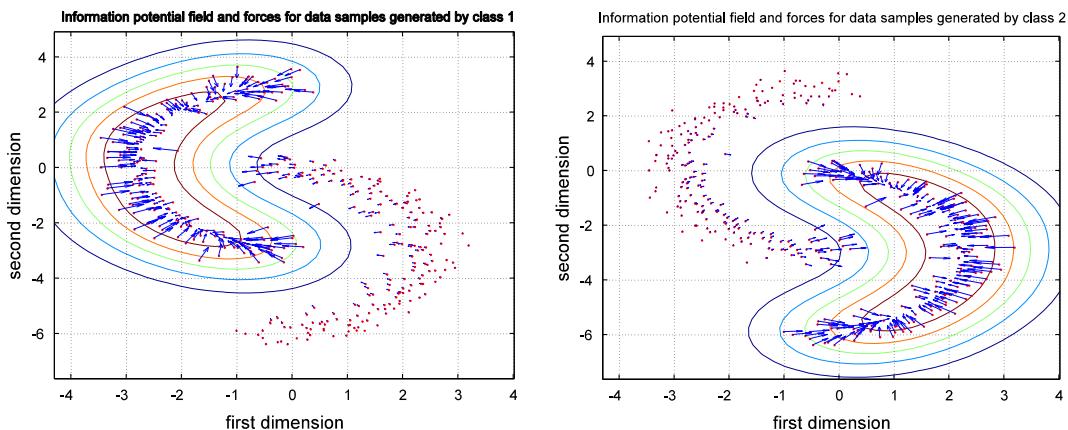

The total forces are presented in Figure 24.8 as well as the difference between the two potential fields generated by each class.

The first important observation is that the interaction of these two fields leads to the maximum likelihood classification rule. If we compute the difference between the information potentials of generated by class 1 and class 2, we are basically comparing the likelihood of a data point with respect to a conditional density given a particular class and the force experienced by the point will drive it to the class it is more likely to belong. Figure 24.9 shows the partition obtained by using the Gaussian kernel with  $\sigma = 1$ .

An interesting problem to use mutual information with the data set is the assessment of the strength of the relation between the class labels and the random vector describing the patterns that is  $\text{QMI}_{\text{ED}}(X; Y)$ . This problem involves the combination of a discrete random variable  $Y$  (the labels) and a real random vector  $X$ . The quantity of interest reduces to:

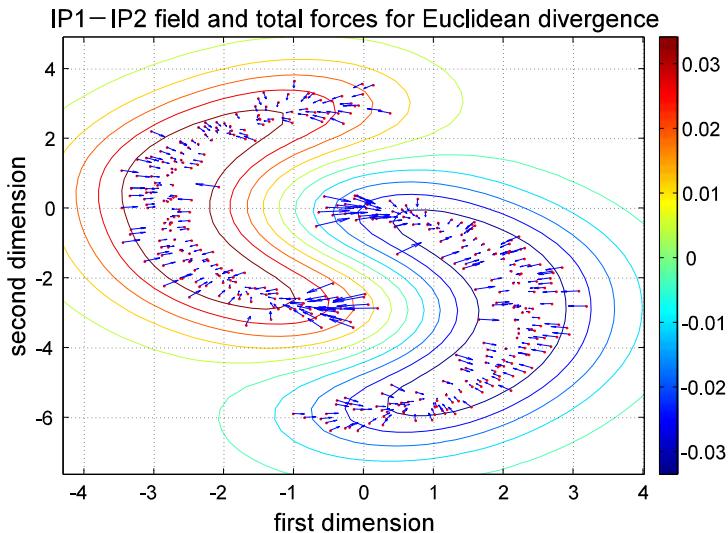

$$\text{QMI}_{\text{ED}}(X; Y) = P(Y = 1)^2 D_{\text{ED}}(p(x|Y = 1)\|p(x)) + P(Y = 2)^2 D_{\text{ED}}(p(x|Y = 2)\|p(x)). \quad (24.71)$$

In this case we are measuring the difference between the two classes by weighting the divergences between the PDF of the data when the class is not known and the density of the data given the class is known. If we relate this problem to classification we can think of it as an approximation to the MAP rule for Parzen density estimation. In our setting  $P(Y = 1) = \frac{N_1}{N_1+N_2}$  and  $P(Y = 2) = \frac{N_2}{N_1+N_2}$ . However, if we set  $N_1 = N_2$  the result from the particle interaction should be the same than the one using  $\bar{D}_{\text{ED}}(p(x|Y = 1)\|p(x|Y = 2))$ .

**FIGURE 24.7**

Information potential and forces created by each class.

**FIGURE 24.8**

$IP_1 - IP_2$  field and total information forces for the two class problem.

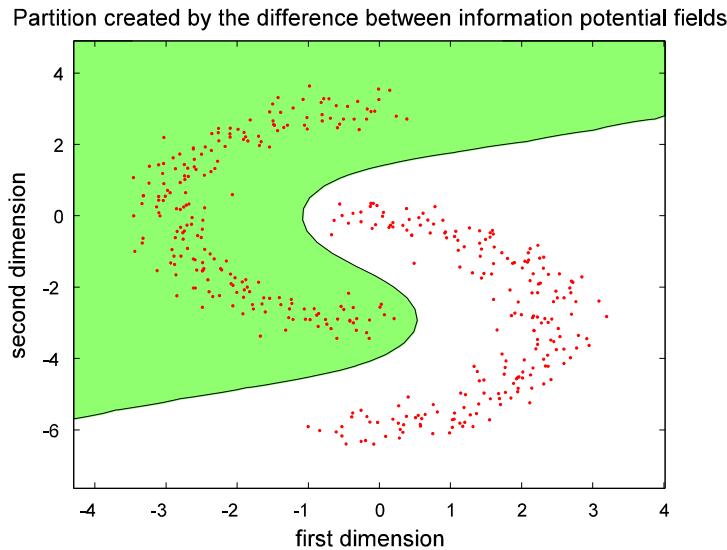

### 1.24.7.3 Information cut for clustering

*Cauchy-Schwarz objective function:* Clustering objective functions encourage the compactness of the clusters. In information theoretic clustering each cluster is represented by a density that should be as far apart as possible from the other densities (clusters). However, distances are defined between two distributions, and therefore it becomes necessary to find a suitable extension that considers more than 2 clusters. In [47], an extension based on Cauchy-Schwarz divergences is proposed. It uses the ratio between the sum of cross-information potentials between all pairs of clusters and the product of information potentials of each cluster. Consider the kernel matrix  $\mathbf{K}$  with all pairwise computations of the kernel function and the membership matrix  $\mathbf{M}$ , where each row contains a binary vector  $\mathbf{m}_i^T$  that indicates the membership of the  $i$ th point associated with the given row. The cost  $J$  associated with the membership matrix  $\mathbf{M}$  is given by:

$$J(\mathbf{M}) = \frac{\mathbf{1}^T \mathbf{K} \mathbf{1} - \sum \text{diag}(\mathbf{M}^T \mathbf{K} \mathbf{M})}{\prod \text{diag}(\mathbf{M}^T \mathbf{K} \mathbf{M})}, \quad (24.72)$$

where the sum and product are over the elements of the diagonal of  $(\mathbf{M}^T \mathbf{K} \mathbf{M})$ . To solve this problem using gradient descend techniques the membership vectors are allowed to take real values.

*Experiments:* Figure 24.10 present the resulting clusters from Cauchy-Schwarz criterion and  $k$ -means for two synthetic datasets. The matrix  $\mathbf{M}$  is initialized with random cluster assignments. As expected  $k$ -means perform poorly since it cannot identify non-convex clusters or cluster with different scales. It has to be noted that the even though these results are achieved the majority of times since they still depend on the initial assignments and the selection of proper kernel sizes.

**FIGURE 24.9**

Partition of the space created by the difference between information potentials due to each class. This is equivalent to the maximum likelihood rule for classification when using Parzen window estimation for the conditional densities given the class.

#### 1.24.7.4 Principle of relevant information

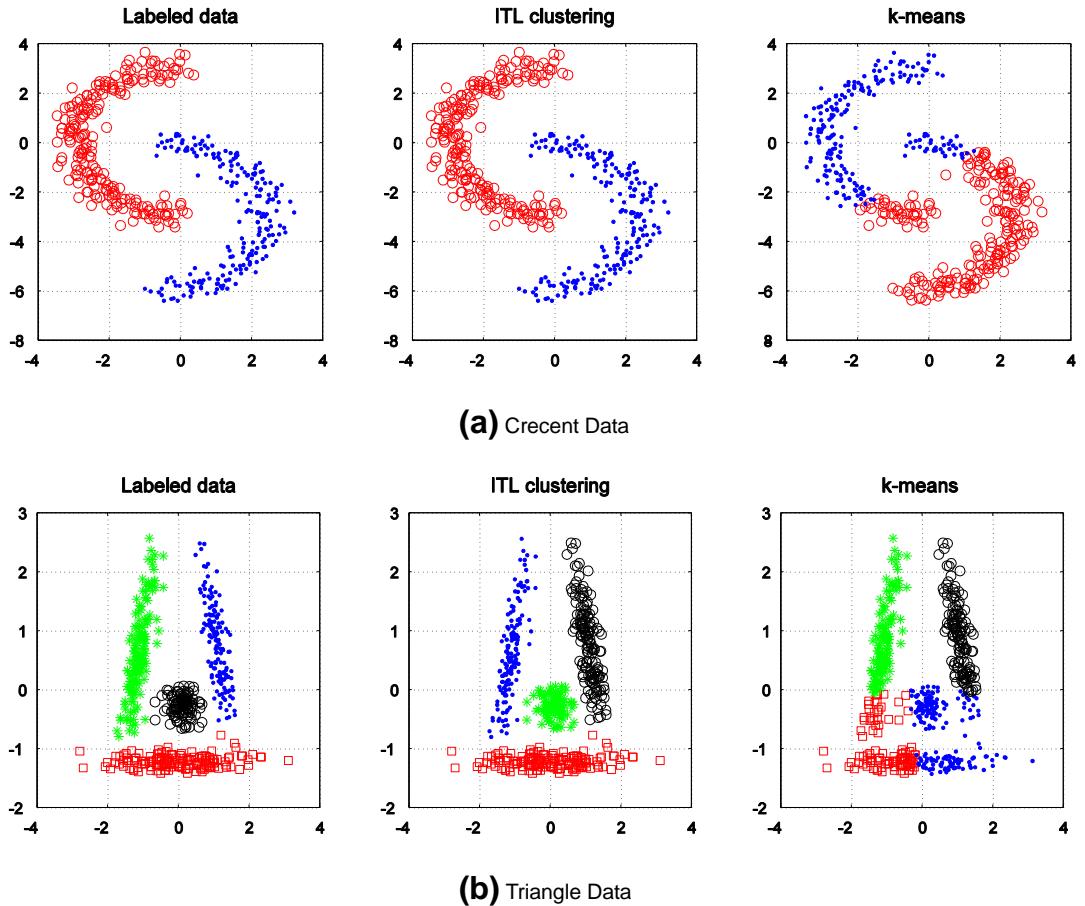

*The PRI as a Weighting Problem:* For the set  $F$  of probability density functions that are square integrable in  $X \subset \mathbb{R}^d$ , the cross-information potential (CIP) is defined as a bilinear form that maps densities  $f_i, f_j \in F$  to the real numbers through the integral,

$$V(f_i, f_j) = \int_X f_i(x) f_j(x) dx. \quad (24.73)$$

It is easy to see that for a basis of uniformly bounded, square integrable probability density functions,  $V(f_i, f_j)$  is a positive semidefinite function on the span  $\{f_i \in F\}$ . Now, consider the set  $G = \{g = \sum_{i=1}^m \alpha_i \kappa_\sigma(x_i, \cdot) | x_i \in \mathbb{R}^d, \sum_{i=1}^m \alpha_i = 1, \alpha_i \geq 0\}$ , where  $\kappa_\sigma$  is a “Parzen” type of kernel which is also square integrable, that is,  $\kappa_\sigma$  is symmetric, nonnegative, has bounded integral (can be normalized), belongs to  $L^2$ , and shift invariant with  $\sigma$  as the scale parameter. Clearly, for any  $g \in G$  we have  $\|g\|^2 \leq \|\kappa_\sigma(x, \cdot)\|^2$ . Hence,  $G$  is bounded. However, if  $X$  is non-compact our search space is also non-compact.

The objective function for the principle of relevant information can be written in terms of IP functionals. Using Parzen based estimation, we restrict the search problem to  $G \subset F$ . In this case, we have that Eq. (24.26) can be rewritten as:

$$J(f) = -\log V(f, f) - \lambda \log \frac{V(f, g)^2}{V(f, f)V(g, g)}. \quad (24.74)$$

**FIGURE 24.10**

Clustering results for synthetic datasets.

Straightforward manipulation of the terms yields an equivalent problem:

$$\arg \min_f J(f) = -(1 - \lambda) \log V(f, f) - 2\lambda \log V(f, g). \quad (24.75)$$

Two important aspects of the above objective are: the choice of the kernel and its size  $\sigma$ , which determines different scale of the analysis; and the trade-off parameter  $\lambda$ , which defines a set of regimes for the possible solutions to the problem. The only available information is contained in the sample  $S = \{x_i\}_{i=1}^N$ . An approximation of the target density  $g$  is then given by its weighted Parzen window estimator  $\hat{g}(x) = \sum_{i=1}^N \alpha_i \kappa(x_i, x)$ . In our experiments, we use  $\alpha_i = \frac{1}{N}$ . To enforce compactness in our search space, we

look for a solution  $f$  that has the same form of  $\hat{g}$ , that is

$$f(x) = \sum_{i=1}^N \beta_i \kappa(x_i, x), \quad (24.76)$$

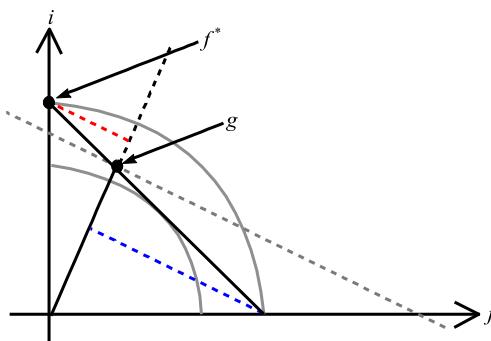

where  $\beta_i \geq 0$ ,  $\sum_{i=1}^N \beta_i = 1$ . By fixing  $\lambda$  and evaluating the information potential between each pair  $(x_i, x_j) \in S \times S$ , we can rewrite (24.69) in matrix notation as:

$$\begin{aligned} \min_{\boldsymbol{\beta}} J(\boldsymbol{\beta}) &= (\lambda - 1) \log \boldsymbol{\beta}^T \mathbf{V} \boldsymbol{\beta} - 2\lambda \log \boldsymbol{\beta}^T \mathbf{V} \boldsymbol{\alpha} \\ \text{s.t. } \boldsymbol{\beta} &\geq 0 \quad \text{and} \quad \boldsymbol{\beta}^T \mathbf{1} = 1, \end{aligned} \quad (24.77)$$

where  $V_{ij} = \int_X \kappa(x_i, x) \kappa(x_j, x) dx$ . It is also important to highlight that for values of  $\lambda \rightarrow 1$  the regularization term almost vanishes, and the maximum information gain (inner product term) can be related to the modes of  $\hat{g}$ , which are approximated by the sharpest functions available in  $G$ , which in our setting, are individual windows that satisfy convex combination constraints. Therefore, we can expect the modes of  $\hat{g}$  to be almost orthogonal components. When  $\lambda$  is very close to one, the cross-entropy term is dominant in the objective and the solution will lie in one of the corners of the simplex. Figure 24.11 depicts the geometrical elements that explain this phenomenon. The semicircles are the loci of minimum and maximum of the  $L^2$  norm that intersect with the simplex. The solution  $f^*$  with the largest norm is the one maximizing the dot product with the target distribution  $g$ .

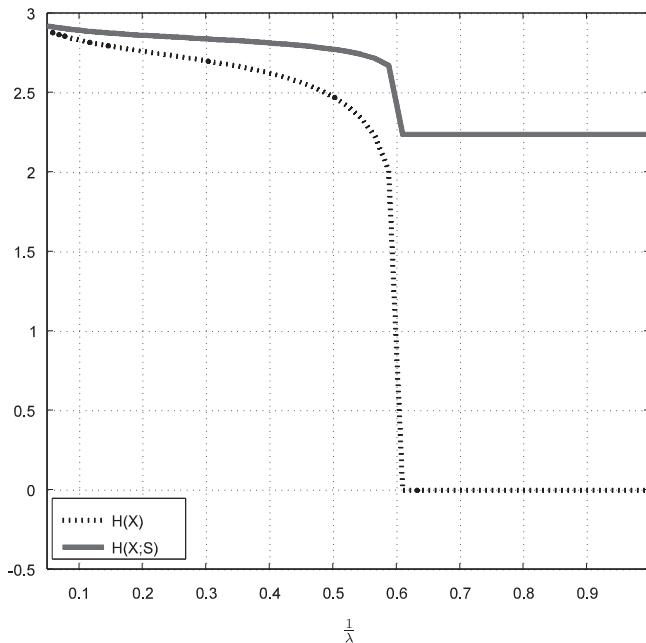

This corner phenomenon motivates the extraction of more than one solution. A reasonable approach is to deflate the target PDF  $\hat{g}$  and run the algorithm on the new function.

We perform an illustrative experiment on a synthetic data set that correspond to a Gaussian surrounded by a circular crown as depicted in Figure 24.13. Figure 24.12 shows different values of the entropy when the trade off parameter  $\lambda$  is varied between 1 and 20. The actual plot shows the inverse of  $\lambda$  to facilitate visualization.

**FIGURE 24.11**

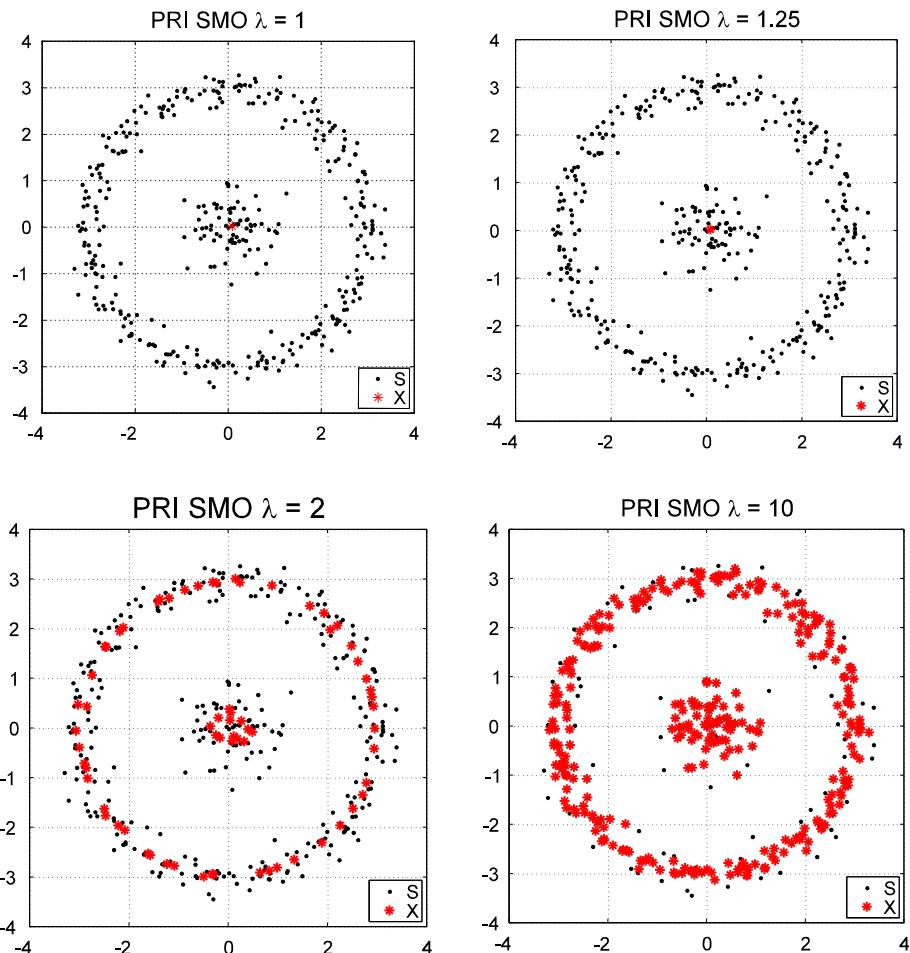

Effect of the PRI objective based on weights.

**FIGURE 24.12**

Entropy of the weighted sample and cross-entropy with respect to the original sample  $S$  for different values of  $\lambda$ . Notice that the values are plotted against  $\frac{1}{\lambda}$  for better visualization.

In this case, we can observe two regimes; for  $\lambda < 1.5$ , all the importance is given to one point, which corresponds to the largest peak on the Parzen density estimate from the observed data  $S$ . Once  $\lambda$  becomes larger than 1.5 more points become active, and the weights progressively equalize across all data points. Figure 24.13 display the resulting support vectors found after optimization for different values of  $\lambda$ .

*Image Retrieval with Partially Occluded Data MNIST:* We employ a subset of the MNIST database to perform experiments on pattern retrieval from partially occluded queries. The weighting scheme for the principle of relevant information is applied to learn the representative samples from the training data. Results are compared against kernel PCA and kernel entropy component analysis for different number of components and different values of  $\lambda$  in the case of PRI. The pattern retrieval application requires pre-imaging of the patterns from the feature space back to the input space to apply KPCA (KECA). We employ the method presented in [48] to compute the pre-images of the projected patterns in the KPCA and KECA subspaces (For more details on this problem see [49, 50]). The principle of relevant information requires a different approach since it does not provide an explicit projection method unlike KPCA and KECA. A simple pre-imaging algorithm can be based on the Nadaraya-Watson kernel regression [51]. In our experiments, we use the Gaussian kernel. The pre-imaging for PRI consists of the following steps:

**FIGURE 24.13**

Resulting support vectors for different values of  $\lambda$ .

- Compute the  $k$ -nearest neighbors on the set of support vectors (training points with nonzero weights) of the query pattern  $x$ .
- Reconstruct using the following equation:

$$x_{\text{rec}} = \frac{\sum_{i=1}^k \kappa_\sigma(x_i, x)x_i}{\sum_{i=1}^k \kappa_\sigma(x_i, x)}, \quad (24.78)$$

where the indexes for  $x_i$  are understood as the  $k$  nearest neighbors of  $x$ .

**Table 24.1** Results for the Image Retrieval from Partially Occluded Queries

Number of components	3	8	15	30	50	100
KPCA	0.59(0.03)	0.55(0.015)	0.53(0.007)	0.50(0.007)	0.48(0.008)	0.47(0.006)
KECA	0.64(0.018)	0.57(0.018)	0.51(0.022)	0.49(0.013)	0.49(0.009)	0.48(0.007)
PRI	0.58(0.013)	0.53(0.004)	0.51(0.007)	0.50(0.009)	0.49(0.01)	0.48(0.01)
$\lambda$	2	3	4	5	6	8
N support vectors	62.7	126	181	232	276	347

Note: The highlighted values indicate the smallest “normalized SNR” in each column.

**FIGURE 24.14**

Sample queries with missing information and their corresponding complete versions.

In this case, we want to see if we can effectively retrieve a digit by presenting an image with a missing portion. The model is trained with complete images and tested with images for which the lower half of the matrix has been replaced with zeros.

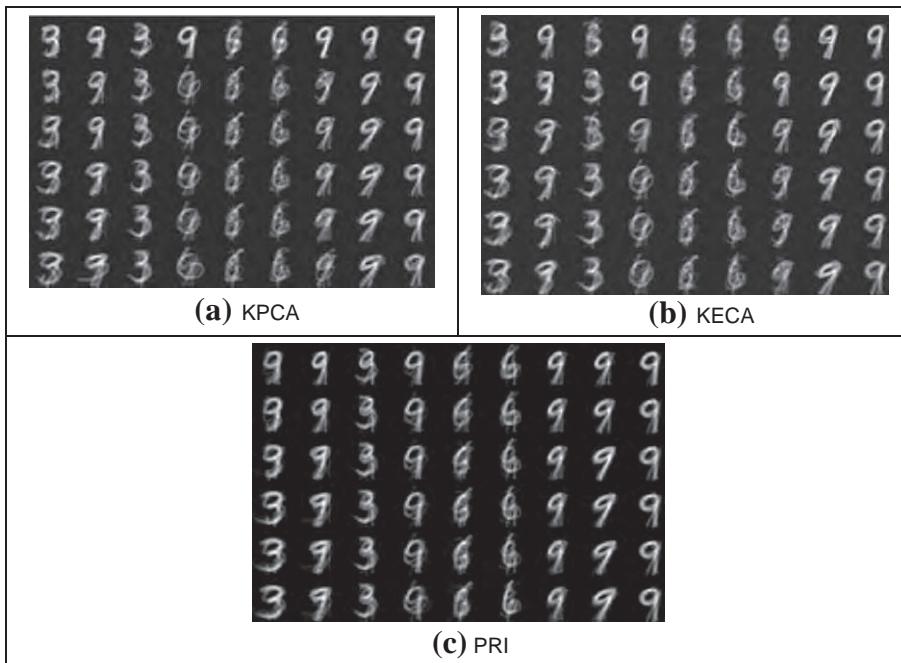

Table 24.1 shows the normalized SNR for the retrieved patterns using a KPCA KECA and the weighted PRI. The numbers correspond to averages from ten Monte Carlo simulations using 200 images per digit (total 600) for training and 50 incomplete images of each digit (150 total) for testing. We also present the average number of support vectors for the RKHS PRI. The standard deviations are also shown. The kernel size is 5, and the number of neighbors for pre-imaging is 10.

Notice that differences between closest results for all methods and also the best performances are within the range set by one standard deviation.

Figure 24.14 shows some of the exemplars that were used for testing along with the incomplete versions that were input to the algorithms. Figure 24.15a shows the reconstructed images for KPCA where each row corresponds to the number of components in Table 24.1. Likewise, Figure 24.15b displays the results for KECA, and Figure 24.15c shows the results of PRI approach for the different  $\lambda$  values in Table 24.1.

### 1.24.7.5 Independent component analysis

*Minimum Renyi's Mutual Information:* The MRMI algorithm is motivated by minimization of mutual dependence between the estimated sources in the context of non-parametric estimation [52,53]. The basic idea is to use an alternative definition of entropy that facilitates the application of non-parametric density estimation techniques such as Parzen windowing.

## FIGURE 24.15

Sample queries with missing information and their corresponding complete versions.

Renyi's mutual information is

$$I_\alpha(Y) = \frac{1}{\alpha - 1} \log \left( \int_{-\infty}^{\infty} \frac{f_Y(y)^\alpha}{\prod_{i=1}^d f_{Y_i}(y_i)^{\alpha-1}} dy \right). \quad (24.79)$$

Although this definition generalizes the concept of KL-divergence, properties such as recursion fail to hold since the formulation followed for Shannon's entropy yields

$$\sum_{i=1}^d H_\alpha(Y_i) - H_\alpha(Y) = \frac{1}{\alpha-1} \log \left( \frac{\int_{-\infty}^\infty f_Y(y)^\alpha dy}{\int_{-\infty}^\infty \prod_{i=1}^d f_{Y_i}(y_i)^{\alpha-1} dy} \right). \quad (24.80)$$

The expression in (24.80) is zero if the  $Y_i$ 's are independent. Unfortunately, zero value is not sufficient condition for independence. Assuming favorable condition on the distribution of the sources, we have that for an orthogonal rotation  $\mathbf{R}$  on a whitened version of the observed variables  $X_i$ , the joint entropy of the estimated sources  $Y = \mathbf{R}P\mathbf{X} = \mathbf{W}\mathbf{X}$  is invariant under orthonormal transformations. Thus minimization of (24.80) can be done only on the sum of the marginal entropies. The objective function is then

$$J(\mathbf{R}) = \sum_{i=1}^d H_\alpha(Y_i). \quad (24.81)$$

For  $\alpha = 2$ , Eq. (24.81) is estimated by using Parzen windowing with a Gaussian kernel; it is easy to note that the minimization of this cost will look for super-Gaussian distributions since sum of output marginal entropies is minimized. Therefore we should expect the algorithm to fail in the presence of sub-Gaussian sources. Nevertheless, switching the sign of some of the terms in the sum  $J(\mathbf{R})$  yields a search procedure that can converge to sub-Gaussian distributions. Therefore an algorithm obtained by assigning individual signs to the marginal entropies  $H_\alpha((\mathbf{R}Y)_i)$  can find sub and super Gaussian sources.

Performance of the algorithms is measured using signal-to-distortion ratio (SDR):

$$\text{SDR} = -10 \log \left[ \frac{1}{d(d-1)} \sum_{i=1}^d \left( \frac{\sum_{j=1}^d |B_{ij}|}{\max_j |B_{ij}|} - 1 \right) \right], \quad (24.82)$$

where  $\mathbf{B} = \mathbf{WA}$ , being  $\mathbf{A}$  the known mixing matrix.

*Synthetic Data:* The aim of the artificial data is to check the validity of our analysis of the expected properties for the algorithms. For this purpose we create a set of artificial signals described as follows:

$$\begin{aligned} x_s(t) &= \sin \left( \frac{2\pi}{T_s} t \right), \\ x_w(t) &= \text{saw} \left( \frac{2\pi}{T_w} t + \theta \right), \\ x_e(t) &= \frac{1}{5} \text{sign}(x_w(t)) (\exp(5x_w(t)) - 1). \end{aligned} \quad (24.83)$$

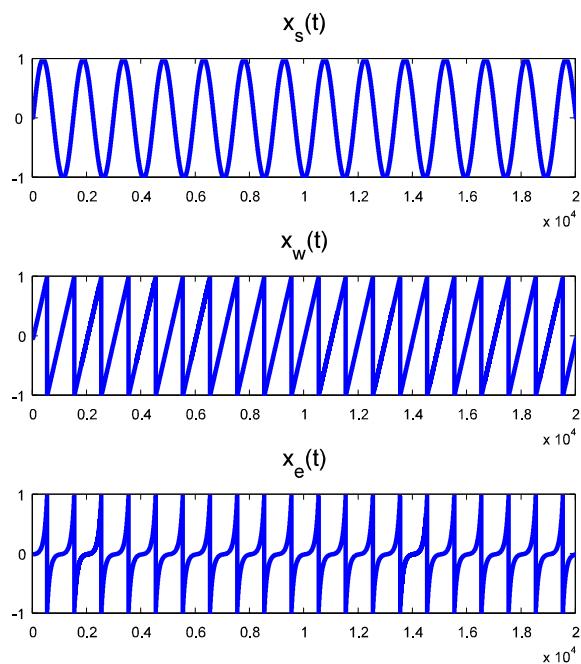

In this case  $x_s(t)$  and  $x_w(t)$  are sub-Gaussian, and  $x_e(t)$  is super-Gaussian. We create two sets of sources  $\mathbf{x}_a(t) = (x_s(t) \ x_w(t))^T$  (both sub-Gaussian) and  $\mathbf{x}_b(t) = (x_s(t) \ x_e(t))^T$  (mixed type sub- and super-Gaussian). Figure 24.16 displays the three simulated sources.

We only want to evaluate the properties of the estimated sources; therefore, we run the update throughout the whole signal using on-line learning mode. Figure 24.17 display the estimated sources using infomax for observed  $\mathbf{x}_a(t)$  and  $\mathbf{x}_b(t)$ , respectively; the corresponding SDRs are 0.8414 and 2.72. As expected the algorithm failed to find the correct de-mixing since the activation function cannot model sub-Gaussian distributions and so prefers a solution for which the estimated sources are apparently super-Gaussian.

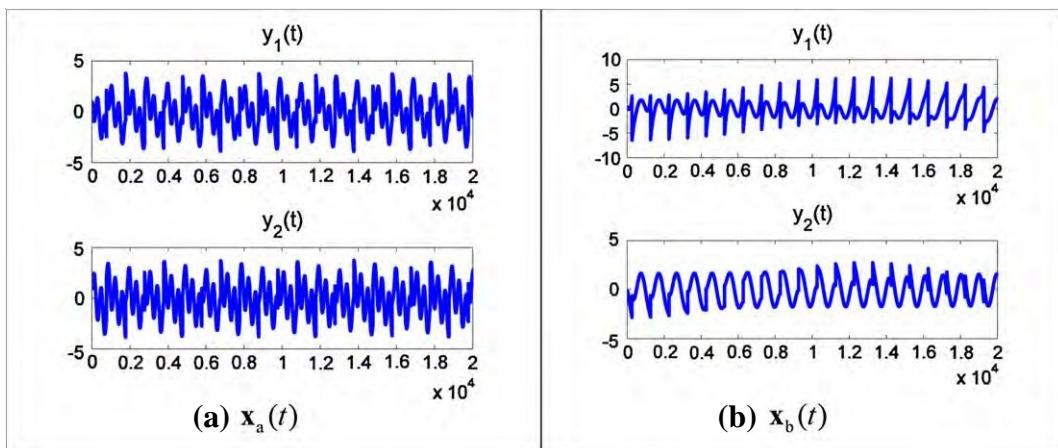

For the MRMI criterion, given that we have a priori knowledge of the source distribution, we switch the sign of the objective function for both sources for the observed  $\mathbf{x}_a(t)$ . The estimated density is calculated taking a uniform random sub-sample of 500 instances from the entire observed signal. The sign of each marginal output entropy (maximum or minimum) is chosen according to the sign of the deviation from the kurtosis for a normal random variable. The objective function from Eq. (24.81) can be modified as follows:

$$J(\mathbf{R}) = - \sum_{i=1}^d \text{sign}(\text{kurt}(Y_i) - 3) H_\alpha(Y_i). \quad (24.84)$$

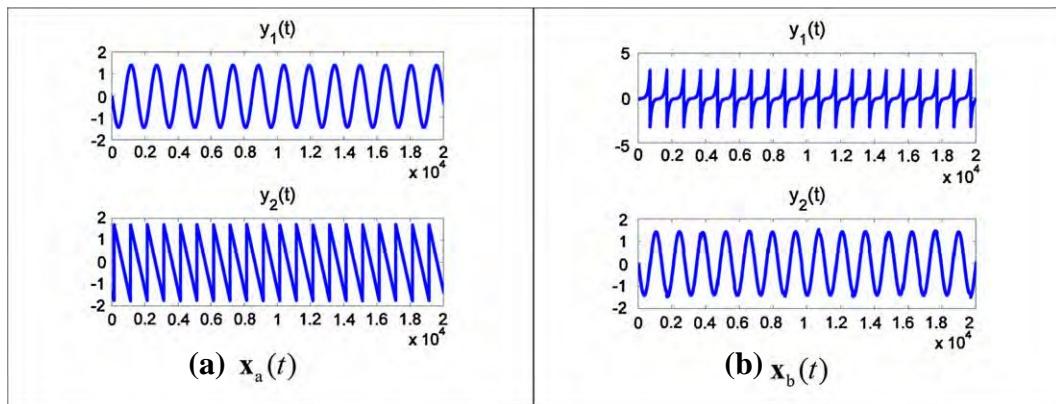

Figure 24.18 shows the extracted sources by using the modified version of MRMI using kurtosis. The SDRs are 22.2165 for  $\mathbf{x}_a(t)$  and  $\mathbf{x}_b(t)$ . Notice that in both cases the modified version succeeded in finding the independent components.

**FIGURE 24.16**

Sub-Gaussian and Super-Gaussian artificial sources.

**FIGURE 24.17**

Estimated sources for infomax.

**FIGURE 24.18**

Estimated sources for modified MRMI.

**Table 24.2** SDR Behavior of 20 Simulations of Infomax in On-Line Mode for Different Training Sample Sizes

SDR	Sub-sample size		
	100	1000	10000
Average	7.8	8.01	8.71
Std Deviation	3.39	4.12	4.26

**Table 24.3** SDR Behavior of 20 Simulations of MRMI for Different Training Sample Sizes and 300 epochs

SDR	Sub-sample size		
	50	100	500
Average	13.92	14.56	14.77
Std Deviation	1.39	0.67	0.439

*Mixture of Audio Signals:* The problem is to separate an interest sound from the background activity (noise). To see the stability and accuracy of the estimation based on the size of the training data we randomly sub-sample the whole signal in different proportions. Table 24.2 displays the average SDR of 20 simulations of infomax along with the standard deviation on sub-sample sizes of 100, 1000, and 10,000 instances. The number of epochs is inversely proportional to the sub-sample size providing the same number of iterations (200,000); the stepsize is  $\eta = 0.3$ . A different procedure is followed for

MRMI. Sample sizes are 50, 100, and 500 and the number of epochs is fixed to 300. Table 24.3 displays the average SDR of 20 simulations of MRMI and their corresponding standard deviations. Kernel is fixed to  $\sigma = 0.5$  since data is whitened, the stepsize is  $\eta = 0.5$ .

### 1.24.8 Conclusions and future trends

Traditional approaches to machine learning and signal processing in general aim to optimize the second order statistics. When data is non-Gaussian, a more appropriate approach would be to capture higher order statistics or information content of signals rather than simply their energy. Especially, information theoretic quantities as optimality criteria attract ever-increasing attention to this end, since they provide a natural framework where information content of available data can be assessed. Combining information theoretic descriptors (such as entropy, divergence, and mutual information) and kernel density estimation, one can obtain a general, nonparametric, and sample based methodology to learn arbitrary nonlinear systems.

In this chapter, we briefly reviewed the general methodology to implement machine learning and adaptation algorithm with information theoretic criteria, which synergistically integrates the general framework of information theory in the design of new cost functions for machine learning and adaptive signal processing. Information based learning not only affects our understanding of optimal signal processing, but also influence the way we approach machine learning, data compression, and adaptation. With smooth nonparametric information estimators, ITL methodology allows simple gradient based learning rule to be constructed for learning nonlinear topologies. In most situations, the performance of ITL learning algorithms compare favorably with existing methods developed under second order statistics criteria. For illustration purpose, we also include in this chapter several application examples.

Information-based learning is still one of the freshest ideas floating around, which has not yet become prevalent today. There are many issues that need to be handled in the next stage. Examples are: (1) how to choose the proper parameters such as the order of the information potential or the kernel size in entropy estimator; (2) how to simplify the computational complexity especially in batch mode learning; (3) how to efficiently implement the algorithms in the hardware. If these issues have been properly resolved, information based learning will become more practical and powerful, and it will find a widespread acceptance in machine learning community.

## 1.25.1 Introduction

A common and widespread problem in science and engineering is the determination of a suitable model to describe or characterize an experimental data set. This determination consists of two tasks: (i) the choice of an appropriate model structure, and (ii) the estimation of the associated model parameters. Given the structure or dimension of the model, the task of parameter estimation is generally done by maximum likelihood or least squares procedures. The choice of the dimension of a model is often facilitated by the use of a model selection criterion. The key idea underlying most model selection criteria is the parsimony principle which says that there should be a tradeoff between data fit and complexity. This chapter examines three broad approaches to model selection commonly applied in the literature: (i) methods that attempt to estimate the distance between the fitted model and the unknown distribution that generated the data (see Section 1.25.2); (ii) Bayesian approaches which use the posterior distribution of the parameters to make probabilistic statements about the plausibility of the fitted models (see Section 1.25.3), and (iii) information theoretic model selection procedures that measure the quality of the fitted models by how well these models compress the data (see Section 1.25.4).

Formally, we observe a sample of  $n$  data points  $\mathbf{y} = (y_1, \dots, y_n)'$  from an unknown probability distribution  $p^*(\mathbf{y})$ . The model selection problem is to learn a good approximation to  $p^*(\cdot)$  using only the observed data  $\mathbf{y}$ . This problem is intractable unless some assumptions are made about the unknown distribution  $p^*(\cdot)$ . The assumption made in this chapter is that  $p^*(\cdot)$  can be adequately approximated by one of the distributions from a set of parametric models  $p(\mathbf{y}|\boldsymbol{\theta}; \gamma)$  where  $\gamma \in \Gamma \subseteq \mathbb{N}$  defines the model structure and the parameter vector  $\boldsymbol{\theta} = (\theta_1, \dots, \theta_k)' \in \Theta_\gamma \subset \mathbb{R}^k$  indexes a particular distribution from the model  $\gamma$ . The dimensionality of  $\boldsymbol{\theta}$  will always be clear from the context. As an example, if we are interested in inferring the order of a polynomial in a linear regression problem, the set  $\Gamma$  may include first-order, second-order and third-order polynomials. The parameter vector  $\boldsymbol{\theta}$  then represents the coefficients for a particular polynomial; for example, the intercept and linear term for the first-order model. The model selection problem is to infer an appropriate model structure  $\gamma$  and parameter vector  $\boldsymbol{\theta}$  that provide a good approximation to the data generating distribution  $p^*(\cdot)$ .

This chapter largely focuses on the inference of the model structure  $\gamma$ . A common approach to estimating the parameters  $\boldsymbol{\theta}$  for a given model  $\gamma$  is the method of maximum likelihood. Here, the

parameter vector is chosen such that the probability of the observed data  $\mathbf{y}$  is maximized, that is

$$\hat{\boldsymbol{\theta}}(\mathbf{y}; \gamma) = \arg \max_{\boldsymbol{\theta} \in \Theta_\gamma} p(\mathbf{y}|\boldsymbol{\theta}; \gamma) \quad (25.1)$$

where  $p(\mathbf{y}|\boldsymbol{\theta}; \gamma)$  denotes the likelihood of the data under the distribution indexed by  $\boldsymbol{\theta}$ . This is a powerful approach to parameter estimation that possesses many attractive statistical properties [1]. However, it is not without its flaws, and as part of this chapter we will examine an alternative method of parameter estimation that should sometimes be preferred to maximum likelihood (see Section 1.25.4.2). The statistical theory underlying model selection is often abstract and difficult to understand in isolation, and it is helpful to consider these concepts within the context of a practical example. To this end, we have chosen to illustrate the application of the model selection criteria discussed in this chapter to the important and commonly used linear regression model.

### 1.25.1.1 Nested and non-nested sets of candidate models

The structure of the set of candidate models  $\Gamma$  can have a significant effect on the performance of model selection criteria. There are two general types of candidate model sets: *nested* sets of candidate models, and *non-nested* sets of candidate models. Nested sets of candidate models have special properties that make model selection easier and this structure is often assumed in the derivation of model selection criteria, such as in the case of the distance based methods of Section 1.25.2. Let us partition the model set  $\Gamma = \{\Gamma_0, \Gamma_1, \Gamma_2, \dots\}$ , where the subsets  $\Gamma_k$  are the set of all candidate models with  $k$  free parameters. A candidate set  $\Gamma$  is considered nested if: (1) there is only one candidate model with  $k$  parameters ( $|\Gamma_k| = 1$  for all  $k$ ), and (2) models  $\gamma \in \Gamma_k$  with  $k$  parameters can exactly represent all distributions indexed by models with less than  $k$  parameters. That is, if  $\gamma_k \in \Gamma$  is a model with  $k$  free parameters, and model  $\gamma_l \in \Gamma$  is a model with  $l$  free parameters, where  $l < k$ , then

$$\forall \boldsymbol{\theta}_l \in \Theta_l, \exists \boldsymbol{\theta}_k \in \Theta_k : \forall \mathbf{y}, \forall p(\mathbf{y}|\boldsymbol{\theta}_l; \gamma_l) = p(\mathbf{y}|\boldsymbol{\theta}_k; \gamma_k).$$

A canonical example of a nested model structure is the polynomial order selection problem. Here, a second-order model can exactly represent any first-order model by setting the quadratic term to zero. Similarly, a third-order model can exactly represent any first-order or second-order model by setting the appropriate parameters to zero, and so on. In the non-nested case, there is not necessarily only a single model with  $k$  parameters, and there is no requirement that models with more free parameters can exactly represent all simpler models. This can introduce difficulties for some model selection criteria, and it is thus important to be aware of the structure of the set  $\Gamma$  before choosing a particular criterion to apply. The concept of nested and non-nested model sets will be made clearer in the following linear regression example.

### 1.25.1.2 Example: the linear model

Linear regression is of great importance in engineering and signal processing as it appears in a wide range of problems such as smoothing a signal with polynomials, estimating the number of sinusoids in noisy data and modeling linear dynamic systems. The linear regression model for explaining data  $\mathbf{y}$  assumes that the means of the observations are a linear combination of  $q$  ( $\geq 0$ ) measured variables, or

covariates, that is,

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}, \quad (25.2)$$

where  $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_q)$  is the *full* design matrix,  $\boldsymbol{\beta} \in \mathbb{R}^q$  are the parameter coefficients and  $\boldsymbol{\varepsilon} = (\varepsilon_1, \dots, \varepsilon_n)'$  are independent and identically distributed Gaussian variates  $\varepsilon_i \sim N(0, \tau)$ . Model selection in the linear regression context arises because it is common to assume that only a subset of the covariates is associated with the observations; that is, only a subset of the parameter vector is non-zero. Let  $\gamma \subseteq \{1, \dots, q\}$  denote an index set determining which of the covariates comprise the design submatrix  $\mathbf{X}_\gamma$ ; the set of all candidate subsets is denoted by  $\Gamma$ . The linear model indexed by  $\gamma$  is then

$$\mathbf{y} = \mathbf{X}_\gamma \boldsymbol{\beta} + \boldsymbol{\varepsilon} \quad (25.3)$$

where  $\boldsymbol{\beta}$  is the parameter vector of size  $|\gamma|$  and

$$\mathbf{X}_\gamma = (\mathbf{x}_{\gamma_1}, \dots, \mathbf{x}_{\gamma_k}).$$

The total number of unknown parameters to be estimated for model  $\gamma$ , including the noise variance parameter, is  $k = |\gamma| + 1$ . The negative log-likelihood for the data  $\mathbf{y}$  is

$$-\log p(\mathbf{y} | \mathbf{X}_\gamma, \boldsymbol{\beta}, \tau; \gamma) = \frac{n}{2} \log 2\pi + \frac{n}{2} \log \tau + \frac{1}{2\tau} (\mathbf{y} - \mathbf{X}_\gamma \boldsymbol{\beta})' (\mathbf{y} - \mathbf{X}_\gamma \boldsymbol{\beta}). \quad (25.4)$$

The maximum likelihood estimates for the coefficient  $\boldsymbol{\beta}$  and the noise variance  $\tau$  are

$$\hat{\boldsymbol{\beta}}(\mathbf{y}; \gamma) = \left( \mathbf{X}'_\gamma \mathbf{X}_\gamma \right)^{-1} \mathbf{X}'_\gamma \mathbf{y}, \quad (25.5)$$

$$\hat{\tau}(\mathbf{y}; \gamma) = \frac{1}{n} (\mathbf{y} - \mathbf{X}_\gamma \hat{\boldsymbol{\beta}}(\mathbf{y}; \gamma))' (\mathbf{y} - \mathbf{X}_\gamma \hat{\boldsymbol{\beta}}(\mathbf{y}; \gamma)), \quad (25.6)$$

which coincide with the estimates obtained by minimising the sum of squared errors (the least squares estimates). The negative log-likelihood evaluated at the maximum likelihood estimates is given by

$$-\log p(\mathbf{y} | \mathbf{X}_\gamma, \hat{\boldsymbol{\beta}}(\mathbf{y}; \gamma), \hat{\tau}(\mathbf{y}; \gamma); \gamma) = \frac{n}{2} \log 2\pi + \frac{n}{2} \log \hat{\tau}(\mathbf{y}; \gamma) + \frac{n}{2}. \quad (25.7)$$

The structure of the set  $\Gamma$  in the context of the linear regression model depends on the nature and interpretation of the covariates. In the case that the covariates are polynomials of increasing order, or sinusoids of increasing frequency, it is often convenient to assume a nested structure on  $\Gamma$ . For example, let us assume that the  $q = 4$  covariates are polynomials such that  $\mathbf{x}_1$  is the zero-order term (constant),  $\mathbf{x}_2$  the linear term,  $\mathbf{x}_3$  the quadratic term and  $\mathbf{x}_4$  the cubic term. To use a model selection criterion to select an appropriate order of polynomial, we can form the set of candidate models  $\Gamma$  as

$$\Gamma = \{\Gamma_1, \Gamma_2, \Gamma_3, \Gamma_4\},$$

where

$$\Gamma_1 = \{1\}, \quad \Gamma_2 = \{1, 2\}, \quad \Gamma_3 = \{1, 2, 3\}, \quad \Gamma_4 = \{1, 2, 3, 4\}.$$

From this structure it is obvious that there is only one model with  $k$  free parameters, for all  $k$ , and that models with more parameters can exactly represent all models with less parameters by setting

the appropriate coefficients to zero. In contrast, consider the situation in which the covariates have no natural ordering, or that we do not wish to impose an ordering; for example, in the case of polynomial regression, we may wish to determine which, if any, of the individual polynomial terms are associated with the observations. In this case there is no clear way of imposing a nested structure, as we cannot *a priori* rule out any particular combination of covariates being important. This is usually called the *all-subsets* regression problem, and the candidate model set then has the following structure

$$\begin{aligned}\Gamma_0 &= \{\emptyset\}, \\ \Gamma_1 &= \{\{1\}, \{2\}, \{3\}, \{4\}\}, \\ \Gamma_2 &= \{\{1, 2\}, \{1, 3\}, \{1, 4\}, \{2, 3\}, \{2, 4\}, \{3, 4\}\}, \\ \Gamma_3 &= \{\{1, 2, 3\}, \{1, 2, 4\}, \{1, 3, 4\}, \{2, 3, 4\}\}, \\ \Gamma_4 &= \{1, 2, 3, 4\},\end{aligned}$$

where  $\emptyset$  denotes the empty set, that is, none of the covariates are to be used. It is clear that models with more parameters can not necessarily represent all models with less parameters; for example, the model  $\{1, 3\}$  cannot represent the model  $\{2\}$  as it is lacking covariate  $x_2$ . Further, there is now no longer just a single model with  $k$  free parameters; in the above example, there are four models with one free parameter, and six models with two free parameters. In general, if there are  $q$  covariates in total, the number of models with  $k$  free parameters is given by  $\binom{q}{k}$ , which may be substantially greater than one for moderate  $q$ .

Throughout the remainder of this chapter, the linear model example will be used to demonstrate the practical application of the model selection criteria that will be discussed.

## 1.25.2 Minimum distance estimation criteria

Intuitively, model selection criteria can be derived by quantifying “how close” the probability density of the fitted model is to the unknown, generating distribution. Many measures of distance between two probability distributions exist in the literature. Due to several theoretical properties, the Kullback-Leibler divergence [2], and its variants, is perhaps the most frequently used information theoretic measure of distance.

As the distribution  $p^*(\cdot)$  that generated the observations  $\mathbf{y}$  is unknown, the basic idea underlying the minimum distance estimation criteria is to construct an *estimate* of how close the fitted distributions are to the truth. In general, these estimators are constructed to satisfy the property of unbiasedness, at least for large sample sizes  $n$ . In particular, the distance-based methods we examine are the well known Akaike information criterion (AIC) (see Section 1.25.2.1) and symmetric Kullback information criterion (KIC) (see Section 1.25.2.2), as well as several corrected variants that improve the performance of these criteria when the sample size is small.

### 1.25.2.1 The Akaike information criterion

Recall the model selection problem as introduced in Section 1.25.1. Suppose a collection of  $n$  observations  $\mathbf{y} = (y_1, \dots, y_n)'$  has been sampled from an unknown distribution  $P^*(\mathbf{y})$  having density function

$p^*(\mathbf{y})$ . Estimation of  $p^*(\mathbf{y})$  is done within a set of nested candidate models  $\Gamma \subseteq \mathbb{N}$ , characterized by probability densities  $p(\mathbf{y}|\boldsymbol{\theta}; \gamma)$ ,  $\gamma \in \Gamma$ , where  $\boldsymbol{\theta} \in \Theta_\gamma \subseteq \mathbb{R}^k$  and  $k = \dim(\Theta_\gamma)$  is the number of free parameters possessed by model  $\gamma$ . Let  $\hat{\boldsymbol{\theta}}(\mathbf{y}; \gamma)$  denote the vector of estimated parameters obtained by maximizing the likelihood  $p(\mathbf{y}|\boldsymbol{\theta}; \gamma)$  over  $\Theta_\gamma$ , that is,

$$\hat{\boldsymbol{\theta}}(\mathbf{y}; \gamma) = \arg \max_{\boldsymbol{\theta} \in \Theta_\gamma} \{p(\mathbf{y}|\boldsymbol{\theta}; \gamma)\}$$

and let  $p(\mathbf{y}|\hat{\boldsymbol{\theta}}(\mathbf{y}; \gamma); \gamma)$  denote the corresponding fitted model. To simplify notation, we introduce the shorthand notation  $\hat{\boldsymbol{\theta}}_\gamma \equiv \hat{\boldsymbol{\theta}}(\mathbf{y}; \gamma)$  to denote the maximum likelihood estimator, and  $p(\mathbf{y}|\hat{\boldsymbol{\theta}}_\gamma) \equiv p(\mathbf{y}|\hat{\boldsymbol{\theta}}(\mathbf{y}; \gamma); \gamma)$  to denote the maximized likelihood for model  $\gamma$ .

To determine which candidate density model best approximates the true unknown model  $p^*(\mathbf{y})$ , we require a measure which provides a suitable reflection of the separation between  $p^*(\mathbf{y})$  and an approximating model  $p(\mathbf{y}|\hat{\boldsymbol{\theta}}_\gamma)$ . The Kullback-Leibler divergence, also known as the cross-entropy, is one such measure. For the two probability densities  $p^* \equiv p^*(\mathbf{x})$  and  $p_{\boldsymbol{\theta}_\gamma} \equiv p(\mathbf{x}|\boldsymbol{\theta}; \gamma)$ , the Kullback-Leibler divergence,  $\Delta_n(\cdot)$ , between  $p^*(\mathbf{x})$  and  $p(\mathbf{x}|\boldsymbol{\theta}; \gamma)$  with respect to  $p^*(\mathbf{x})$  is defined as

$$\begin{aligned} 2\Delta_n(p^*, p_{\boldsymbol{\theta}_\gamma}) &= E_{\mathbf{x} \sim p^*} \left[ 2 \log \frac{p^*(\mathbf{x})}{p(\mathbf{x}|\boldsymbol{\theta}; \gamma)} \right] \\ &= E_{\mathbf{x} \sim p^*} [-2 \log p(\mathbf{x}|\boldsymbol{\theta}; \gamma)] - E_{\mathbf{x} \sim p^*} [-2 \log p^*(\mathbf{x})] \\ &= d_n(p^*, p_{\boldsymbol{\theta}_\gamma}) - d_n(p^*, p^*), \end{aligned}$$

where

$$d_n(p^*, p_{\boldsymbol{\theta}_\gamma}) = E_{\mathbf{x} \sim p^*} [-2 \log p(\mathbf{x}|\boldsymbol{\theta}; \gamma)], \quad (25.8)$$

and  $E_{\mathbf{x} \sim p^*}[\cdot]$  represents the expectation with respect to  $p^*(\mathbf{x})$ , that is,  $\mathbf{x} \sim p^*(\cdot)$ . Ideally, the selection of the best model from the set of candidate models  $\Gamma$  would be done by choosing the model with the minimum KL divergence from the data generating distribution  $p^*(\cdot)$ , that is

$$\hat{\gamma} = \arg \min_{\gamma \in \Gamma} \left\{ \Delta_n \left( p^*, p_{\hat{\boldsymbol{\theta}}_\gamma} \right) \right\},$$

where  $\hat{\boldsymbol{\theta}}_\gamma$  is the maximum likelihood estimator of the parameters of model  $\gamma$  based on the observed data  $\mathbf{y}$ . Since  $d_n(p^*, p^*)$  does not depend on the fitted model  $\hat{\boldsymbol{\theta}}_\gamma$ , any ranking of the candidate models according to  $\Delta_n(p^*, p_{\hat{\boldsymbol{\theta}}_\gamma})$  is equivalent to ranking the models according to  $d_n(p^*, p_{\hat{\boldsymbol{\theta}}_\gamma})$ . Unfortunately, evaluating  $d_n(p^*, p_\gamma)$  is not possible since doing so requires the knowledge of  $p^*(\cdot)$  which is the aim of model selection in the first place.

As noted by Takeuchi [3], twice the negative maximized log-likelihood,  $-2 \log p(\mathbf{y}|\hat{\boldsymbol{\theta}}_\gamma)$ , acts as a downwardly biased estimator of  $d_n(p^*, p_{\hat{\boldsymbol{\theta}}_\gamma})$  and is therefore not suitable for model comparison by itself. An unbiased estimate of the KL divergence is clearly of interest and could be used as a tool for model selection. It can be shown that the bias in estimation is given by

$$E_{\mathbf{y} \sim p^*} \left[ E_{\mathbf{x} \sim p^*} \left[ -2 \log p(\mathbf{x}|\hat{\boldsymbol{\theta}}(\mathbf{y}; \gamma); \gamma) \right] \right] - E_{\mathbf{y} \sim p^*} \left[ -2 \log p(\mathbf{y}|\hat{\boldsymbol{\theta}}(\mathbf{y}; \gamma); \gamma) \right], \quad (25.9)$$

which, under suitable regularity conditions can be asymptotically estimated by [4,5]

$$2\text{Tr}(\boldsymbol{\Omega}^{-1}(\boldsymbol{\theta}_0; \gamma)\boldsymbol{\Sigma}(\boldsymbol{\theta}_0; \gamma)), \quad (25.10)$$

where

$$\boldsymbol{\Omega}(\boldsymbol{\theta}_0; \gamma) = -E_{\mathbf{x} \sim p^*} \left[ \frac{\partial^2 \log p(\mathbf{x}|\boldsymbol{\theta}; \gamma)}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'} \right] \Big|_{\boldsymbol{\theta}=\boldsymbol{\theta}_0}, \quad (25.11)$$

$$\boldsymbol{\Sigma}(\boldsymbol{\theta}_0; \gamma) = E_{\mathbf{x} \sim p^*} \left[ \left( \frac{\partial \log p(\mathbf{x}|\boldsymbol{\theta}; \gamma)}{\partial \boldsymbol{\theta}} \right) \left( \frac{\partial \log p(\mathbf{x}|\boldsymbol{\theta}; \gamma)}{\partial \boldsymbol{\theta}} \right)' \right] \Big|_{\boldsymbol{\theta}=\boldsymbol{\theta}_0}, \quad (25.12)$$

and  $\text{Tr}(\cdot)$  denotes the trace of a matrix. The parameter vector  $\boldsymbol{\theta}_0$  defined by

$$\boldsymbol{\theta}_0 = \arg \min_{\boldsymbol{\theta} \in \Theta_\gamma} \{ \Delta_n(p^*, p_{\boldsymbol{\theta}}) \} \quad (25.13)$$

indexes the distribution in the model  $\gamma$  that is closest to the data generating distribution  $p^*(\cdot)$  in terms of KL divergence. Unfortunately, the parameter vector  $\boldsymbol{\theta}_0$  is unknown and so one cannot compute the required bias adjustment. However, Takeuchi [3] noted that under suitable regularity conditions, the maximum likelihood estimate can be used in place of  $\boldsymbol{\theta}_0$  to derive an approximation to (25.10), leading to the Takeuchi Information Criterion (TIC)

$$\text{TIC}(\gamma; \mathbf{y}) = -2 \log p(\mathbf{y}|\hat{\boldsymbol{\theta}}_\gamma) + 2\text{Tr}(\boldsymbol{\Omega}^{-1}(\mathbf{y}; \gamma)\boldsymbol{\Sigma}(\mathbf{y}; \gamma)), \quad (25.14)$$

where

$$\boldsymbol{\Omega}(\mathbf{y}; \gamma) = - \frac{\partial^2 \log p(\mathbf{y}|\boldsymbol{\theta}; \gamma)}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'} \Big|_{\boldsymbol{\theta}=\hat{\boldsymbol{\theta}}_\gamma}, \quad (25.15)$$

$$\boldsymbol{\Sigma}(\mathbf{y}; \gamma) = \sum_{i=1}^n \left( \frac{\partial \log p(y_i|\boldsymbol{\theta}; \gamma)}{\partial \boldsymbol{\theta}} \Big|_{\boldsymbol{\theta}=\hat{\boldsymbol{\theta}}_\gamma} \right) \left( \frac{\partial \log p(y_i|\boldsymbol{\theta}; \gamma)}{\partial \boldsymbol{\theta}} \Big|_{\boldsymbol{\theta}=\hat{\boldsymbol{\theta}}_\gamma} \right)' \quad (25.16)$$

are empirical estimates of the matrices (25.11) and (25.12), respectively. To use the TIC for model selection, we choose the model  $\gamma \in \Gamma$  with the smallest TIC score, that is

$$\hat{\gamma}_{\text{TIC}}(\mathbf{y}) = \arg \min_{\gamma \in \Gamma} \{ \text{TIC}(\gamma; \mathbf{y}) \}.$$

The model with the smallest TIC score corresponds to the model we believe to be the closest in terms of KL divergence to the data generating distribution  $p^*(\cdot)$ . Under suitable regularity conditions, the TIC is an unbiased estimate of the KL divergence between the fitted model  $p_{\hat{\boldsymbol{\theta}}_\gamma}$  and the data generating model  $p^*(\cdot)$ , that is

$$E_{\mathbf{y} \sim p^*} [\text{TIC}(\gamma; \mathbf{y})] = E_{\mathbf{y} \sim p^*} [d_n(p^*, p_{\hat{\boldsymbol{\theta}}_\gamma})] + o(1),$$

where  $o(1)$  is a quantity that vanishes as  $n \rightarrow \infty$ . The empirical matrices (25.15) and (25.16) are a good approximation to (25.11) and (25.12) only if the sample size  $n$  is very large. As this is often not the case in practice, the TIC is rarely used.

The dependence of the TIC on the empirical matrices can be avoided if one assumes that the data generating distribution  $p^*(\cdot)$  is a distribution contained in the model  $\gamma$ . In this case, the matrices (25.11) and (25.12) coincide. Thus,  $\text{Tr}(\boldsymbol{\Omega}^{-1}(\boldsymbol{\theta}_0; \gamma) \boldsymbol{\Sigma}(\boldsymbol{\theta}_0; \gamma))$  reduces to the number of parameters  $k$ , and we obtain the widely known and extensively used Akaike's Information Criterion (AIC) [6]

$$\text{AIC}(\gamma; \mathbf{y}) = -2 \log p(\mathbf{y} | \hat{\boldsymbol{\theta}}_\gamma) + 2k. \quad (25.17)$$

An interesting way to view the AIC (25.17) is as a penalized likelihood criterion. For a given model  $\gamma$ , the negative maximized log-likelihood measures how well the model fits the data, while the “ $2k$ ” penalty measures the complexity of the model. Clearly, the complexity is an increasing function of the number of free parameters, and this acts to naturally balance the complexity of a model against its fit. Practically, this means that a complex model must fit the data well to be preferred to a simpler model with a similar quality of fit.

Similar to the TIC, the AIC is an asymptotically unbiased estimator of the KL divergence between the generating distribution  $p^*(\cdot)$  and the fitted distribution  $p_{\hat{\boldsymbol{\theta}}_\gamma}$ , that is

$$E_{\mathbf{y} \sim p^*} [\text{AIC}(\gamma; \mathbf{y})] = E_{\mathbf{y} \sim p^*} \left[ d_n(p^*, p_{\hat{\boldsymbol{\theta}}_\gamma}) \right] + o(1).$$

When the sample size is large and the number of free parameters is small relative to the sample size, the  $o(1)$  term is approximately zero, and the AIC offers an excellent estimate of the Kullback-Leibler divergence. However, in the case that  $n$  is small, or  $k$  is large relative to  $n$ , the  $o(1)$  term may be quite large, and the AIC does not adequately correct the bias, making it unsuitable for model selection.

To address this issue, Hurvich and Tsai [7] proposed a small sample correction to the AIC in the linear regression setting. This small sample AIC, referred to as  $\text{AIC}_c$ , is given by

$$\text{AIC}_c(\gamma; \mathbf{y}) = -2 \log p(\mathbf{y}, \hat{\boldsymbol{\theta}}_\gamma) + \frac{2kn}{n - k - 1} \quad (25.18)$$

for a model  $\gamma$  with  $k$  free parameters, and has subsequently been applied to models other than linear regressions. From (25.18) it is clear that the penalty term is substantially larger than  $2k$  when the sample size  $n$  is not significantly larger than  $k$ , and that as  $n \rightarrow \infty$  the  $\text{AIC}_c$  is equivalent to the regular AIC (25.17). Practically, a large body of empirical evidence strongly suggests that the  $\text{AIC}_c$  performs significantly better as a model selection tool than the AIC, largely irrespective of the problem. The approach taken by Hurvich and Tsai to derive their  $\text{AIC}_c$  criterion is not the only way of deriving small sample minimum distance estimators based on the KL divergence; for example, the work in [8] derives alternative AIC-like criteria based on variants of the KL divergence, while [9] offers an alternative small sample criterion obtained through bootstrap approximations.

For the reader interested in the theoretical details and complete derivations of the AIC, including all regularity conditions, we highly recommend the excellent text by Linhart and Zucchini [5]. We also recommend the text by McQuarrie and Tsai [10] for a more practical treatment of AIC and  $\text{AIC}_c$ .

### 1.25.2.2 The Kullback information criterion

Since the Kullback-Leibler divergence is an asymmetric measure, an alternative directed divergence can be obtained by reversing the roles of the two models in the definition of the measure. A undirected

measure of model dissimilarity can be obtained from the sum of the two directed divergences. This measure is known as Kullback's symmetric divergence, or  $J$ -divergence [11]. Since the  $J$ -divergence combines information about model dissimilarity through two distinct measures, it functions as a gauge of model disparity which is arguably more sensitive than either of its individual components. The  $J$ -divergence,  $J_n(\cdot)$ , between the true generating distribution  $p^*(\cdot)$  and a distribution  $p_{\theta_\gamma}$  is given by

$$\begin{aligned} 2J_n(p^*, p_{\theta_\gamma}) &= 2\Delta_n(p^*, p_{\theta_\gamma}) + 2\Delta_n(p_{\theta_\gamma}, p^*) \\ &= d_n(p^*, p_{\theta_\gamma}) - d_n(p^*, p^*) + d_n(p_{\theta_\gamma}, p^*) - d_n(p_{\theta_\gamma}, p_{\theta_\gamma}), \end{aligned}$$

where

$$d_n(p_{\theta_\gamma}, p_{\theta_\gamma}) = \mathbb{E}_{\mathbf{x} \sim p_{\theta_\gamma}} [-2 \log p(\mathbf{x}|\boldsymbol{\theta}; \gamma)], \quad (25.19)$$

$$d_n(p_{\theta_\gamma}, p^*) = \mathbb{E}_{\mathbf{x} \sim p_{\theta_\gamma}} [-2 \log p^*(\mathbf{x})]. \quad (25.20)$$

As in Section (1.25.2.1), we note that the term  $d_n(p^*, p^*)$  does not depend on the fitted model  $\boldsymbol{\theta}_\gamma$  and may be dropped when ranking models. The quantity

$$K_n(p^*, p_\gamma) = d_n(p^*, p_{\theta_\gamma}) + d_n(p_{\theta_\gamma}, p^*) - d_n(p_{\theta_\gamma}, p_{\theta_\gamma})$$

may then be used as a surrogate for the  $J$ -divergence, and leads to an appealing measure of dissimilarity between the generating distribution and the fitted candidate model. In a similar fashion to the AIC, twice the negative maximized log-likelihood has been shown to be a downwardly biased estimate of the  $J$ -divergence. Cavanaugh [12] derives an estimate of this bias, and uses this correction to define a model selection criterion called KIC (symmetric Kullback information criterion), which is given by

$$\text{KIC}(\gamma; \mathbf{y}) = -2 \log p(\mathbf{y}|\hat{\boldsymbol{\theta}}_\gamma) + 3k. \quad (25.21)$$

Comparing (25.21) to the AIC (25.17), we see that the KIC complexity penalty is slightly greater. This implies that the KIC tends to prefer simpler models (that is, those with less parameters) than those selected by minimising the AIC. Under suitable regularity conditions, the KIC satisfies

$$\mathbb{E}_{\mathbf{y} \sim p^*} [\text{KIC}(\gamma; \mathbf{y})] = \mathbb{E}_{\mathbf{y} \sim p^*} [K_n(p^*, p_{\theta_\gamma})] + o(1).$$

Empirically, the KIC has been shown to outperform AIC in large sample linear regression and autoregressive model selection, and tends to lead to less overfitting than AIC. Similarly to the AIC, when the sample size  $n$  is small the bias correction term  $3k$  is too small, and the KIC performs poorly as a model selection tool. Seghouane and Bekara [13] derived a corrected KIC, called  $\text{KIC}_c$ , in the context of linear regression that is suitable for use when the sample size is small relative to the total number of parameters  $k$ . The  $\text{KIC}_c$  is

$$\text{KIC}_c(\gamma; \mathbf{y}) = -2 \log p(\mathbf{y}|\hat{\boldsymbol{\theta}}_\gamma) + \frac{2kn}{n-k-1} - n\psi\left(\frac{n-k-1}{2}\right) + n \log \frac{n}{2}, \quad (25.22)$$

where  $\psi(\cdot)$  denotes the digamma function. The digamma function can be difficult to compute, and approximating the digamma function by a second-order Taylor series expansion yields the so called AKIC<sub>c</sub>, which is given by

$$\text{AKIC}_c(\gamma; \mathbf{y}) = -2 \log p(\mathbf{y}|\hat{\boldsymbol{\theta}}_\gamma) + \frac{k(3n-k-1)}{n-k-1} + \frac{k-1}{n-k-1}. \quad (25.23)$$

The second term in (25.22) appears as the complexity penalty in the  $AIC_c$  (25.18), which is not surprising given that the  $J$ -divergence is a sum of two KL divergence functions. Empirically, the  $KIC_c$  has been shown to outperform the KIC as a model selection tool when the sample size is small.

### 1.25.2.3 Example application: linear regression

We now demonstrate the application of the minimum distance estimation criteria to the problem of linear regression introduced in Section 1.25.1.2. Recall that in this setting,  $\gamma$  specifies which covariates from the full design matrix  $\mathbf{X}$  should be used in the fitted model. The total number of parameters is therefore  $k = |\gamma| + 1$ , where the additional parameter accounts for the fact that we must estimate the noise variance. The various model selection criteria are listed below:

$$AIC(\gamma; \mathbf{y}) = n \log(2\pi\hat{\tau}(\mathbf{y}; \gamma)) + n + 2k, \quad (25.24)$$

$$AIC_c(\gamma; \mathbf{y}) = n \log(2\pi\hat{\tau}(\mathbf{y}; \gamma)) + n + \frac{2kn}{n - k - 1}, \quad (25.25)$$

$$KIC(\gamma; \mathbf{y}) = n \log(2\pi\hat{\tau}(\mathbf{y}; \gamma)) + n + 3k, \quad (25.26)$$

$$KIC_c(\gamma; \mathbf{y}) = n \log(2\pi\hat{\tau}(\mathbf{y}; \gamma)) + n + \frac{2kn}{n - k - 1} - n\psi\left(\frac{n - k - 1}{2}\right). \quad (25.27)$$

It is important to stress that all these criteria are derived within the context of a nested set of candidate models  $\Gamma$  (see Section 1.25.1.1). In the next section we will briefly examine the problems that can arise if these criteria are used in situations where the candidates are not nested.

### 1.25.2.4 Consistency and efficiency

Let  $\gamma^*$  denote the model that generated the observed data  $\mathbf{y}$  and assume that  $\gamma^*$  is a member of the set of candidate models  $\Gamma$  which is fixed and does not grow with sample size  $n$ ; recall that the model  $\gamma^*$  contains the data generating distribution  $p^*(\cdot)$  as a particular distribution. Furthermore, of all the models that contain  $p^*(\cdot)$ , the model  $\gamma^*$  has the least number of free parameters. A model selection criterion is consistent if the probability of selecting the true model  $\gamma^*$  approaches one as the sample size  $n \rightarrow \infty$ . None of the distance based criteria examined in this chapter are consistent model selection procedures. This means that even for extremely large sample sizes, there is a non-zero probability that these distance based criteria will overfit and select a model with more free parameters than  $\gamma^*$ . Consequently, if the aim of the experiment is to discover the true model, the aforementioned distance based criteria are inappropriate. For example, in the linear regression setting, if the primary aim of the model selection exercise is to determine only those covariates that are associated with the observations, one should not use the AIC or KIC (and their variants).

In contrast, if the true model is of infinite order, which in many settings may be deemed more realistic in practice, then the true model lies outside the class of candidate models. In this case, we cannot hope to discover the true model, and instead would like our model selection criterion to at least provide good predictions about future data arising from the same source. A criterion that minimizes the one-step mean squared error between the fitted model and the generating distribution  $p^*(\cdot)$  with high probability as  $n \rightarrow \infty$  is termed *efficient*. The AIC and KIC, and their corrected variants are all asymptotically efficient [4]. This suggests that for large sample sizes, model selection by distance based criteria will lead to adequate prediction errors even if the true model lies outside the set of candidate models  $\Gamma$ .

### 1.25.2.5 The AIC and KIC for non-nested sets of candidate models

The derivations of the AIC and KIC, and their variants, depend on the assumption that the candidate model set  $\Gamma$  is nested. We conclude this section by briefly examining the behavior of these criteria when they are used to select a model from a non-nested candidate model set. First, consider the case that  $\Gamma$  forms a nested set of models, and let  $\gamma^* \in \Gamma$  be the true model, that is, the model that generated the data; this means that  $\gamma^*$  is the model in  $\Gamma$  with the least number of free parameters, say  $k^*$ , that contains the data generating distribution  $p^*(\cdot)$  as a particular distribution. If  $n$  is sufficiently large, the probability that the model selected by minimising the AIC will have  $k^* + 1$  parameters is at least 16%, with the equivalent probability for KIC being approximately 8% [10].

Consider now the case in which  $\Gamma$  forms a non-nested set of candidate models. A recent paper by Schmidt and Makalic [14] has demonstrated that in this case, the AIC is a downwardly biased estimator of the Kullback-Leibler divergence even asymptotically in  $n$ , and this downward bias is determined by the size of the sets  $\Gamma_k$ . This implies, that in the case of all-subsets regression, the probability of overfitting is an increasing function of the number of covariates under consideration,  $q$ , and this probability cannot be reduced even by increasing the sample size.

As an example of how great this probability may be, we consider an all-subsets regression in which the generating distribution is the null model; that is, none of the measured covariates  $\mathbf{x}_i$  are associated with the observations  $\mathbf{y}$ . Even if there is only as few as  $q = 10$  covariates available for selection, the probability of erroneously preferring a non-null model to the null model using the AIC is approximately 81%, and by the time  $q = 50$ , this probability rises to 99.9%. Although [14] examines only the AIC, similar arguments follow easily for the KIC. It is therefore recommended that while both criteria are appropriate for nested model selection, neither of these distance based criteria should be used for model selection in a non-nested situation, such as the all-subsets regression problem.

### 1.25.2.6 Applications

Minimum distance estimation criteria have been widely applied in the literature, and we present below an inexhaustive list of successful applications:

- univariate linear regression models [7,13],
- multivariate linear regression models with arbitrary noise covariance matrices [15,16],
- autoregressive model selection [7,12,17],
- selection of smoothing parameters in nonparametric regression [18],
- signal denoising [19,20],
- selection of the size of a multilayer perceptron network [21].
- model selection in the presence of missing data [22].

For details of many of these applications the reader is referred to [10].

---

## 1.25.3 Bayesian approaches to model selection

Section 1.25.2 has described model selection criteria that are designed to explicitly minimise the distance between the estimated models and the true model that generated the observed data  $\mathbf{y}$ . An alternative

approach, based on Bayesian statistics [23], is now discussed. The Bayesian approach to statistical analysis differs from the “classical” approach through the introduction of a *prior distribution* that is used to quantify an experimenter’s *a priori* (that is, before the observation of data) beliefs about the source of the observed data. A central quantity in Bayesian analysis is the so-called *posterior distribution*; given a prior distribution,  $\pi_{\theta}(\theta|\gamma)$ , over the parameter space  $\theta \in \Theta_{\gamma}$ , and the likelihood function,  $p(\mathbf{y}|\theta, \gamma)$ , the posterior distribution of the parameters given the data may be found by applying Bayes’ theorem, yielding

$$p(\theta|\mathbf{y}, \gamma) = \frac{p(\mathbf{y}|\theta, \gamma)\pi_{\theta}(\theta|\gamma)}{p(\mathbf{y}|\gamma)}, \quad (25.28)$$

where

$$p(\mathbf{y}|\gamma) = \int_{\Theta_{\gamma}} p(\mathbf{y}|\theta, \gamma)\pi_{\theta}(\theta|\gamma)d\theta \quad (25.29)$$

is known as the marginal probability of  $\mathbf{y}$  for model  $\gamma$ , and is a normalization term required to render (25.28) a proper distribution. In general, the specification of the prior distribution may itself depend on further parameters, usually called *hyperparameters*, but for the purposes of the present discussion this possibility will not be considered. The main strength of the Bayesian paradigm is that it allows uncertainty about models and parameters to be defined directly in terms of probabilities; there is no need to appeal to more abstruse concepts, such as the “confidence interval” of classical statistics. However, there is in general no free lunch in statistics, and this strength comes at a price: the specification and origin of the prior distribution. There are essentially two main schools of thought on this topic: (i) subjective Bayesianism, where prior distributions are viewed as serious expressions of subjective belief about the process that generated the data, and (ii) objective Bayesianism [24], where one attempts to express prior ignorance through the use of uninformative, objective distributions, such as the Jeffreys’ prior [11], reference priors [25] and intrinsic priors [26]. The specification of the prior distribution is the basis of most criticism leveled at the Bayesian school, and an extensive discussion on the merits and drawbacks of Bayesian procedures, and the relative merits of subjective and objective approaches, is beyond the scope of this tutorial (there are many interesting discussions on this topic in the literature, see for example, [27, 28]). However, in this section of the tutorial, an approach to the problem of prior distribution specification based on asymptotic arguments will be presented.

While (25.28) specifies a probability distribution over the parameter space  $\Theta_{\gamma}$ , conditional on the observed data, it gives no indication of the likelihood of the model  $\gamma$  given the observed data. A common approach is based on the marginal distribution (25.29). If a further prior distribution,  $\pi_{\gamma}(\gamma)$ , over the set of candidate models  $\gamma \in \Gamma$  is available, one may apply Bayes’ theorem to form a posterior distribution over the models themselves, given by

$$p(\gamma|\mathbf{y}) = \frac{p(\mathbf{y}|\gamma)\pi_{\gamma}(\gamma)}{\sum_{\gamma' \in \Gamma} p(\mathbf{y}|\gamma')\pi_{\gamma'}(\gamma')}. \quad (25.30)$$

Model selection then proceeds by choosing the model  $\hat{\gamma}(\mathbf{y})$  that maximizes the probability (25.30), that is

$$\hat{\gamma}(\mathbf{y}) = \arg \max_{\gamma \in \Gamma} \{p(\mathbf{y}|\gamma)\pi_{\gamma}(\gamma)\}, \quad (25.31)$$

where the normalizing constant may be safely ignored. An interesting consequence of the posterior distribution (25.30) is that the posterior-odds in favor of some model,  $\gamma_1$ , over another model  $\gamma_0$ , usually

called the Bayes factor [29, 30], can be found from the ratio of posterior probabilities, that is,

$$\text{BF}(\gamma_1, \gamma_0) = \frac{p(\mathbf{y}|\gamma_1)\pi_\gamma(\gamma_1)}{p(\mathbf{y}|\gamma_0)\pi_\gamma(\gamma_0)}. \quad (25.32)$$

This allows for a straightforward and highly interpretable quantification of the uncertainty in the choice of any particular model. The most obvious weakness in the Bayesian approach, ignoring the origin of the prior distributions, is computational. As a general rule, the integral in the definition of the marginal distribution (25.29), does not admit a closed-form solution and one must resort to numerical approaches or approximations. The next section will discuss a criterion based on asymptotic arguments that circumvents both the requirement to specify an appropriate prior distribution as well as the issue of integration in the computation of the marginal distribution.

### 1.25.3.1 The Bayesian information criterion (BIC)

The Bayesian Information Criterion (BIC), also sometimes known as the Schwarz Information Criterion (SIC), was proposed by Schwarz [31]. However, the resulting criterion is not unique and was also derived from information theoretic considerations by Rissanen [32], as well as being implicit in the earlier work of Wallace and Boulton [33]; the information theoretic arguments for model selection are discussed in detail in the next section of this chapter. The BIC is based on the Laplace approximation for high dimensional integration [34]. Essentially, under certain regularity conditions, the Laplace approximation works by replacing the distribution to be integrated by a suitable multivariate normal distribution, which results in a straightforward integral. Making the assumptions that the prior distribution is such that its effects are “swamped” by the evidence in the data, and that the maximum likelihood estimator converges on the posterior mode as  $n \rightarrow \infty$ , one may apply the Laplace approximation to (25.29) yielding

$$\pi_\gamma(\gamma) \int_{\Theta_\gamma} p(\mathbf{y}|\boldsymbol{\theta}, \gamma) \pi_\boldsymbol{\theta}(\boldsymbol{\theta}|\gamma) d\boldsymbol{\theta} \simeq \frac{(2\pi)^{k/2} p(\mathbf{y}|\hat{\boldsymbol{\theta}}(\mathbf{y}; \gamma), \gamma) \pi_\boldsymbol{\theta}(\hat{\boldsymbol{\theta}}_\gamma(\mathbf{y}; \gamma)|\gamma) \pi_\gamma(\gamma)}{|\mathbf{J}_n(\hat{\boldsymbol{\theta}}(\mathbf{y}; \gamma); \gamma)|^{1/2}}, \quad (25.33)$$

where  $\simeq$  denotes that the ratio of the left and right hand side approaches one as the sample size  $n \rightarrow \infty$ . In (25.33),  $k = \dim(\Theta_\gamma)$  is the total number of continuous, free parameters for model  $\gamma$ ,  $\hat{\boldsymbol{\theta}}_\gamma(\mathbf{y}; \gamma)$  is the maximum likelihood estimate, and  $\mathbf{J}(\cdot)$  is the  $(k \times k)$  expected Fisher information matrix for  $n$  data points, given by

$$\mathbf{J}_n(\boldsymbol{\theta}_0; \gamma) = -E_{\boldsymbol{\theta}_0} \left[ \frac{\partial^2 \log p(\mathbf{y}|\boldsymbol{\theta}, \gamma)}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'} \Bigg|_{\boldsymbol{\theta}=\boldsymbol{\theta}_0} \right]. \quad (25.34)$$

The technical conditions under which (25.33) holds are detailed in [31]; in general, if the maximum likelihood estimates are consistent, that is, they converge on the true, generating value of  $\boldsymbol{\theta}$  as  $n \rightarrow \infty$ , and also satisfy the central limit theorem, the approximation will be satisfactory, at least for large sample sizes. To find the BIC, begin by taking negative logarithms of the right hand side of (25.33)

$$-\log p(\mathbf{y}|\hat{\boldsymbol{\theta}}(\mathbf{y}; \gamma), \gamma) + \frac{1}{2} \log |\mathbf{J}_n(\hat{\boldsymbol{\theta}}(\mathbf{y}; \gamma); \gamma)| - \log \pi_\boldsymbol{\theta}(\hat{\boldsymbol{\theta}}(\mathbf{y}; \gamma)|\gamma) - \frac{k}{2} \log 2\pi - \log \pi_\gamma(\gamma). \quad (25.35)$$

A crucial assumption made is that the Fisher information satisfies

$$\mathbf{J}_1(\boldsymbol{\theta}; \gamma) = \lim_{n \rightarrow \infty} \left\{ \frac{\mathbf{J}_n(\boldsymbol{\theta}; \gamma)}{n} \right\}, \quad (25.36)$$

where  $\mathbf{J}_1(\cdot)$  is the asymptotic *per sample* Fisher information matrix satisfying  $|\mathbf{J}_1(\cdot)| > 0$ , and is free of dependency on  $n$ . This assumption is met by a large range of models, including linear regression models, autoregressive moving-average (ARMA) models and generalized linear models (GLMs) to name a few. This allows the determinant of the Fisher information matrix for  $n$  samples to be rewritten as

$$\begin{aligned} |\mathbf{J}_n(\boldsymbol{\theta}; \gamma)| &\approx n^k \cdot |\mathbf{J}_1(\boldsymbol{\theta}; \gamma)|, \\ &= n^k \cdot O(1), \end{aligned}$$

where  $O(1)$  denotes a quantity that is constant in  $n$ . Using this result, (25.35) may be dramatically simplified by assuming that  $n$  is large and discarding terms that are  $O(1)$  with respect to the sample size, yielding the BIC

$$\text{BIC}(\gamma; \mathbf{y}) = -\log p(\mathbf{y}|\hat{\boldsymbol{\theta}}(\mathbf{y}; \gamma), \gamma) + \frac{k}{2} \log n. \quad (25.37)$$

Model selection using BIC is then done by finding the  $\gamma \in \Gamma$  that minimises the BIC score (25.37), that is,

$$\hat{\gamma}_{\text{BIC}}(\mathbf{y}) = \arg \min_{\gamma \in \Gamma} \{\text{BIC}(\gamma; \mathbf{y})\}. \quad (25.38)$$

It is immediately obvious from (25.37) that a happy consequence of the approximations that are employed is the removal of the dependence on the prior distribution  $\pi_{\boldsymbol{\theta}}(\cdot)$ . However, as usual, this comes at a price. The BIC satisfies

$$-\log \int_{\Theta_{\gamma}} p(\mathbf{y}|\boldsymbol{\theta}, \gamma) \pi_{\boldsymbol{\theta}}(\boldsymbol{\theta}|\gamma) d\boldsymbol{\theta} = \text{BIC}(\gamma; \mathbf{y}) + O(1), \quad (25.39)$$

where the  $O(1)$  term is only guaranteed to be negligible for large  $n$ . For any finite  $n$ , this term may be arbitrarily large, and may have considerable effect on the behavior of BIC as a model selection tool. Thus, in general, BIC is only appropriate for use when the sample size is quite large relative to the number of parameters  $k$ . However, despite this drawback, when used correctly the BIC has several pleasant, and important, properties that are now discussed. The important point to bear in mind is that like all approximations, it can only be employed with confidence in situations that meet the conditions under which the approximation was derived.

### 1.25.3.2 Properties of BIC

#### 1.25.3.2.1 Consistency of BIC

A particularly important, and defining, property of BIC is the consistency of  $\hat{\gamma}_{\text{BIC}}(\mathbf{y})$  as  $n \rightarrow \infty$ . Let  $\gamma^* \in \Gamma$  be the true model, that is, the model that generated the data; this means that  $\gamma^*$  is the model in  $\Gamma$  with the least number of free parameters that contains the data generating distribution  $p^*(\cdot)$  as a particular distribution. Further, let the set of all models  $\Gamma$  be independent of the sample size  $n$ ; this means that the number of candidate models that are being considered does not increase with increasing sample size. Then, if all models in  $\Gamma$  satisfy the regularity conditions under which BIC was derived, and in particular (25.36), the BIC estimate satisfies

$$\Pr(\hat{\gamma}_{\text{BIC}}(\mathbf{y}) = \gamma^*) \rightarrow 1 \quad (25.40)$$

as  $n \rightarrow \infty$  [35,36]. In words, this says that the BIC estimate of  $\gamma$  converges on the true, generating model with probability one in the limit as the sample size  $n \rightarrow \infty$ , and this property holds irrespective of whether  $\Gamma$  forms a nested or non-nested set of candidate models. Practically, this means that as the sample size grows the probability that the model selected by the minimising the BIC score overfits or underfits the true, generating model, tends to zero. This is an important property if the discovery of relevant parameters is of more interest than making good predictions, and is not shared by any of the distance-based criteria discussed in Section 1.25.2. An argument against the importance of model selection consistency stems from the fact that the statistical models under consideration are abstractions of reality, and that the true, generating model is not a member of the set  $\Gamma$ . Regardless of this criticism, empirical studies suggest that the BIC tends to perform well in comparison to asymptotically efficient criteria such as AIC and KIC when the underlying generating process may be described by a small number of strong effects [10], and thus occupies a useful niche in the gallery of model selection techniques.

### 1.25.3.2.2 Bayesian Interpretations of BIC

Due to the fact that the BIC is an approximation of the marginal probability of data  $\mathbf{y}$  (25.29), it admits the full range of Bayesian interpretations. For example, by computing the BIC scores for two models  $\gamma_0$  and  $\gamma_1$ , one may compute an approximate negative log-Bayes factor of the form

$$-\log \text{BF}(\gamma_1, \gamma_0) \approx \text{BIC}(\gamma_0; \mathbf{y}) - \text{BIC}(\gamma_1; \mathbf{y}).$$

Therefore, the exponential of the negative difference in BIC scores for  $\gamma_1$  and  $\gamma_0$  may be interpreted as an approximate posterior-odds in favor of  $\gamma_1$ . Further, the BIC scores may be used to perform model averaging. Selection of a single best model from a candidate set is known to be statistically unstable [37], particularly if the sample size is small and many models have similar criterion scores. Instability in this setting is defined as the variability in the choice of the single best model under minor perturbations of the observed sample. It is clear that if many models are given similar criterion scores, then changing a single data point in the sample can lead to significant changes in the ranking of the models. In contrast to model selection, model averaging aims to improve predictions by using a weighted mixture of all the estimated models, the weights being proportional to the strength of evidence for the particular model. By noting that the BIC score is approximately equal to the negative log-posterior probability of the model, a Bayesian predictive density for future data  $\mathbf{y}_1$ , conditional on an observed sample  $\mathbf{y}_0$ , may be found by marginalising out the model class indicator  $\gamma$ , that is,

$$p(\mathbf{y}_1 | \mathbf{y}_0) \approx \frac{\sum_{\gamma \in \Gamma} p(\mathbf{y}_1 | \hat{\theta}(\mathbf{y}_0; \gamma), \gamma) e^{-\text{BIC}(\gamma; \mathbf{y}_0)}}{\sum_{\gamma \in \Gamma} e^{-\text{BIC}(\gamma; \mathbf{y}_0)}}. \quad (25.41)$$

Although such a mixture often outperforms a single best model when used to make predictions about future data [38], there are several drawbacks to the model averaging approach. The first is that the resulting density lacks the property of parsimony, as no model is excluded from the mixture, and therefore all model parameters contribute to the mixture. In the case of linear regression, for example, this means the ability to decide whether particular covariates are “relevant” is lost. The second drawback is that the predictive density (25.41) is in general not of the same form as any its component models, which can lead to interpretability issues.

### 1.25.3.3 Example application: linear regression

We conclude our examination of the BIC with an example of an application to linear regression models. Recalling that in this context the model indicator  $\gamma \subseteq \{1, \dots, q\}$  specifies which covariates, if any, should be used from the full design matrix  $\mathbf{X} \in \mathbb{R}^{(n \times q)}$  to explain the observed samples  $\mathbf{y}$ . The BIC score for a particular covariate set  $\gamma \in \Gamma$  is given by

$$\text{BIC}(\gamma; \mathbf{y}) = \frac{n}{2} \log(2\pi\hat{\tau}(\mathbf{y}; \gamma)) + \frac{n}{2} + \left(\frac{k+1}{2}\right) \log n, \quad (25.42)$$

where  $\hat{\tau}(\cdot; \gamma)$  is the maximum likelihood estimator of the noise variance for model  $\gamma$ , and the  $(k+1)$  accounts for the fact that the variance must be estimated from the data along with the  $k$  regression parameters. The BIC score (25.42) contains the terms  $(1/2)(n + \log n)$  which are constant with respect to  $\gamma$  and may be omitted if the set of candidate models only consists of linear regressions; if the set  $\Gamma$  also contains models from alternative classes, such as artificial neural networks, then these terms are required to fully characterize the marginal probability in comparison to this alternative class of models. The consistency property of BIC is particularly useful in this setting, as it guarantees that if the data were generated from (25.42) then as  $n \rightarrow \infty$ , minimising the BIC score will recover the true model, and thus determine exactly which covariates are associated with  $\mathbf{y}$ .

Given the assumption of Gaussian noise, the Bayesian mixture distribution is a weighted mixture of Gaussian distributions and thus has a particularly simple conditional mean. Let  $\boldsymbol{\alpha}(\gamma)$  denote a  $(q \times 1)$  vector with entries

$$\alpha_i(\gamma) = \begin{cases} \hat{\beta}_{(j: \gamma_j=i)}(\mathbf{y}; \gamma) & i \in \gamma \\ 0 & \text{otherwise} \end{cases},$$

that is, the vector  $\boldsymbol{\alpha}(\gamma)$  contains the maximum likelihood estimates for the covariates in  $\gamma$ , and zeros for those covariates that are not in  $\gamma$ . Then, the conditional mean of the predictive density for future data with design matrix  $\mathbf{X}_1$ , conditional on an observed sample  $\mathbf{y}_0$ , is simply a linear combination of the  $\boldsymbol{\alpha}(\gamma)$

$$E[\mathbf{y}_1 | \mathbf{X}_1, \mathbf{y}_0] = \mathbf{X}_1 \left( \sum_{\gamma \in \Gamma} \boldsymbol{\alpha}(\gamma) e^{-\text{BIC}(\gamma; \mathbf{y}_0)} \right),$$

which is essentially a linear regression with a special coefficient vector. While this coefficient vector will be dense, in the sense that none of its entries will be exactly zero, it retains the high degree of interpretability that makes linear regression models so attractive.

### 1.25.3.4 Priors for the model structure $\gamma$

One of the primary assumptions made in the derivation of the BIC is that the effects of the prior distribution for the model,  $\pi_\gamma(\cdot)$ , can be safely neglected. However, in some cases the number of models contained in  $\Gamma$  is very large relative to the sample size, or may even grow with growing sample size, and this assumption may no longer be valid. An important example is that of regression models in the context of genetic datasets; in this case, the number of covariates is generally several orders of magnitude greater than the number of samples. In this case, it is possible to use a modified BIC of the form

$$\text{BIC}(\gamma; \mathbf{y}) = -\log p(\mathbf{y} | \hat{\theta}(\mathbf{y}; \gamma), \gamma) + \frac{k}{2} \log n - \log \pi_\gamma(\gamma), \quad (25.43)$$

which requires specification of the prior distribution  $\pi_\gamma(\cdot)$ . In the setting of regression models, there are two general flavors of prior distributions for  $\gamma$  depending on the structure represented by  $\Gamma$ . The first case is that of *nested* model selection. A nested model class has the important property that all models with  $k$  parameters contain all models with less than  $k$  parameters as special cases. A standard example of this is polynomial regression in which the model selection criterion must choose the order of the polynomial. A uniform prior over  $\Gamma$  is an appropriate, and standard, choice of prior for nested model classes. Use of such a prior in (25.43) inflates the BIC score by a term of  $\log |\Gamma|$ ; this term is constant for all  $\gamma$ , and may consequently be ignored when using the BIC scores to rank the models.

In contrast, the second general case, known as *all-subsets regression*, is less straightforward. In this setting, there are  $q$  covariates, and  $\Gamma$  contains all possible subsets of  $\{1, \dots, q\}$ . This implies that the model class is no longer nested. It is tempting to assume a uniform prior over the members of  $\Gamma$ , as this would appear to be an uninformative choice. Unfortunately, such a prior is heavily biased towards subsets containing approximately half of the covariates. To see this, note that  $\Gamma$  contains a total of  $\binom{q}{k}$  subsets that include  $k$  covariates. This number may be extremely large when  $k$  is close to  $q/2$ , even for moderate  $q$ , and thus these subsets will be given a large proportion of the prior probability. For example, if  $q = 20$  then  $|\Gamma| \approx 10^6$  and  $\binom{20}{10} \approx 1.8 \times 10^5$ . Practically, this means that subsets with  $k = 10$  covariates are given approximately one-fifth of the total prior probability; in contrast, subsets with a single covariate receive less than one percent of the prior probability. To address this issue, an alternative approach is to use a prior which assigns equal prior probability to each set of subsets of  $k$  covariates, for all  $k$ , that is,

$$-\log \pi_\gamma(\gamma) = \log \binom{q}{|\gamma|} + \log(q+1). \quad (25.44)$$

This prior (or ones very similar) also arise from both empirical Bayes [39] and information theoretic arguments [27, 40], and have been extensively studied by Scott and Berger [41]. This work has demonstrated that priors of the form (25.44) help Bayesian procedures overcome the difficulties associated with all-subsets model selection that adversely affect distance based criteria such as AIC and KIC [14].

In fact, Chen and Chen [42] have proposed a generalization of this prior as part of what they call the “extended BIC.” An important (specific) result of this work is the proof that using the prior (25.44) relaxes conditions required for the consistency of the BIC. Essentially, the total number of covariates may now be allowed to depend on the sample size  $n$  in the sense that  $q = O(n^\kappa)$ , where  $\kappa$  is a constant satisfying  $0 < \kappa < \infty$ , implying that  $|\Gamma|$  grows with increasing  $n$ . Then, under certain identifiability conditions on the complete design matrix  $\mathbf{X}$  detailed in [42], and assuming that  $\gamma^* \in \Gamma$ , the BIC given by (25.43) using the prior (25.44) almost surely selects the true model  $\gamma^*$  as  $n \rightarrow \infty$ .

### 1.25.3.5 Markov-Chain Monte-Carlo Bayesian methods

We conclude this section by briefly discussing several alternative approaches to Bayesian model selection based on random sampling from the posterior distribution,  $p(\theta|y)$ , which fall under the general umbrella of Markov Chain Monte Carlo (MCMC) methods [43]. The basic idea is to draw a sample of parameter values from the posterior distribution, using a technique such as the Metropolis-Hastings algorithm [44, 45] or the Gibbs sampler [46, 47]. These techniques are in general substantially more complex than the information criteria based approaches, both computationally and in terms of implementation, and

this complexity generally brings with it greater flexibility in the specification of prior distributions as well as less stringent operating assumptions.

The most obvious way to apply MCMC methods to Bayesian model selection is through direct evaluation of the marginal (25.29). Unfortunately, this is a very difficult problem in general, and the most obvious approach, the so called harmonic mean estimator, suffers from statistical instability and convergence problems and should be avoided. In the particular case that Gibbs sampling is possible, and that the posterior is unimodal, Chib [48] has provided an algorithm to compute the approximate marginal probability from posterior samples.

An alternative to attempting to directly compute the marginal probability is to view the model indicator  $\gamma$  as the parameter of interest and randomly sample from the posterior  $p(\gamma|\mathbf{y})$ . This allows for the space of models  $\Gamma$  to be explored by simulation, and approximate posterior probabilities for each of the models to be determined by the frequency at which a particular model appears in the sample. There have been a large number of papers published that discuss this type of approach, and important contributions include the reversible jump MCMC algorithm of Green [49], the stochastic search variable selection algorithm [50], the shotgun stochastic search algorithm [51], and an interesting paper from Casella and Moreno [28] that combines objective Bayesian priors with a stochastic search procedure for regression models.

Finally, there has been a large amount of recent interest in using regularisation and “sparsity inducing” priors to combine Bayesian model selection with parameter estimation. In this approach, special priors over the model parameters are chosen that concentrate prior probability on “sparse” parameter vectors, that is, parameter vectors in which some of the elements are exactly zero. These methods have been motivated by the Bayesian connections with non-Bayesian penalized regression procedures such as the non-negative garotte [52] and the LASSO [53]. A significant advantage of this approach is that one needs only to sample from, or maximize over, the posterior of a single model containing all parameters of interest, and there is no requirement to compute marginal probabilities or to explore discrete model spaces. This is a rapidly growing area of research, and some important contributions of note include the relevance vector machine [54], Bayesian artificial neural networks [55] and the Bayesian LASSO [56,57].

## 1.25.4 Model selection by compression

This section examines the minimum message length (MML) (see Section 1.25.4.1) and minimum description length (MDL) (see Section 1.25.4.6) principles of model selection. Unlike the aforementioned distance based criteria, the MML and MDL principles are based on information theory and data compression. Informally, given a dataset and a set of candidate models, both MML and MDL advocate choosing the model that yields the briefest encoding of a hypothetical message comprising the model and the data. This optimal model is the simplest explanation of the data amongst the set of competing models. In this fashion, MML and MDL treat codelengths of compressed data as a measure of model complexity and, therefore, a yardstick for evaluating the explanatory power of competing models. Since data compression is equivalent to statistical learning of regularity in the data, this is intuitively a sensible procedure. It is important to note that one does not need to encode the models or the data in order to do MML and MDL inference. All that is required is to be able to calculate codelengths which can then be used for model comparison. Before discussing how MML and MDL compute codelengths of models

and data, a brief discussion of information theory is necessary. For a detailed treatment of information theory, the interested reader is recommended [58].

To aid in understanding the fundamental information theory concepts, it is helpful to consider the following hypothetical scenario. There exists a sender who is transmitting a data set (message) to a receiver over a transmission channel. The receiver does not know the content of the message. The message,  $\mathcal{M}$ , is recorded using some alphabet  $\mathcal{X}$ , such as a subset of the English alphabet  $\mathcal{X} = \{a, b, c\}$ , and comprises a sequence of symbols formed from  $\mathcal{X}$ ; for example, the message using  $\mathcal{X} = \{a, b, c\}$  may be  $\mathcal{M} = \{bcc\}$ . The transmission channel is noiseless and does not modify transmissions in any fashion. Without loss of generality, we assume the coding alphabet used on the transmission channel is the binary alphabet  $\mathcal{Y} = \{0, 1\}$ . Prior to sending the message, the sender and the receiver agree on a suitable codebook which will be used to transmit all messages on this channel. The codebook is a mapping  $C : \mathcal{X} \rightarrow \mathcal{Y}^*$  from the source alphabet  $\mathcal{X}$  to the target alphabet  $\mathcal{Y}^*$ , where  $\mathcal{Y}^*$  is the set of all strings obtained by concatenating elements of  $\mathcal{Y}$ . Some possible codebooks are:

$$C_1 = \{a \rightarrow 0, b \rightarrow 10, c \rightarrow 11\}, \quad (25.45)$$

$$C_2 = \{a \rightarrow 00, b \rightarrow 01, c \rightarrow 10\}, \quad (25.46)$$

$$C_3 = \{a \rightarrow 0, b \rightarrow 01, c \rightarrow 001\}. \quad (25.47)$$

For example, if the codebook  $C_1$  (25.45) is used by the sender, the message  $\{bcc\}$  is mapped to the target code  $\{1011110\}$ . If the sender uses codebook  $C_2$  instead, the message is encoded as  $\{01101000\}$ . The task of the sender and receiver is to choose a codebook such that the transmitted message is uniquely decodable by the receiver and as brief as possible.

If the codebook  $C$  possess the prefix property, a message transmitted using  $C$  is uniquely decodable requiring no delimiters between successive symbols. The prefix property states that no codeword is a prefix of any other codeword. In the above example, codebooks  $C_1$  and  $C_2$  possess the prefix property, while codebook  $C_3$  does not as the code 0 for source symbol  $a$  is a prefix to both codes 01 and 001. Since there exist infinitely many prefix codes, the sender and the receiver may choose the prefix code that results in the briefest possible encoding of the message  $\mathcal{M}$ . Intuitively, symbols in the message that appear more frequently should be assigned smaller codewords, while symbols that are very rare can be given longer codewords in order to reduce the average length of the encoding. This optimization problem is now formally explored. Note, that in the rest of the section we only consider codebooks which are uniquely decodable and possess the prefix property.

Let  $X$  denote a discrete random variable defined over the support (source alphabet)  $\mathcal{X}$  with probability distribution function  $p_X(\cdot)$ . The random variable  $X$  represents the sender of the message. Furthermore, let  $l : \mathcal{X} \rightarrow \mathbb{R}_+$  denote the codelength function which gives the codeword length for each symbol in the source alphabet  $\mathcal{X}$ . For example,  $l(a) = 1$  bit for the codebook  $C_1$ , while  $l(a) = 2$  bits, for the codebook  $C_2$ . The average codelength per symbol from source alphabet  $\mathcal{X}$  with probability distribution function  $p_X(\cdot)$  is defined as

$$E[l(X)] = \sum_{x \in \mathcal{X}} p_X(x)l(x), \quad (25.48)$$

where  $E$  denotes the expected value of a random variable. We wish to choose the function  $l(\cdot)$  such that the codelength for data from the random variable  $X$  is on average the shortest possible; that is we seek

a function  $l(\cdot)$  that minimises

$$\arg \min_{l(x), x \in \mathcal{X}} \{E[l(X)]\}. \quad (25.49)$$

The solution to this optimization problem is

$$l(X) = \log 1/p_X(x), \quad (25.50)$$

which is the Shannon information of a random variable [59]. The unit of information is derived from the base of the logarithm; commonly binary and natural logarithms are used corresponding to the bit and the nit (nat) units respectively. In the rest of this section, all logarithms are assumed to be natural logarithms, unless stated otherwise.

The Shannon information agrees with the previous intuition that high probability symbols should be assigned shorter codewords, while low probability symbols should be given longer code words. At first, it may seem troubling that Shannon information allows for non-integer length codewords. After all, how does one encode and transmit symbols of length, say, 0.2 of a nit? However, this is not an issue in practice as there exist sophisticated coding algorithms, such as arithmetic codes [60], that allow for efficient encoding in the presence of non-integer codewords. It is important to re-iterate here that MML and MDL model selection does not require any actual encoding of data to be performed; all that is required is a function to compute codelengths for data and models. Model selection is then performed by computing codelengths for all candidate models and choosing the one with the smallest codelength as optimal.

The minimum possible average codelength per symbol for a discrete random variable  $X$  is known as the Shannon entropy of  $X$  and is defined as

$$H(X) = E[\log 1/p_X(X)] = \sum_{x \in \mathcal{X}} p_X(x) \log 1/p_X(x) \quad (25.51)$$

with the convention that  $0 \log 0 = 0$ ; since  $x \log x \rightarrow 0$  as  $x \rightarrow 0$ , this is reasonable. The entropy of a random variable is always non-negative,  $H(X) \geq 0$ , and is a measure of uncertainty in the random variable. The maximum entropy is attained when there is maximum uncertainty in  $X$ , that is, when  $X$  is uniformly distributed over the support  $\mathcal{X}$ . For example, the entropy of a random variable  $X$  with support  $\mathcal{X} = \{1, 2, 3, 4, 5, 6\}$  and probability distribution function

$$p_X(j) = \frac{1}{6} \quad (j = 1, \dots, 6) \quad (25.52)$$

is approximately 2.585 bits or 1.792 nits. As another example, the entropy of random variable  $X$  following a Geometric distribution ( $\mathcal{X} = \{0, 1, 2, \dots\}$ ) with distribution function

$$p_X(X|\lambda) = (1 - \lambda)^x \lambda \quad (0 < \lambda \leq 1) \quad (25.53)$$

is given by

$$H(X|\lambda) = -\frac{1}{\lambda} [(1 - \lambda) \log(1 - \lambda) + \lambda \log \lambda], \quad (25.54)$$

where  $H(X|\lambda) = 0$  for  $\lambda = 1$ , and  $H(X|\lambda) \rightarrow \infty$  as  $\lambda \rightarrow 0$ .

The entropy of a random variable is the minimum average codelength per symbol with the length of each codeword  $X$  given by  $l(X) = \log 1/p_X(\cdot)$ . By the law of large numbers, it can also be shown that

using codelengths of the form  $l(X)$  results in a code that is optimal not only on average, but also optimal for the actually generated sequences of data. It is of interest to quantify the inefficiency resulting from encoding symbols generated by  $p_X(\cdot)$  using an alternative distribution function  $q_X(X)$ , where  $p_X(\cdot) \neq q_X(\cdot)$  for at least one  $X \in \mathcal{X}$ . The extra number of nits (or bits) required per symbol on average if  $q_X(\cdot)$  is used instead of  $p_X(\cdot)$  is given by the Kullback-Leibler (KL) divergence (see Section 1.25.2). The KL divergence is always non-negative, and is only equal to zero when  $p_X(\cdot) = q_X(\cdot)$ , for all  $X \in \mathcal{X}$ . In words, the briefest encoding for data from source  $p_X(\cdot)$  is achieved using  $p_X(\cdot)$  as the coding distribution and any other distribution, say  $q_X(\cdot)$ , will necessarily result in messages with a longer average codelength.

Recall that both MML and MDL seek models that result in the shortest codelength of a hypothetical message comprising the observed data and the model. That is, both MML and MDL seek models that result in the best compression of the observed data. Formally, this is a sensible procedure since the set of compressible strings from any data source is in fact quite small in comparison to incompressible strings from the same source. This is quantified by the following *no hypercompression inequality* (p. 136 [61]). Given a sample of  $n$  data points  $\mathbf{y} = (y_1, \dots, y_n)$  generated from a probability distribution  $p_X(\cdot)$ , the probability of compressing  $\mathbf{y}$  by *any* code is

$$p(\log 1/p_X(y_1, \dots, y_n) \geq \log 1/q_X(y_1, \dots, y_n) + K) \leq 2^{-K}. \quad (25.55)$$

In words, the inequality states that the probability of compressing  $\mathbf{y}$  by  $K$  bits using any code is small and decreases exponentially with increasing  $K$ . Clearly, the sender and the receiver would like  $K$  to be as large as possible leading to the briefest encoding of the observed data. For any moderate  $K$ , it is highly unlikely for a random model to result in a compression of  $K$ -bits as the number of models that can compress the data in such a manner is vanishingly small with  $K$ . In the next section, we examine model selection with the minimum message principle which is based on information theory and data compression.

#### 1.25.4.1 Minimum message length (MML)

The Minimum Message Length (MML) principle for model selection was introduced by Wallace [27] and collaborators in the late 1960s [33], and has been continuously refined in the following years [62, 63]. The MML principle connects the notion of compression with statistical inference, and uses this connection to provide a unified framework for model selection and parameter estimation. Recalling the transmitter-receiver framework outlined in Section 1.25.4, consider the problem of efficiently transmitting some observed data  $\mathbf{y}$  from the transmitter to the receiver. Under the MML principle, the model that results in the shortest encoding of a decodable message comprising the model and data is considered optimal. For this message to be decodable, the receiver and the transmitter must agree on a common language prior to any data being transmitted. In the MML framework, the common knowledge is a set of parametric models  $\Gamma$ , each comprising a set of distributions  $p(\mathbf{y}|\boldsymbol{\theta}, \gamma)$  indexed by  $\boldsymbol{\theta}$ , and a prior distribution  $\pi(\boldsymbol{\theta}, \gamma) = \pi_{\boldsymbol{\theta}}(\boldsymbol{\theta}|\gamma)\pi_{\gamma}(\gamma)$ . The use of a subjective prior distribution means that MML is an unashamedly Bayesian principle built on information theoretic foundations.

Given a model from  $\gamma$  and a prior distribution  $\pi_{\boldsymbol{\theta}}(\cdot)$  over  $\Theta_{\gamma}$ , we may define an (implicit) prior probability distribution,  $r(\mathbf{y}|\gamma)$ , on the  $n$ -dimensional data space  $\mathcal{Y}^n$ . This distribution  $r(\cdot)$ , called the marginal distribution of the data, characterizes the probability of observing any particular data set  $\mathbf{y}$  given our choice of prior beliefs reflected by  $\pi_{\boldsymbol{\theta}}(\cdot)$ , and plays an important role in conventional Bayesian

inference (see Section 1.25.3). The marginal distribution is

$$r(\mathbf{y}|\gamma) = \int_{\boldsymbol{\theta} \in \Theta_\gamma} p(\mathbf{y}|\boldsymbol{\theta}, \gamma) \pi_{\boldsymbol{\theta}}(\boldsymbol{\theta}|\gamma) d\boldsymbol{\theta}. \quad (25.56)$$

The receiver and the transmitter both have knowledge of the prior density  $\pi_{\boldsymbol{\theta}}(\boldsymbol{\theta}|\gamma)$  and the likelihood function  $p(\mathbf{y}|\boldsymbol{\theta}, \gamma)$ , and therefore the marginal distribution. Under the assumption that our prior beliefs accurately reflect the unknown process that generated the data  $\mathbf{y}$ , the average length of the shortest message that communicates the data  $\mathbf{y}$  to the receiver using the model  $\gamma$  is the entropy of  $r(\mathbf{y}|\gamma)$ . The marginal distribution is then used to construct a codebook for the data resulting in a decodable message with codelength

$$I_0(\mathbf{y}) = -\log r(\mathbf{y}|\gamma) = -\log \int_{\boldsymbol{\theta} \in \Theta_\gamma} p(\mathbf{y}|\boldsymbol{\theta}, \gamma) \pi_{\boldsymbol{\theta}}(\boldsymbol{\theta}|\gamma) d\boldsymbol{\theta}. \quad (25.57)$$

This is the most efficient encoding of the data using the model  $\gamma$  under the assumed likelihood function and prior density. While the marginal distribution is commonly used in Bayesian inference for model selection (as discussed in Section 1.25.3), the fact that the parameter vector  $\boldsymbol{\theta}$  is integrated out means that it may not be used to make inferences about the particular distribution in  $\Theta_\gamma$  that generated the data. That is, the message does not convey anything about the quality of any particular distribution in  $\Theta_\gamma$  in regards to encoding the observed data and cannot be used for point estimation. Following Wallace ([27], pp. 152–153), we shall refer to this code as the *non-explanation* code for the data.

In the MML framework, the message transmitting the observed data comprises two components, commonly named the *assertion* and the *detail*. The assertion is a codeword naming a particular distribution indexed by  $\boldsymbol{\theta} \in \Theta_\gamma$  from the model  $\gamma$ , rather than a range of possible distributions in  $\gamma$ . The detail is a codeword that states the data  $\mathbf{y}$  using the distribution  $\boldsymbol{\theta}$  that was named in the assertion. The total, joint codelength of the message is then

$$I(\mathbf{y}, \boldsymbol{\theta}, \gamma) = I(\boldsymbol{\theta}, \gamma) + I(\mathbf{y}|\boldsymbol{\theta}, \gamma), \quad (25.58)$$

where  $I(\boldsymbol{\theta}, \gamma)$  and  $I(\mathbf{y}|\boldsymbol{\theta}, \gamma)$  denote the length of the assertion and detail respectively. The length of the assertion measures the complexity of a particular distribution  $\boldsymbol{\theta}$  in model  $\gamma$ , while the detail length measures the quality of the fit of the distribution  $\boldsymbol{\theta}$  to the data  $\mathbf{y}$ . Thus, the total, joint codelength automatically captures the tradeoff between model complexity and model capacity. Intuitively, a complex model with many free parameters can be tuned to fit a large range of data sets, leading to a short detail length. However, since all parameters need to be transmitted to the receiver, the length of the assertion will be long. In contrast, a simple model with few free parameters requires a short assertion, but may not fit the data well, potentially resulting in a long detail. This highlights the first defining feature of the MML principle: *the measure of model complexity and model fit are both expressed in the same unit, namely the codelength*. The minimum message length principle advocates choosing the model  $\gamma$  and distribution  $\boldsymbol{\theta}$  that minimises this two-part message, that is,

$$\left\{ \hat{\boldsymbol{\theta}}(\mathbf{y}; \gamma), \hat{\gamma}_{\text{MML}}(\mathbf{y}) \right\} = \arg \min_{\gamma \in \Gamma, \boldsymbol{\theta} \in \Theta_\gamma} \{I(\mathbf{y}, \boldsymbol{\theta}, \gamma)\}.$$

This expression highlights the second defining feature of the MML principle: *minimization of the codelength is used to perform both selection of a model structure,  $\gamma \in \Gamma$ , as well as estimation of the*

model parameters,  $\theta \in \Theta$ . This is in contrast to both the distance based criteria of Section 1.25.2, and the Bayesian information criterion introduced in Section 1.25.3, which only select a structure  $\gamma$  and do not provide an explicit framework for parameter estimation. It remains to determine how one computes the codelength (25.58).

In general, while the set of candidate models  $\Gamma$  will usually be countable,<sup>1</sup> the parameter space  $\Theta_\gamma$  for a model  $\gamma$  is commonly continuous. The continuity of  $\Theta_\gamma$  creates a problem for the transmitter when designing a codebook for the members of  $\Theta_\gamma$  needed for the assertion, as valid codebooks can only be constructed from discrete distributions. This problem may be circumvented by quantizing the continuum  $\Theta_\gamma$  into a discrete, countable subset  $\bar{\Theta}_\gamma = \{\bar{\theta}_1, \bar{\theta}_2, \dots\} \subset \Theta_\gamma$ . Given a subset  $\bar{\Theta}_\gamma$  we can define a distribution over  $\bar{\Theta}_\gamma$ , say  $h(\cdot|\gamma)$ . This distribution implicitly defines a codelength for the members of  $\bar{\Theta}_\gamma$ . The assertion length for stating a particular  $\theta \in \bar{\Theta}_\gamma$  is then  $I(\theta, \gamma) = -\log h(\theta|\gamma)\pi_\gamma(\gamma)$ . The length of the detail, encoded using the distribution indexed by  $\theta \in \bar{\Theta}_\gamma$  is  $I(\mathbf{y}|\theta, \gamma) = -\log p(\mathbf{y}|\theta, \gamma)$ , which is the negative log-likelihood of the observed data  $\mathbf{y}$ . The question remains: how do we choose the quantisation  $\bar{\Theta}_\gamma$  and the distribution  $h(\cdot|\gamma)$ ? The minimum message length principle specifies that the quantisation  $\bar{\Theta}_\gamma$  and the distribution  $h(\cdot|\gamma)$  be chosen such that the *average* codelength of the resulting two-part message is minimum, the average being taken with respect to the marginal distribution. Formally, for a model  $\gamma$ , the MML two-part codebook solves the following minimization problem:

$$\min_{\bar{\Theta}, h} \left\{ \sum_{\mathbf{y} \in \mathcal{Y}^n} r(\mathbf{y}|\gamma) I(\mathbf{y}, \theta, \gamma) \right\}. \quad (25.59)$$

In the literature, this procedure is referred to as strict minimum message length (SMML) [62]. For computational reasons, the SMML procedure commonly described in the literature solves an equivalent minimization problem by partitioning the dataspace  $\mathcal{Y}^n$ , which implicitly defines the parameter space quantisation  $\bar{\Theta}_\gamma$  and the distribution  $h(\cdot|\gamma)$  (for a detailed exposition the reader is referred to Chapter 3 of [27]). Model selection and parameter estimation by SMML proceeds by choosing the model/parameter pair from  $\bar{\Theta}_\gamma$  and  $\Gamma$  that results in the shortest two-part message, given  $h(\cdot|\gamma)$ . Interestingly, this is equivalent to performing *maximum a posteriori* (MAP) estimation over the quantised parameter space  $\bar{\Theta}_\gamma$ , treating  $h(\cdot|\gamma)$  as a special ‘‘quantised prior’’ which is implicitly defined by both the quantisation  $\bar{\Theta}_\gamma \subset \Theta_\gamma$  and the original continuous prior distribution  $\pi_\theta(\cdot)$  over  $\Theta_\gamma$ .

Analysis of the SMML code shows that it is approximately  $(1/2)(\log(k\pi) - 1)$  nits longer than the non explanation code (25.57), where  $k$  is the dimensionality of  $\Theta_\gamma$  (pp. 237–238, [27]). This is not surprising given that the SMML code makes a statement about the particular distribution from  $\Theta_\gamma$  which was used to code the data, rather than using a mixture of distributions as in the non-explanation code. This apparent ‘‘inefficiency’’ in SMML allows the codelength measure to be used not only for model selection (as in the case of the non-explanation code), but also provides a theoretically sound basis for parameter estimation.

While the SMML procedure possesses many attractive theoretical properties (see for example, pp. 187–195 of [27] and the ‘‘false oracle’’ property discussed in [64]), the minimization problem (25.59) is in general NP-hard [65], and exact solutions are computationally tractable in only a few

---

<sup>1</sup>A set  $A$  is countable if its members can be put into a one-to-one correspondence with the natural numbers, that is,  $A \leftrightarrow \mathbb{N}$ .

simple cases. The difficulties arise primarily due to the fact that a complete quantisation of the continuous parameter space must be found, which is a non-trivial problem that does not scale well with increasing dimensionality of  $\mathcal{Y}^n$ . In the next section we shall examine an approximation to the two-part message length that exploits the fact that we are only interested in computing the *length* of the codes, rather than the codebooks. This allows us to circumvent the problematic issue of complete quantisation by using only local properties of the likelihood and prior distribution, resulting in an implementation of the MML principle that is applicable to many commonly used statistical models.

### 1.25.4.2 The Wallace-Freeman message length approximation (MML87)

To circumvent the problem of determining a complete quantisation of the parameter space, Wallace and Freeman [63] presented a formula that gives an approximate length of the two-message for a particular  $\boldsymbol{\theta} \in \Theta_\gamma$  and data set  $\mathbf{y}$ . Rather than finding an optimal quantisation for the entire parameter space  $\Theta_\gamma$ , the key idea underlying their approach is to find an optimal *local* quantisation for the particular  $\boldsymbol{\theta}$  named in the assertion. The important implication of this approach is that the quantisation, and therefore the resulting message length formula, depends only on the particular  $\boldsymbol{\theta}$  that is of interest. Under certain regularity conditions, the Wallace-Freeman approximation states that the joint codelength of a distribution  $\boldsymbol{\theta} \in \Theta_\gamma$  in model  $\gamma$ , and data  $\mathbf{y}$ , is

$$I_{87}(\mathbf{y}, \boldsymbol{\theta}, \gamma) = -\underbrace{\log \pi_{\boldsymbol{\theta}}(\boldsymbol{\theta}|\gamma) \pi_\gamma(\gamma)}_{I_{87}(\boldsymbol{\theta}, \gamma)} + \underbrace{\frac{1}{2} \log |\mathbf{J}_n(\boldsymbol{\theta}; \gamma)| + \frac{k}{2} \log \kappa_k + \frac{k}{2} - \log p(\mathbf{y}|\boldsymbol{\theta}, \gamma)}_{I_{87}(\mathbf{y}|\boldsymbol{\theta}, \gamma)}, \quad (25.60)$$

where  $k = \dim(\Theta_\gamma)$  is the total number of continuous, free parameters for model  $\gamma$  and  $\mathbf{J}(\cdot)$  is the Fisher information matrix for  $n$  data points given by

$$\mathbf{J}_n(\boldsymbol{\theta}_0; \gamma) = -\mathbf{E}_{\boldsymbol{\theta}_0} \left[ \frac{\partial^2 \log p(\mathbf{y}|\boldsymbol{\theta}, \gamma)}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'} \Big|_{\boldsymbol{\theta}=\boldsymbol{\theta}_0} \right]. \quad (25.61)$$

The quantity  $\kappa_k$  is the normalized second moment of an optimal quantising lattice in  $k$ -dimensions ([66]). Following ([27], p. 237), the need to determine  $\kappa_k$  for arbitrary dimension  $k$  is circumvented by use of the following approximation

$$\frac{k}{2} (\log \kappa_k + 1) \approx -\frac{k}{2} \log (2\pi) + \frac{1}{2} \log (k\pi) + \psi(1) = c(k),$$

where  $\psi(\cdot)$  is the digamma function, and  $\psi(1) \approx -0.5772$ . Model selection, and parameter estimation, is performed by choosing the model/parameter pair that minimises the joint codelength, that is,

$$\left\{ \hat{\gamma}_{87}(\mathbf{y}), \hat{\boldsymbol{\theta}}_{87}(\mathbf{y}; \hat{\gamma}_{87}(\mathbf{y})) \right\} = \arg \min_{\gamma \in \Gamma, \boldsymbol{\theta} \in \Theta_\gamma} \{ I_{87}(\mathbf{y}, \boldsymbol{\theta}, \gamma) \}. \quad (25.62)$$

Unlike the SMML codelength, the MML87 codelength (25.60) is a continuous function of the continuous model parameters  $\boldsymbol{\theta}$  which makes the minimization problem (25.62) considerably easier. Again, it is important to re-iterate that unlike the distance based criteria (AIC, KIC, etc.) and the BIC, minimization

of the MML87 formula yields both estimates of model structure as well as model parameters. Further, the MML87 parameter estimates possess attractive properties in comparison with estimates based on other principles such as maximum likelihood or maximum posterior mode.

An important issue remains: under what conditions is the MML87 formula valid? In brief, the MML87 codelength is generally valid if: (i) the maximum likelihood estimates associated with the likelihood function obey the central limit theorem everywhere in  $\Theta_\gamma$ , and (ii) the local curvature of the prior distribution  $\pi_\theta(\cdot)$  is negligible compared to the curvature of the negative log-likelihood everywhere in  $\Theta_\gamma$ . An important point to consider is how close the Wallace–Freeman approximate codelength is to the exact SMML codelength given by (25.59). If the regularity conditions under which the MML87 formula was derived are satisfied, then the MML87 codelength is, on average, practically indistinguishable from the exact SMML codelength (pp. 230–231, [27]).

In the particular case that the prior  $\pi_\theta(\theta|\alpha, \gamma)$  is *conjugate*<sup>2</sup> with the likelihood  $p(\mathbf{y}|\theta, \gamma)$ , and depends on some parameters  $\alpha$  (usually referred to as “hyperparameters”), Wallace (pp. 236–237, [27]) suggested a clever modification of the MML87 formula that makes it valid even if the curvature of the prior is significantly greater than the curvature of the likelihood. The idea is to first propose some imaginary “prior data”  $\mathbf{y}_\alpha$  whose properties depend only on the prior hyperparameters  $\alpha$ . It is then possible to view the prior  $\pi_\theta(\theta|\alpha, \gamma)$  as a *posterior* of the likelihood of this prior data  $\mathbf{y}_\alpha$  and some initial uninformative prior  $\pi_0(\theta)$  that does not depend on the hyperparameters  $\alpha$ . Formally, we seek the decomposition

$$\pi_\theta(\theta|\alpha, \gamma) \propto \pi_0(\theta)p(\mathbf{y}_\alpha|\theta, \gamma), \quad (25.63)$$

where  $p(\mathbf{y}_\alpha|\theta, \gamma)$  is the likelihood of  $m$  imaginary prior samples and  $\pi_0(\theta)$  is an uninformative prior. The new Fisher Information  $\mathbf{J}_{n+m}(\theta; \gamma)$  is then constructed from the new combined likelihood  $p(\mathbf{y}, \mathbf{y}_\alpha|\theta, \gamma) = p(\mathbf{y}|\theta)p(\mathbf{y}_\alpha|\theta, \gamma)$ , and the “curved prior” MML87 approximation is simply

$$I_{87}^*(\mathbf{y}, \theta, \gamma) = -\log \pi_\theta(\theta|\alpha, \gamma)\pi_\gamma(\gamma) + \frac{1}{2} \log |\mathbf{J}_{n+m}(\theta; \gamma)| - \log p(\mathbf{y}|\theta, \gamma) + c(k), \quad (25.64)$$

$$= -\log \pi_0(\theta)\pi_\gamma(\gamma) + \frac{1}{2} \log |\mathbf{J}_{n+m}(\theta; \gamma)| - \log p(\mathbf{y}, \mathbf{y}_\alpha|\theta, \gamma) + c(k). \quad (25.65)$$

This new Fisher information matrix has the interesting interpretation of being the asymptotic lower bound of the inverse of the variance of the maximum likelihood estimator using the combined data  $(\mathbf{y}, \mathbf{y}_\alpha)$  rather than for simply the observed data  $\mathbf{y}$ . It is even possible in this case to treat the hyperparameters as unknown, and use an extended message length formula to estimate both the model parameters  $\theta$  and the prior hyperparameters  $\alpha$  in this hierarchical structure [67, 68].

What is the advantage of using the MML87 estimates over the traditional maximum likelihood and MAP estimates? In addition to possessing important invariance and consistency properties that are discussed in the next sections, there is a large body of empirical evidence demonstrating the excellent performance of the MML87 estimator in comparison to traditional estimators such as maximum likelihood and the *maximum a posteriori* (MAP) estimator, particularly for small to moderate sample sizes. Examples include the normal distribution [27], factor analysis [69], estimation of multiple means [67], the von Mises and spherical von Mises-Fisher distribution [70, 71] (pp. 266–269, [27])

---

<sup>2</sup>The use of a conjugate prior ensures that the posterior distribution of the parameters is of the same mathematical form as the conjugate prior distribution.

and autoregressive moving average models [72]. In the next sections we will discuss some important properties of the Wallace-Freeman approximation. For a detailed treatment of the MML87 approximation, we refer the interested reader to Chapter 5 of [27].

#### 1.25.4.2.1 Model selection consistency

Recall from Section 1.25.3.2 that the BIC procedure yields a consistent estimate of the true, underlying model, say  $\gamma^* \in \Gamma$ , that generated the data. The estimate  $\hat{\gamma}_{87}$  is also a consistent estimate of  $\gamma^*$  as  $n \rightarrow \infty$  under certain conditions. Assuming that the Fisher information matrix satisfies

$$\mathbf{J}_1(\boldsymbol{\theta}; \gamma) = \lim_{n \rightarrow \infty} \left\{ \frac{\mathbf{J}_n(\boldsymbol{\theta}; \gamma)}{n} \right\}, \quad (25.66)$$

with  $|\mathbf{J}_1(\cdot)| > 0$ , the MML87 codelength approximation can be rewritten as

$$I_{87}(\mathbf{y}, \boldsymbol{\theta}, \gamma) = -\log p(\mathbf{y}|\boldsymbol{\theta}, \gamma) + \frac{k}{2} \log n + O(1). \quad (25.67)$$

This is clearly equivalent to the well known BIC discussed in Section 1.25.3.1, and thus the estimator  $\hat{\gamma}_{87}$  is consistent as  $n \rightarrow \infty$ . For a more rigorous and general proof, the reader is directed to [73].

#### 1.25.4.2.2 Invariance

There is in general no unique way to parameterise the distributions that comprise a statistical model. For example, the normal distribution is generally expressed in terms of mean and variance parameters, say  $(\mu, \tau)$ . However, the alternate parameterisations  $(\mu, \sqrt{\tau})$  and  $(e^{-\mu}, \tau)$  are equally valid and there is no reason, beyond ease of interpretation, to prefer any particular parameterisation. A sensible estimation procedure should be invariant to the parameterisation of the model; that is, it should give the same answer irrespective of how the inference question is framed. While the commonly used maximum likelihood estimator possesses the invariance property, both the *maximum a posteriori* estimator and posterior mean estimator based on the Bayesian posterior distribution  $p(\boldsymbol{\theta}|\mathbf{y}, \gamma)$  given by (25.28) are *not invariant*. The SMML and MML87 are *invariant* under one-to-one reparameterisations, and thus provide an important alternative Bayesian estimation procedure.

#### 1.25.4.2.3 Parameter estimation consistency

Consider the case that the data  $\mathbf{y}$  is generated by a particular distribution  $\boldsymbol{\theta}^*$  from the model  $\gamma$ , that is,  $\boldsymbol{\theta}^* \in \Theta_\gamma$ . A sequence of estimators,  $\hat{\boldsymbol{\theta}}_n$ , of parameter  $\boldsymbol{\theta}$  is consistent if and only if

$$\Pr \left\{ |\hat{\boldsymbol{\theta}}_n - \boldsymbol{\theta}^*| \geq \varepsilon \right\} \rightarrow 0$$

for any  $\varepsilon > 0$  as  $n \rightarrow \infty$ . In words, this means that as we accumulate more and more data about the parameters the estimator converges to the true parameter value  $\boldsymbol{\theta}^*$ . If we consider the case that the dimensionality of  $\Theta_\gamma$  does not depend on  $n$ , and the Fisher information matrix satisfies (25.36) then the maximum likelihood estimator is consistent under suitable regularity conditions [74]. The consistency of the MML87 estimator in this particular case follows by noting that minimising the asymptotic message length (25.67) is equivalent to maximizing the likelihood; similar arguments can also be used to establish the consistency of the MAP and mean posterior estimators in this case.

The situation is strikingly different in the case that the dimensionality of the parameter space depends on the sample size. In this setting there is usually a small number of parameters of interest for which information grows with increasing sample size, and a large number of auxiliary “nuisance” parameters for which an increasing sample size brings no new information. Maximum likelihood estimation, as well as the MAP and mean posterior estimation, of the parameters of interest is in general inconsistent. In contrast, the MML87 estimator has been shown to provide consistent estimates in the presence of many nuisance parameters in several important statistical models, including the Neyman-Scott problem [75], factor analysis [69, 76] (also pp. 297–303 in [27]), multiple cutpoint estimation [77] and mixture modeling ([78] and pp. 275–297 in [27]). While a general proof of the consistency of the MML principle in the presence of nuisance parameters does not currently exist, *there have been no problems studied so far in which it has failed to yield consistent estimates*.

#### 1.25.4.2.4 Similarities with Bayesian inference

There are many similarities between the minimum message length principle and the more conventional Bayesian approaches such as those discussed in Section 1.25.3 (see [79] for a detailed discussion). The differences in codelengths (MML87 or otherwise) between two models may be used to compute an approximate Bayes factor, that is,

$$-\log \text{BF}(\gamma_1, \gamma_0) \approx I(\mathbf{y}, \boldsymbol{\theta}, \gamma_0) - I(\mathbf{y}, \boldsymbol{\theta}, \gamma_1).$$

The usual interpretations applied to regular Bayes factors apply equally well to the approximate Bayes factors determined by codelength differences. Further, the codelength measure may be used to perform model averaging over the set of candidate models  $\Gamma$  in a similar fashion to BIC, as discussed in Section 1.25.3.1. In this case, we use (25.41), replacing the BIC score with the codelength, and (ideally) replacing the maximum likelihood estimate with the appropriate minimum message length estimate.

#### 1.25.4.3 Other message length approximations

Recently, Schmidt [72, 80] introduced a new codelength approximation that can be used for models for which the application of the Wallace-Freeman approximation is problematic. The new approximation, called MML08, is more computationally tractable than the strict MML procedure, but requires evaluation of sometimes difficult integrals. The joint MML08 codelength of data  $\mathbf{y}$  and parameters  $\boldsymbol{\theta}$ , for model  $\gamma$ , is given by

$$\begin{aligned} I_{08}(\boldsymbol{\theta}, \mathbf{y}, \gamma) &= \underbrace{-\log \pi_\gamma(\gamma) \int_{\Omega_\theta} \pi_\theta(\boldsymbol{\phi}|\gamma) d\boldsymbol{\phi}}_{I_{08}(\boldsymbol{\theta}, \gamma)} \\ &\quad - \underbrace{\log p(\mathbf{y}|\boldsymbol{\theta}, \gamma) + \left( \frac{1}{\int_{\Omega_\theta} \pi(\boldsymbol{\phi}|\gamma) d\boldsymbol{\phi}} \right) \int_{\Omega_\theta} \pi_\theta(\boldsymbol{\phi}|\gamma) \Delta(\boldsymbol{\theta}||\boldsymbol{\phi}) d\boldsymbol{\phi}}_{I_{08}(\mathbf{y}|\boldsymbol{\theta}, \gamma)}, \end{aligned} \quad (25.68)$$

where  $\Delta(\cdot)$  is the Kullback-Leibler divergence and  $\Omega_\theta \subset \Theta_\gamma$  is chosen to minimise the codelength. The MML08 is a generalization of the previously proposed MMLD codelength approximation [81, 82]

and is invariant under transformations of the parameters. The MML08 approximation has been applied to the problem of order selection for autoregressive moving average models [72]. Efficient algorithms to compute approximate MMLD and MML08 codelengths are given in [72, 83, 84].

#### 1.25.4.4 Example: MML linear regression

We continue our running example by applying the minimum message length principle to the selection of covariates in the linear regression model. By choosing different prior distributions for the coefficients  $\beta$  we can arrive at many different MML criteria (for example, [85, 86] and pp. 270–272, [27]); however, provided the chosen prior distribution is not unreasonable all codelength criteria will perform approximately equivalently, particularly for large sample sizes. Two recent examples of MML linear regression criteria, called “MML<sub>u</sub>” and “MML<sub>g</sub>,” that do not require the specification of any subjective prior information are given in [68]. The MML<sub>u</sub> criterion exploits some properties of the linear model with Gaussian noise to derive a data driven, proper uniform prior for the regression coefficients. Recall that in the linear regression case, the model index  $\gamma$  specifies the covariates to be used from the full design matrix  $\mathbf{X}$ . For a given  $\gamma$ , the MML<sub>u</sub> codelength for a linear regression model is

$$\begin{aligned} & \left(\frac{n-k}{2}\right) \log 2\pi + \left(\frac{n-k}{2}\right) (\log \hat{\tau}_{87}(\mathbf{y}; \gamma) + 1) + \frac{k}{2} \log (\pi_\gamma' \mathbf{y}) \\ & - \log \Gamma\left(\frac{k}{2} + 1\right) + \frac{1}{2} \log (k+1) - \log \pi_\gamma(\gamma), \end{aligned} \quad (25.69)$$

where the MML<sub>u</sub> parameter estimates are given by

$$\hat{\tau}_{87}(\mathbf{y}; \gamma) = \left(\frac{1}{n-k}\right) (\mathbf{y}' \mathbf{y} - R(\gamma)), \quad (25.70)$$

$$\hat{\beta}_{87}(\mathbf{y}; \gamma) = \left(\mathbf{X}_\gamma' \mathbf{X}_\gamma\right)^{-1} \mathbf{X}_\gamma' \mathbf{y}. \quad (25.71)$$

Here,  $k = |\gamma|$  denotes the number of covariates in the regression model  $\gamma$ ,  $\pi_\gamma(\gamma)$  is a suitable prior for the model index (see Section 1.25.3.4 for a discussion of suitable priors), and

$$R(\gamma) = \hat{\beta}(\mathbf{y}; \gamma)' (\mathbf{X}_\gamma' \mathbf{X}_\gamma) \hat{\beta}(\mathbf{y}; \gamma) \quad (25.72)$$

is the fitted sum-of-squares for the least-squares estimates (25.5). Due to the use of a uniform prior on the regression coefficients, and the nature of the Fisher information matrix, the MML87 estimates of the regression coefficients coincide with the usual maximum likelihood estimates (25.5). In contrast to the maximum likelihood estimate of  $\tau$ , given by (25.6), the MML87 estimate is exactly unbiased even for finite sample sizes  $n$ .

The MML<sub>g</sub> criterion further demonstrates the differences in parameter estimation that are possible by using the MML principle. This criterion is based on a special hierarchical Gaussian prior, and uses some recent extensions to the MML87 codelength to estimate the parameters of the prior distribution in addition to the regression coefficients [67]. For a given  $\gamma$ , the MML<sub>g</sub> codelength for a linear regression model is

$$\left(\frac{n-k+2}{2}\right) (\log \hat{\tau}_{87}(\mathbf{y}; \gamma) + 1) + \left(\frac{k-2}{2}\right) \log \left(\frac{R(\gamma)}{\delta}\right) + \frac{\delta}{2} + \frac{1}{2} \log (n-k) k^2 - \log \pi_\gamma(\gamma), \quad (25.73)$$

where  $\delta = \max(1, k - 2)$ . This formula is applicable only when  $k > 0$ , and  $m(\gamma) > 0$ , where

$$m(\gamma) = \left( \frac{R(\gamma)}{\delta} - \hat{\tau}_{87}(\mathbf{y}; \gamma) \right)_+,$$

and  $(\cdot)_+ = \max(0, \cdot)$  is the positive-part function. The codelength for a “null” model ( $k = 0$ ) is given by

$$\binom{n}{2} (\log \hat{\tau}_{87}(\mathbf{y}; \gamma) + 1) + \frac{1}{2} \log(n-1) + \frac{1}{2}. \quad (25.74)$$

We note that (25.73) corrects a minor mistake in the simplified form of  $\text{MML}_g$  in [68], which erroneously excluded the additional “ $\delta/2$ ” term. The  $\text{MML}_g$  estimates of  $\beta$  and  $\tau$  are given by

$$\hat{\tau}_{87}(\mathbf{y}; \gamma) = \left( \frac{1}{n-k+2} \right) (\mathbf{y}'\mathbf{y} - R(\gamma)), \quad (25.75)$$

$$\hat{\beta}_{87}(\mathbf{y}; \gamma) = \left( \frac{m(\gamma)}{m(\gamma) + \hat{\tau}_{87}(\mathbf{y}; \gamma)} \right) (\mathbf{X}'_{\gamma} \mathbf{X}_{\gamma})^{-1} \mathbf{X}'_{\gamma} \mathbf{y}, \quad (25.76)$$

which are closely related to the unbiased estimate (25.70) of  $\tau$  used by the  $\text{MML}_u$  criterion. The  $\text{MML}_g$  estimates of the regression coefficients  $\beta$  are the least-squares estimates scaled by a quantity less than unity which is called a *shrinkage* factor [87]. This factor depends crucially on the estimated strength of the noise variance and signal strength, and if the noise variance is too large,  $m(\gamma) = 0$  and the coefficients are completely shrunk to zero (that is, none of the covariates are deemed associated with the observations). Further, it turns out that the  $\text{MML}_g$  shrinkage factor is optimal in the sense that for  $k \geq 3$ , the shrunken estimates of  $\beta$  will, on average, be better at predicting future data arising from the same source than the corresponding least squares estimates [88].

#### 1.25.4.5 Applications of MML

The MML principle has been applied to a large number statistical models. Below is an inexhaustive list of some of the many successful applications of MML; a more complete list may be found in [82].

- Mixture modeling [33, 78, 89].
- Decision trees/graphs [90–92].
- Casual Networks [93, 94].
- Artificial neural networks [95, 96].
- Linear Regression [68, 85, 86, 97].
- Autoregressive moving average (ARMA) models [72, 98, 99].
- Discrete time series [77, 100].
- Hierarchical Bayesian Models [67, 68].

Detailed derivations of the message length formulas for many of these models, along with discussions of their behavior, can also be found in Chapters 6 and 7 of [27].

#### 1.25.4.6 The minimum description length (MDL) principle

The minimum description length (MDL) principle [101, 102] was independently developed by Jorma Rissanen from the late 1970s [32, 103, 104], and embodies the same idea of statistical inference via data

compression as the MML principle. While there are many subtle, and not so subtle, differences between MML and MDL, the most important is the way in which they view prior distributions (for a comparison of early MDL and MML, see [105]). The MDL principle views prior distributions purely as devices with which to construct codelengths, and the bulk of the MDL research has been focused on finding ways in which the specification of subjective prior distributions may be avoided. In the MML principle, the codebook is constructed to minimise the average codelength of data drawn from the marginal distribution, which captures our prior beliefs about the data generating source. The MDL principle circumvents the requirement to explicitly specify prior beliefs, and instead appeals to the concept of minimising the worst-case behavior of the codebook. Formally, we require the notion of coding *regret*

$$R(\mathbf{y}) = I(\mathbf{y}, \gamma) + \log p(\mathbf{y}|\hat{\theta}(\mathbf{y}; \gamma), \gamma), \quad (25.77)$$

where  $I(\mathbf{y}, \gamma)$  is the codelength of the data  $\mathbf{y}$  using model  $\gamma$ , and  $\hat{\theta}(\mathbf{y}; \gamma) \in \Theta_\gamma$  is the maximum likelihood estimator. As the maximum likelihood estimator minimises the codelength of the data (without stating anything about the model), the negative log-likelihood evaluated at the maximum represents an ideal target codelength for the data. Unfortunately, this is only realizable if the sender and receiver have *a priori* knowledge of the maximum likelihood estimator, which in an inferential setting is clearly nonsensical.

Clearly, one would like to keep the regret as small as possible in some sense, to ensure that the chosen codebook is efficient. The MML approach minimises average excess codelength over the marginal distribution, which requires an explicit prior distribution. To avoid this requirement, Rissanen advocates choosing a codebook that minimises the maximum (worst-case) coding regret (25.77), that is finding the probability distribution  $f$  that solves the following problem:

$$\min_f \left\{ \max_{\mathbf{y} \in \mathcal{Y}^n} \left\{ -\log f(\mathbf{y}) + \log p(\mathbf{y}|\hat{\theta}(\mathbf{y}; \gamma), \gamma) \right\} \right\}. \quad (25.78)$$

The solution to this optimization problem is known as the normalized maximum likelihood (NML) [106, 107] (or Shtarkov [108]) distribution, and the resulting codelength is given by

$$I_{\text{NML}}(\mathbf{y}, \gamma) = -\log p(\mathbf{y}|\hat{\theta}(\mathbf{y}; \gamma), \gamma) + \log \int_{\mathbf{x} \in \mathcal{X}^n} p(\mathbf{x}|\hat{\theta}(\mathbf{x}; \gamma), \gamma) d\mathbf{x}. \quad (25.79)$$

In MDL parlance, the second term on the right hand side of (25.79) is called the *parametric complexity* of the model  $\gamma$ . The parametric complexity has several interesting interpretations: (i) it is the logarithm of the normalizing constant required to render the infeasible maximum likelihood codes realizable; (ii) it is the (constant) regret obtained by the normalized maximum likelihood codes with respect to the unattainable maximum likelihood codes, and (iii) it is the logarithm of the number of distinguishable distributions contained in the model  $\gamma$  at sample size  $n$  [109]. In addition to the explicit lack of prior distributions, the NML code (25.79) differs from the MML two-part codes in the sense that it does not explicitly depend on any particular distribution in the model  $\gamma$ . This means that like the marginal distribution discussed in Section 1.25.4.1, the NML codes cannot be used for point estimation of the model parameters  $\theta_\gamma$ .

Practically, the normalizing integral in (25.79) is difficult to compute for many models. Rissanen has derived an asymptotic approximation to the NML distribution which is applicable to many commonly used statistical models (including for example, linear models with Gaussian noise and autoregressive

moving average models) [106]. Under this approximation, the codelength formula is given by

$$I_{\text{ANML}}(\mathbf{y}, \gamma) = -\log p(\mathbf{y}|\hat{\theta}(\mathbf{y}; \gamma), \gamma) + \frac{k}{2} \log \left( \frac{n}{2\pi} \right) + \log \int_{\theta \in \Theta_\gamma} \sqrt{|\mathbf{J}_1(\theta; \gamma)|} d\theta, \quad (25.80)$$

where  $k$  is the number of free parameters for the model  $\gamma$ ,  $n$  is the sample size and  $\mathbf{J}_1(\cdot)$  is the per sample Fisher information matrix given by (25.36). The approximation (25.80) swaps an integral over the dataspace for an often simpler integral over the parameter space. For models that satisfy the regularity conditions discussed in [106], the approximate NML codelength satisfies

$$I_{\text{NML}}(\mathbf{y}, \gamma) = I_{\text{ANML}}(\mathbf{y}, \gamma) + o(1),$$

where  $o(1)$  denotes a term that disappears as  $n \rightarrow \infty$ .

The NML distribution is only one of the coding methods considered by Rissanen and co-workers in the MDL principle; the interested reader is referred to Grünwald's book [61] for a detailed discussion of the full spectrum of coding schemes developed within the context of MDL inference.

#### 1.25.4.7 Problems with divergent parametric complexity

The NML distribution offers a formula for computing codelengths that is free of the requirement to specify suitable prior distributions, and therefore appears to offer a universal approach to model selection by compression. Unfortunately, the formula (25.79) is not always applicable as the parametric complexity can diverge, even in commonly used models [110]; this also holds for the approximate parametric complexity in (25.80). To circumvent this problem, Rissanen [106] recommends bounding either the dataspace, for (25.79), or the parameter space, for (25.80), so that the parametric complexity is finite. In the case of linear regression models with Gaussian noise, Rissanen extends this idea even further by treating the hyperparameters that specify the bounding region as parameters, and re-applying the NML formula to arrive at a parameter-free criterion (see [111] for details). Other models with infinite parametric complexity which have been addressed in a similar manner include the Poisson and geometric distributions [110] and stationary autoregressive models [112].

Unfortunately, the choice of bounding region is in general arbitrary, and different choices will lead to different codelength formulae, and hence different behavior. In this sense, the choice of bounding region is akin to the selection of a prior distribution in MML; however, advocates of the Bayesian approach argue that selection of a prior density is significantly more transparent, and interpretable, than the choice of a bounding region.

#### 1.25.4.8 Sequential variants of MDL

One way to overcome the problems of infinite parametric complexity is to code the data sequentially. In this framework, one uses the first  $t$  datapoints,  $(y_1, \dots, y_t)$ , to construct a predictive model that is used to code  $y_{t+1}$ . This process may be repeated until the entire dataset  $(y_1, \dots, y_n)$  has been “transmitted”, and the resulting codelength may be used for model selection. This idea was first proposed as part of the predictive MDL procedure [101, 113].

More recently, the idea has been refined with the introduction of the sequentially normalized maximum likelihood (SNML) model [114], and the related conditional normalized maximum likelihood (CNML) model [115]. These exploit the fact that the parametric complexity, *conditional* on some observed data, is often finite, even if the unconditional parametric complexity diverges. Additionally,

the CNML distributions can be used to make predictions about future data arising from the same source in a similar manner to the Bayesian predictive distribution. A recent paper comparing SNML and CNML against Bayesian and MML approaches in the particular case of exponential distributions found that the SNML predictive distribution has favorable properties in comparison to the predictive distribution formed by “plugging in” the maximum likelihood estimates [116]. Further information on variants of the MDL principle is available in [61, 102].

#### 1.25.4.9 Relation to MML and Bayesian inference

It is of interest to compare the NML coding scheme to the codebooks advocated by the MML principle. This is most easily done by comparing the approximate NML codelength (25.80) to the Wallace-Freeman approximate codelength (25.60). Consider the so-called Jeffreys prior distribution:

$$\pi_{\theta}(\theta; \gamma) = \frac{\sqrt{|\mathbf{J}_n(\theta; \gamma)|}}{\int_{\alpha \in \Theta_{\gamma}} \sqrt{|\mathbf{J}_n(\alpha; \gamma)|} d\alpha}. \quad (25.81)$$

The normalizing term in the above equation is the approximate parametric complexity in (25.80). Substituting (25.81) into the Wallace-Freeman code (25.60) leads to the cancellation of the Fisher information term, and the resulting Wallace-Freeman codelength is within  $O(\log k)$  of the approximate NML codelength. This difference in codelengths is attributed to the fact that MML codes state a specific member of the set  $\Theta_{\gamma}$  which is used to transmit the data, while the NML distribution makes no such assertion. The close similarity between the MDL and MML codelengths was demonstrated in [116] in the context of coding data arising from exponential distributions. A further comparison of MDL, the NML distribution and MML can be found in [27], pp. 408–415.

The close equivalence of the approximate NML and Wallace-Freeman codes implies that like the BIC, the approximate NML criterion is a consistent estimator of the true model  $\gamma^*$  that generated the data, assuming  $\gamma^* \in \Gamma$ , and that the normalizing integral is finite. In fact, the earliest incarnation of MDL introduced in 1978 [32] was exactly equivalent to the Bayesian information criterion, which was also introduced in 1978. This fact has caused some confusion in the engineering community, where the terms MDL and BIC are often used interchangeably to mean the “ $k$ -on-two  $\log n$ ” criterion given by (25.37) (this issue and its implications are discussed, for example, in [117]).

We conclude this section with a brief discussion of the differences and similarities between the MML and MDL principles. This is done to attempt to clear up some of the confusion and misunderstandings surrounding these two principles. The MDL principle encompasses a range of compression schemes (such as the NML model, the Bayesian model, etc.), which are unified by the deeper concept of *universal models* for data compression. In recent times, the MDL community has focused on those universal models that attain minimax regret with respect to the maximum likelihood codes to avoid the specification of subjective prior distributions. The two-part codebooks used in the MML principle are also types of universal models, and so advocates of the MDL school often suggest that MML is subsumed in the MDL principle. However, as the above coincidence of Wallace-Freeman and NML demonstrates, the MDL universal models can be implemented in the MML framework by the appropriate choice of prior distribution, and thus the MML school tend to suggest that MDL is essentially a special case of the MML theory, particularly given the time-line of developments in the two camps.

Practically, the most important difference between the two principles is in the choice of two-part (for MML) versus one-part (for MDL) coding schemes. The two-part codes chosen by MML allow for

the explicit definition of new classes of parameter estimators, in addition to model selection criteria, which are not obtainable by the one-part MDL codes. As empirical, and theoretical evidence strongly supports the general improvement of the MML estimators over the maximum likelihood and Bayesian MAP estimators, this difference seems to be of perhaps the greatest importance.

#### 1.25.4.10 Example: MDL linear regression

An MDL criterion for the linear regression example is now examined. Given the importance of linear regression, there have been a range of MDL inspired criteria developed, for example, the predictive MDL criterion [101],  $g$ -MDL [118], Liang and Barron's approach [119], sequentially normalized least squares [120, 121] and normalized maximum likelihood based methods [40, 111, 122]. We choose to focus on the NML criterion introduced by Rissanen in 2000 [111] as it involves no user specified hyperparameters and does not depend on the ordering of the data, a problem which affects the predictive and sequential procedures. Recall that in the linear regression case, the model index  $\gamma$  specifies which covariates are to be used from the full design matrix  $\mathbf{X}$ . For a given  $\gamma$ , the NML codelength, up to constants, is

$$\left(\frac{n-k}{2}\right) \log \hat{\tau}(\mathbf{y}; \gamma) + \frac{k}{2} \log \left(\frac{\hat{R}(\gamma)}{n}\right) - \log \Gamma\left(\frac{n-k}{2}\right) - \log \Gamma\left(\frac{k}{2}\right) - \log \pi_\gamma(\gamma), \quad (25.82)$$

where  $\hat{\tau}(\mathbf{y}; \gamma)$  is the maximum likelihood estimate of  $\tau$  given by (25.6),

$$\hat{R}(\gamma) = \hat{\beta}(\mathbf{y}; \gamma)' (\mathbf{X}'_\gamma \mathbf{X}_\gamma) \hat{\beta}(\mathbf{y}; \gamma) \quad (25.83)$$

and  $\hat{\beta}(\mathbf{y}; \gamma)$  are the least-squares estimates of the model coefficients  $\beta$  for subset  $\gamma$  given by (25.5). As in the case of the BIC given by (25.43), and the MML linear regression criteria given by (25.69) and (25.73, 25.74), the codelength includes a prior  $\pi_\gamma(\cdot)$  required to state the subset  $\gamma$ , and suitable choices are discussed in Section 1.25.3.4.

Interestingly, Hansen and Yu [123] have shown that NML is either asymptotically consistent or asymptotically efficient depending on the nature of the data generating distribution. In this way, the NML criterion can be viewed as a “bridge” between the AIC-based criteria and the BIC. Given the close similarity between the NML and MML linear regression criteria [68], this property is expected to also hold for the MML linear regression criteria.

#### 1.25.4.11 Applications of MDL

Below is an incomplete list of successful applications of the MDL principle to commonly used statistical models:

- the multinomial distribution [124],
- causal models and Naïve Bayes classification [125, 126],
- variable bin-width histograms [127, 128],
- linear regression [111, 118, 122],
- signal denoising [40, 111],
- autoregressive models [112],
- statistical genetics [129, 130].

Of particular interest is the multinomial distribution as it is one of the few models for which the exact parametric complexity is finite without any requirement for bounding, and may be efficiently computed in polynomial time using the clever algorithm discussed in [124]. This algorithm has subsequently been used to compute codelengths in histogram estimation and other similar models.

## 1.25.5 Simulation

We conclude with a brief simulation demonstrating the practical application of the distance based, Bayesian and information theoretic model selection criteria discussed in this chapter. The simulation compares the  $AIC_c$  (25.25),  $KIC_c$  (25.27),  $BIC$  (25.42),  $MML_u$  (25.69),  $MML_g$  (25.73, 25.74) and  $NML$  (25.82) criteria on the problem of polynomial order selection with linear regression. Datasets of various sample sizes  $25 \leq n \leq 500$  were generated from the polynomial model

$$y^* = x^3 - 0.5x^2 - 5x - 1.5, \quad x \in [-3, 3] \quad (25.84)$$

with design points  $x$  uniformly generated from the compact set  $x \in [-3, 3]$  [13, 102]. The noise variance  $\tau$  was chosen to yield a signal-to-noise ratio of ten. Recalling the linear regression example from Section 1.25.1.2, the complete design matrix consisted of polynomial bases  $x^i$  for  $(i = 0, \dots, q)$ ,

$$\mathbf{X} = (\mathbf{x}^0, \mathbf{x}^1, \dots, \mathbf{x}^q). \quad (25.85)$$

For each generated data set, each of the six criteria were used to select a nested polynomial model up to the maximum polynomial of order  $q = 20$ . The simulation was repeated  $10^4$  times and the zero-order polynomial model was not considered. The criteria were compared on two important metrics: (i) order selection, and (ii) squared prediction error. The results are presented in Table 25.1.

The simulation is highly illustrative of the general behaviors of the model selection criteria under consideration. For small sample sizes ( $n \leq 50$ ), the  $KIC_c$  criterion performs adequately in terms of order selection, but like the  $AIC_c$ , this performance does not improve with increasing sample size. This is not surprising given that both  $AIC_c$  and  $KIC_c$  are not consistent model selection procedures. While  $BIC$  performs relatively poorly for the smallest sample sizes, its performance dramatically improves when the sample size is larger. The asymptotic approximation from which  $BIC$  is derived is inadequate for small sample sizes which explains its poor performance. In contrast, the  $MML$  and  $NML$  criteria perform well for all sample sizes in terms of both order selection and prediction error. In this particular example, the  $MML_u$  and  $NML$  criteria are virtually indistinguishable, while the  $MML_g$  criterion performs slightly better. For larger sample sizes ( $n \geq 125$ ) all four consistent criteria performed essentially the same.

This brief simulation serves to demonstrate the general behavior of the six criteria and should not be taken as indicative of their performance in other model selection problems. For a more detailed comparison of some recent regression methods, including  $MML_u$ ,  $MML_g$  and  $NML$ , see [122]. The  $MML_u$ ,  $MML_g$  and  $NML$  criteria were found to be amongst the best of the eight criteria considered in all experiments conducted by the authors.<sup>3</sup>

---

<sup>3</sup>Unfortunately, through no fault of the authors, the formulae for  $MML_g$  given in [122] is missing the  $\delta/2$  term that is present in formula (25.73) in this tutorial. However, this has not effected the experimental results as the simulation code uses the correct formula (see Section 1.25.4.4).

**Table 25.1** Polynomial Order Selected by the Criteria (Expressed as Percentages) and Squared Error in Estimated Coefficients

	Criterion	Sample size						
		25	50	75	100	125	150	500
$\hat{p} = p$	AIC <sub>c</sub>	86.2	79.5	76.9	76.0	74.7	74.5	74.0

# Music Mining

# 26

George Tzanetakis

*Department of Computer Science, University of Victoria, Victoria, Canada*

## 1.26.1 Introduction

During the first ten years of the 21st century we have witnessed a dramatic shift in how music is produced, distributed, and consumed. Several factors including advances in digital signal processing, faster computers, and steadily increasing digital storage capacity and network bandwidth have made digital music distribution a reality. It is now possible to purchase and listen to music as well as find all sorts of associated information about it from any computer or smart phone. Currently, portable music players and phones can store thousands of music tracks, and millions of tracks are accessible through streaming over the Internet in digital music stores and personalized radio stations.

Enabling anyone with access to a computer and the Internet to listen to essentially most of recorded music in human history is a remarkable technological achievement that would probably be considered impossible even twenty years ago. The research area of Music Information Retrieval (MIR) gradually emerged during this time period in order to address the challenge of effectively accessing and interacting with these vast digital collections of music and associated information such as meta-data, reviews, blogs, rankings, and usage/download patterns.

As a research area, data mining emerged from the interaction between the database community that needed to address the challenge of extracting useful not explicitly represented information from large collections of data, and the machine learning community which explored algorithms that can improve their performance over time as they are exposed to more data. Music mining refers to the application of ideas from the field of data mining to the extraction of useful information from large collections of music and is the topic of this chapter. It can be viewed as a subset of music information retrieval research.

Music is pervasive and plays an important role in the daily lives of most people today. It is an extremely complex human creation that somehow strongly affects our intellect and emotions. In order to create effective tools for interacting with large music collections we need to design algorithms that can extract high-level information from music signals and use that information in a variety of mining tasks. Techniques from audio signal processing have been used to extract various low-level and mid-level audio features that can subsequently be used to represent music tracks to perform various music mining tasks. In addition it is possible to apply traditional data mining techniques to other sources of music related information such as reviews, lyrics, blogs, rankings and usage patterns.

Music has several important characteristics and challenges that make it a particularly interesting research area for data mining. Similarly to image search it requires sophisticated content analysis

algorithms to extract useful information from the raw signal. At the same time it has very rich structured context information associated with it. For example a particular song especially if it is popular might be mentioned in thousands of web pages and blogs. It also has lyrics which can be analyzed and by virtue of being performed by a particular artist has many associations to other pieces of music. This rich tapestry of relevant information provides many opportunities for data mining but at the same time its heterogeneity is a challenge for many algorithms that require more homogeneous and structured data. The sheer amount of data required both for storing the audio but also for storing calculated audio features poses significant system scalability challenges and requires efficient large scale algorithms. The focus of this chapter is music mining in large music collections and does not cover tasks in MIR that deal with individual music tracks such as transcription, audio-score alignment and structural analysis among others. The choice of topics as well as how much detail they are described were to a large extent determined by the corresponding volume of published work in each music mining topic.

The remainder of this chapter is organized as follows. The first Section provides an overview of audio feature extraction for audio signals which forms the foundation of many music mining algorithms. The following sections describe various music mining tasks such as classification, clustering, tag annotation, advanced data mining, and visualization. The goal is to provide an overview of the music mining problems that researchers have explored and describe in some detail basic system configurations to solve these tasks. The particular techniques chosen are representative examples that are straightforward to explain rather than a comprehensive list of all possibilities. We also discuss open problems and future trends in music mining. The final section provides pointers to further reading about these topics.

---

## 1.26.2 Ground truth acquisition and evaluation

In the data mining literature, frequently the primary concern is the algorithm(s) used for extracting information from the data. This data is assumed to be readily available and in the format required for the particular task. However, in many specific applications areas such as music mining the data acquisition process is critical and not trivial. In mining algorithms typically there is a clear distinction between data that is somehow automatically extracted and the desired information that the mining algorithm somehow “extracts.” In order to assess how well a particular mining algorithm performs, we need to know in some way, what the “correct” answer should be. There are several general strategies that have been used to acquire this “ground truth” information. In most cases human users are involved in the process. With access to this ground truth information for a particular dataset, different music mining algorithms and systems can be evaluated, compared, and contrasted. In this section, we discuss the process of ground truth acquisition and evaluation in a generic way that is applicable to most music mining tasks. Many music mining tasks can be viewed as ways of associating music and text. Free-form text (frequently called tags) is the most general type of annotation and subsumes specific annotations such as genre, style, and emotion/motion. In the following sections issues more specific to each task are examined in more detail.

In terms of ground truth acquisition the simplest case is when the desired annotations are readily available by some external authority. For example online music stores provide genre labels for most of their music that can be directly used to train genre classification algorithms. For more specialized types of information expert annotation can be used. For example the personalized radio company Pandora utilizes music experts to annotate pieces of music with 400 attributes. Expert data is reliable and of high

quality but it is costly to acquire and therefore harder to scale to large music collections. An alternative approach is to utilize average users/listeners to perform the annotation. The time honored approach to acquiring ground truth, especially in academic work, is the survey typically of undergraduate students. Surveys can be carefully designed and therefore the data obtained tends to be reliable. However, they are time consuming and costly and therefore limited in terms of scalability. More recently there has been a surge in the use of “social” tags which are simply words entered by users to characterize their photos or music. Last.fm is a music discovery Web site that relies on such social tags. By the beginning of 2007, Last.fm’s large base of 40 million monthly users had built an unstructured vocabulary of 960,000 free-text tags and used it to annotate millions of songs. By harvesting the collective effort of millions of users social tagging can scale to large collections. However it comes with its own set of issues. As there is no restriction in the vocabulary, used there is a lot of inconsistency and noise in the data. Another important issue is that there is a sparsity (or lack of) tags for new artists/tracks which has been termed the cold-start problem. This is a specific case of the more general problem of popularity bias in which popular multimedia items tend to be recommended to most users simply because there is a lot of information about them. An interesting alternative that combines some of the control of surveys with the scalability and large number of users of social tags is the concept of annotation games. These are games in which a large group of users are presented with a song, and a list of tags. The goal of the game is to “guess” the tags that other users apply for that song. When a large group of users agree on a tag then the song has a strong association with it. Such annotation games belong to the larger category of games with a purpose in which players play the game because it is engaging and entertaining, while at the same time in the process of playing provide valuable information. The most famous such game is the ESP game that has been used for image annotation. Even though similar annotation games have been proposed for music they have not yet received large scale usage.

Assuming that ground truth for a particular task is available it is important to be able to evaluate different algorithms that attempt to solve it. Music mining is an emerging research area with a history of about ten years. Typically early work in a particular music mining task involves assembling a collection of music and associated ground truth for the task. In many cases only the original researchers have access to the data and the work is hard to replicate. Over time some of these datasets have been shared helping make more meaningful comparisons between different algorithms and systems. A big challenge in music mining is the difficulty of sharing data given the multiple copyrights associated with music information. The Music Information Retrieval Evaluation eXchange (MIREX) is an annual evaluation campaign for music information retrieval (MIR) algorithms that is coupled to the International Conference of the Society for Music Information Retrieval (ISMIR). It is organized by the graduate school of library and information sciences at the University of Illinois at Urbana-Champaign. Participating groups submit their systems that follow specific input/output conventions and they are evaluated on data that for some tasks is accessible only by the MIREX organizers and not the participants. In addition to dealing this way with copyright issues it also helps avoid overfitting which is an important problem for data mining algorithms in general. Overfitting refers to the situation where the performance of a mining algorithm in training data is misleadingly higher than its performance on data it has not encountered before. If the full datasets used for evaluation are available it is possible to over-optimize learning algorithms to fit their specific characteristics to the expense of generalization performance, i.e., the performance of the algorithm on data that it has not encountered during training. In the remainder of this chapter representative results from MIREX will be provided for the music mining tasks that are described, when they are available.

### 1.26.3 Audio feature extraction

Audio feature extraction forms the basis of many music mining tasks. Even though a full exposition is beyond the scope of this chapter, a short overview is provided as it is important in understanding what type of information is represented and how it is extracted. The goal of audio feature extraction is to calculate a succinct representation that summarizes musical information about the underlying audio signal. The representation should capture in a statistical sense the different types of musical information that humans are aware of when listening to music.

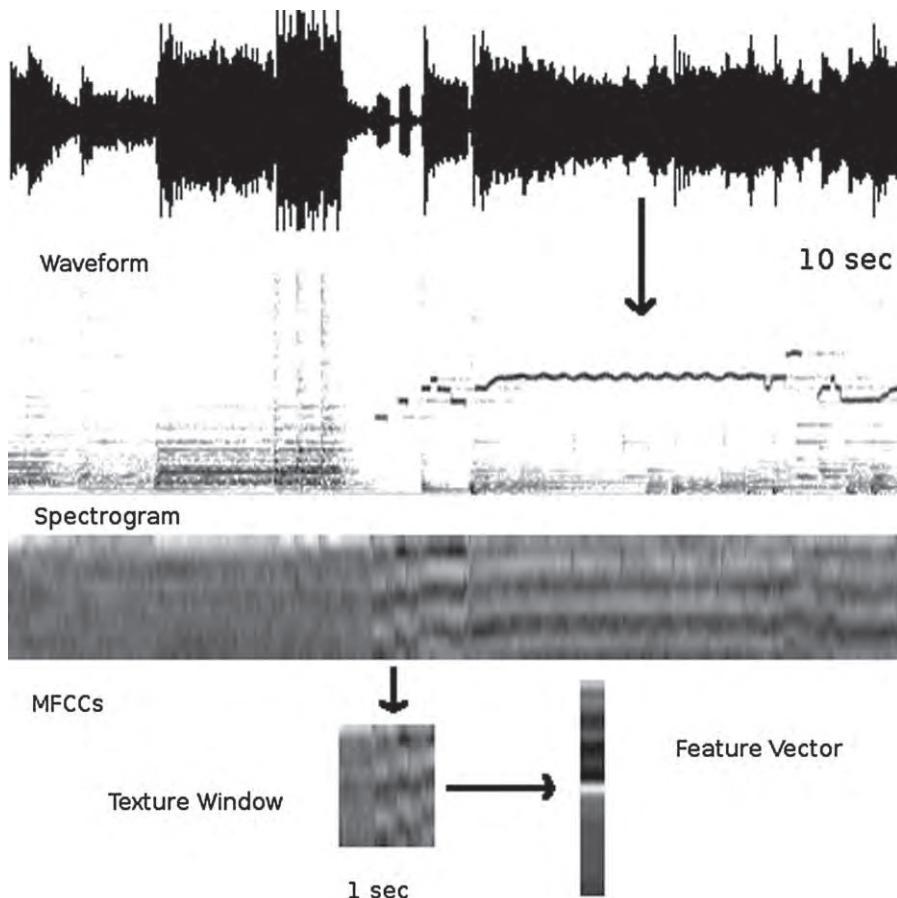

The three basic facets of music information that have mostly been explored in the existing literature are timbre, rhythm, and harmony. Rather than providing formal definitions, which are still debated among musicologists, we describe these terms informally without going into details that would require some knowledge of music theory. Timbre refers to the characteristics of the musical sound that are independent of the actual notes played and are related to the instruments playing and their sound. For example the exact same music piece played by a rock band with electric guitars and drums will sound very different than the same music piece performed by a jazz big band. Rhythm refers to the periodic repeating hierarchical structure that underlies the music independently of what instruments are playing. For example the famous beginning of the 5th Symphony by Beethoven will have the same rhythm independently of whether it is played by a symphonic orchestra or a cheap toy piano. Harmony refers to the simultaneous sounding of groups of discrete pitches/notes as well as how these groups evolve over time. For example a dance remix of a tune by the Beatles will have the same harmony or chord structure with the original while the rhythm and timbre will be completely different.

There are many variations in timbral feature extraction but most systems follow a common general template. The audio signal is broken into small slices (typically around 10–40 ms) and some form of frequency analysis, such as the Discrete Fourier Transform, is performed, followed by a summarization step in which a set of numbers (the feature vector) is calculated. This feature vector attempts to summarize/capture the content information of that short slice in time. After this stage the music track can then be represented as a sequence (trajectory) of feature vectors (points) in a high-dimensional feature space. That sequence can then be characterized using a more compact representation for subsequent classification.

Most audio features are extracted in three stages: (1) spectrum calculation, (2) frequency-domain summarization, and (3) time-domain summarization. In spectrum calculation, a short-time slice (typically around 10–40 ms) of waveform samples is transformed to a frequency domain representation. The most common such transformation is the Short Time Fourier Transform (STFT). During each short-time slice the signal is assumed to be approximately stationary and is windowed to reduce the effect of discontinuities at the start and end of the frame. This frequency domain transformation preserves all the information in the signal and therefore the resulting spectrum still has high dimensionality. For analysis purposes, it is necessary to find a more succinct description that has significantly lower dimensionality while still retaining the desired content information. Frequency domain summarization converts the high dimensional spectrum (typically 512 or 1024 coefficients) to a smaller set of number features (typically 10–30). A common approach is to use various descriptors of the spectrum shape such as the Spectral Centroid and Bandwidth. Another widely used frequency domain summarization of the Spectrum are the Mel-Frequency Cepstral Coefficients (MFCCs), a representation which originated from the speech and speaker recognition community. MFCC summarize spectral information (the energy distribution of

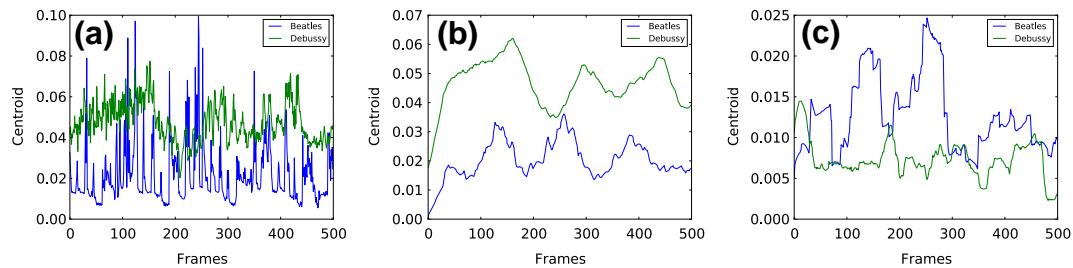

different frequencies) by taking into account, to some extent, the characteristics of the human auditory system. Such features depend on the instrumentation of a piece, how the timbral “texture” changes over time as well as how humans perceive this information. The goal of time domain summarization is to characterize the musical signal at longer time scales than the short-time analysis slices. Typically this summarization is performed across so called “texture” windows of approximately 2–3 s or it can be also performed over the entire piece of music. Figure 26.1 shows graphically feature extraction, frequency and time summarization.

Several variations on time domain summarization have been proposed. A popular approach is to fit Gaussian densities with diagonal covariance or full-covariance and then use the resulting parameters as the feature vector. Another approach has been the use of auto-regressive models that model the evolution of the feature vectors within the time window of interest.

**FIGURE 26.1**

Feature extraction and texture window.

**FIGURE 26.2**

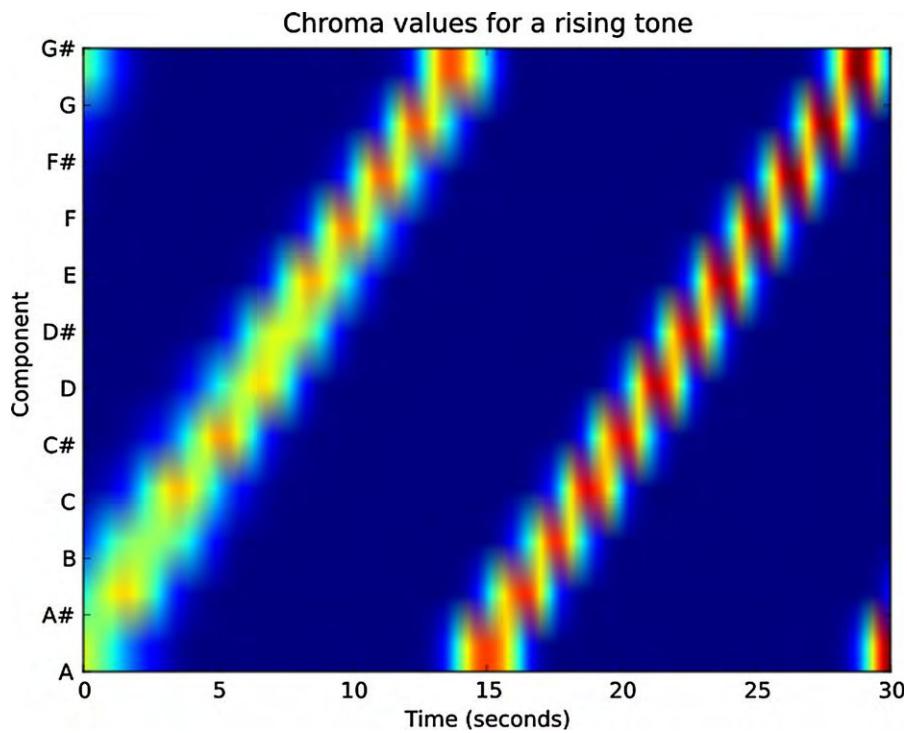

The time evolution of audio features is important in characterizing musical content. The time evolution of the spectral centroid for two different 30-second excerpts of music is shown in (a). The result of applying a moving mean and standard deviation calculation over a texture window of approximately 1 s is shown in (b) and (c).

A more detailed view of summarization (or as is sometimes called aggregation) is shown in Figure 26.2. It shows how the time evolution audio features, in this case the spectral centroid, can be summarized by applying a moving mean and standard deviation.

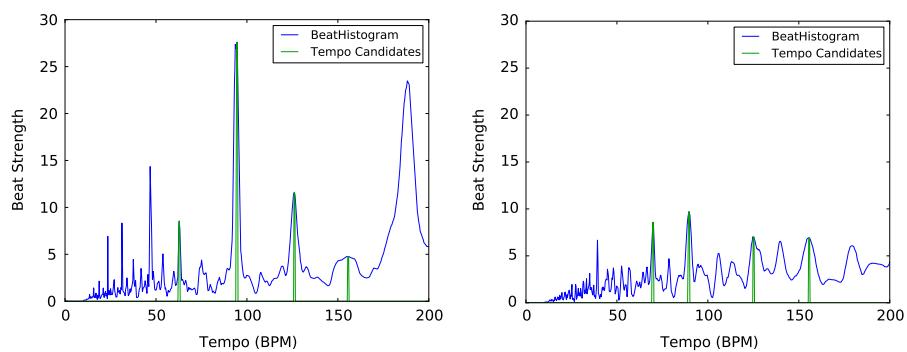

Automatic music transcription is the process of converting an audio signal to a musical score (a symbolic representation containing only information about pitch and rhythm). It is a hard problem and existing techniques can only deal with simple “toy” examples. Instead the most commonly used pitch-based representation are the pitch and pitch-class profiles (other alternative names used in literature are pitch histograms and chroma-vectors for Pitch Class Profiles). The pitch profile measures the occurrence of specific discrete musical pitches in a music segment and the pitch class profile considers all octaves equivalent essentially folding the pitch profile into 12 pitch classes. Due to space limitations we can not go into details about how pitch profiles are calculated. Broadly speaking they can either be computed by summing the energy of different frequency bins that correspond to particular pitches or alternatively multiple pitch estimation can be performed and the results can be accumulated into a profile. Figure 26.3 shows a chromagram (i.e., a sequence of chroma vectors over time) corresponding to a continuous pitch glide over two octaves. The successive activation of the chromatic scale notes as well as the warping in octaves can be observed.

Automatically extracting information related to rhythm is also important. Rhythmic information is hierarchical in nature and involves multiple related periodicities. A typical representation is a beat histogram (or sometimes called a beat spectrum) that provides a “salience” value for every possible periodicity. A typical approach applies onset detection to generate an onset strength signal that has high energy values at the time locations where there are significant changes in the audio spectrum such as the start of new notes. The periodicities of the onset strength signal at the range of human rhythm (approximately 30–180 beats/min) are calculated using autocorrelation. Another more recent approach is to identify rhythmic patterns that are characteristic of a particular genre automatically and characterize each piece as a occurrence histogram over a set of basic rhythmic patterns.

Figure 26.4 shows two example beat histograms from 30 s clips of HipHop Jazz (left) and Bossa Nova (right). As can be seen in both histograms the prominent periodicities or candidate tempos are clearly visible. Once the tempo of the piece is identified the beat locations can be calculated by locally fitting tempo hypothesis with regularly spaced peaks of the onset strength signal.

**FIGURE 26.3**

Chromagram for pitch glide over two octaves.

**FIGURE 26.4**

Beat histograms of HipHop/Jazz and Bossa Nova.

### 1.26.4 Extracting context information about music

In addition to information extracted by analyzing the audio content of music, there is a wealth of information that can be extracted by analyzing information on the web as well as patterns of downloads/listening. We use the general term musical context to describe this type of information. In some cases such as song lyrics the desired information is explicitly available somewhere on the web and the challenge is to appropriately filter out irrelevant information from the corresponding web pages. Text-based search engines such as Google and Bing can be leveraged for the initial retrieval that can then be followed by some post-processing based on heuristics that are specific to the music domain. Other types of information are not as straightforward and can require more sophisticated mechanisms such as the term weighting used in text retrieval systems, or natural language processing techniques such as entity detection. Such techniques are covered in detail in the literature as they are part of modern day search engines. As an illustrative example we will consider the problem of detecting the country of origin of a particular artist. As a first attempt one can query a search engine for various pairs of artist name and countries and simply count the number of pages returned. The country with the highest number of pages returned is returned as the country of origin. A more sophisticated approach is to analyze the retrieved web pages using term weighting. More specifically consider country  $c$  as a term. The document frequency  $DF(c, a)$  is defined as the total number of web pages retrieved for artist  $a$  in which the country term  $c$  appears at least once. The term frequency  $TF(c, a)$  is defined as the total number of occurrences of the country term  $c$  in all pages retrieved for artist  $a$ . The basic idea of term frequency-inverse document frequency weighting (TF-IDF) is to “penalize” terms that appear in many documents (in our case the documents retrieved for all artists) and increase the weight of terms that occur frequently in the set of web pages retrieved for a specific artists. There are several TF-IDF weighting schemes. For example a logarithmic formulation is:

$$TFIDF(c, a) = \ln(1 + TF(c, a)) * \ln\left(1 + \frac{n}{DF(c)}\right), \quad (26.1)$$

where  $DF(c)$  is the document frequency of a particular country  $c$  over the documents returned for all artists  $a$ . Using the above equation the weight of every country  $c$  can be calculated for a particular artist query  $a$ . The country with the highest weight is then selected as the predicted country of origin.

---

### 1.26.5 Similarity search

Similarity retrieval (or query-by-example) is one of the most fundamental MIR tasks. It is also one of the first tasks that were explored in the literature. It was originally inspired by ideas from text information retrieval and this early influence is reflected in the naming of the field as Music Information Retrieval (MIR). Today most people with computers use search engines on a daily basis and are familiar with the basic idea of text information retrieval. The user submits a query consisting of some words to the search engine and the search engine returns a ranked list of web pages sorted by how relevant they are to the query.

Similarity retrieval can be viewed as an analogous process where instead of the user querying the system by providing text the query consists of an actual piece of music. The system then responds

by returning a list of music pieces ranked by their similarity to the query. Typically the input to the system consists of the query music piece (using either a symbolic or audio representation) as well as additional metadata information such as the name of the song, artist, year of release, etc. Each returned item typically also contains the same types of meta-data. In addition to the audio content and meta-data other types of user generated information can also be considered such as ratings, purchase history, social relations and tags. Similarity retrieval can also be viewed as a basic form of playlist generation in which the returned results form a playlist that is “seeded” by the query. However more complex scenarios of playlist generation can be envisioned. For example a start and end seed might be specified or additional constraints such as approximate duration or minimum tempo variation can be specified. Another variation is based on what collection/database is used for retrieval. The term playlisting is more commonly used to describe the scenario where the returned results come from the personal collection of the user, while the term recommendation is more commonly used in the case where the returned results are from a store containing a large universe of music. The purpose of the recommendation process is to entice the user to purchase more music pieces and expand their collection. Although these three terms (similarity retrieval, music recommendation, automatic playlisting) have somewhat different connotations the underlying methodology for solving them is mostly similar so for the most part we will use them interchangeably. Another related term, that is sometimes used, is personalized radio in which the idea is to play music that is targeted to the preferences of a specific user.

One can distinguish three basic approaches to computing music similarity. Content-based similarity is performed by analyzing the actual content to extract the necessary information. Metadata approaches exploit sources of information that are external to the actual content such as relationships between artists, styles, tags or even richer sources of information such as web reviews and lyrics. Usage-based approaches track how users listen and purchase music and utilize this information for calculating similarity. Examples include collaborative filtering in which the commonalities between purchasing histories of different users are exploited, tracking peer-to-peer downloads or radio play of music pieces to evaluate their “hotness” and utilizing user generated rankings and tags.

There are trade-offs involved in all these three approaches and most likely the ideal system would be one that combines all of them intelligently. Usage-based approaches suffer from what has been termed the “cold-start” problem in which new music pieces for which there is no usage information can not be recommended. Metadata approaches suffer from the fact that metadata information is frequently noisy or inaccurate and can sometimes require significant semi-manual effort to clean up. Finally content-based methods are not yet mature enough to extract high-level information about the music.

From a data mining perspective similarity retrieval can be considered a ranking problem. Given a query music track  $q$  and a collection of music tracks  $D$  the goal of similarity retrieval is to return a ranked list of the music tracks in  $D$  sorted by similarity so that the most similar objects are at the top of the list. In most approaches, this ranking is calculated by defining some similarity (or distance) metric between pairs of music tracks. The most basic formulation is to represent each music track as a single feature vector of fixed dimensionality  $\mathbf{x} = [x_1, x_2, \dots, x_n]^T$  and use standard distance metrics such as L1 (Manhattan) or L2 (Euclidean) or Mahalanobis on the resulting high dimensional space. This feature vector is calculated using audio feature extraction techniques as described in the previous section. Unless the distance metric is specifically designed to handle features with different dynamic ranges the feature vectors are typically normalized for example by scaling all of them so that their maximum value over the dataset is 1 and their minimum value is 0. A more complex alternative is

to treat each music track as a distribution of feature vectors. This is accomplished by assuming that the feature vectors are samples of an unknown underlying probability density function that needs to be estimated. By assuming a particular parametric form for the pdf (for example a Gaussian Mixture Model) the music track is then represented as a parameter vector  $\theta$  that is estimated from the data. This way the problem of finding the similarity between music tracks is transformed to the problem of somehow finding how similar are two probability distributions that are estimated from the samples available. Several such measures of probability distance have been proposed such as histogram intersection, symmetric Kullback-Leibler divergence and earth mover's distance. In general computation of such probabilistic distances are more computationally intensive than geometric distances on feature vectors and in many cases require numerical approximation as they can not be obtained analytically. An alternative to audio feature extraction is to consider similarity based on text such as web pages, user tags, blogs, reviews, and song lyrics. The most common model when dealing with text is the so called "bag of words" representation in which each document is represented as an unordered set of its words without taking into account any syntax or structure. Each word is assigned a weight that indicates the importance of the word for some particular task. The document can then be represented as a feature vector comprising of the weights corresponding to all the words of interest. From a data mining perspective the resulting feature vector is no different than the ones extracted from audio feature extraction and can be handled using similar techniques. In the previous section we described a particular example of text based feature extraction for the purpose of predicting the country of origin as an artist.

As an example of how a text-based approach can be used to calculate similarity consider the problem of finding how similar are two artists  $A$  and  $B$ . Each artist is characterized by a feature vector consisting of term weights for the terms they have in common. The cosine similarity between the two feature vectors is defined as the cosine of the angle between the vectors and has the property that it is not affected by the magnitude of the vector (which would correspond to the absolute number of times terms appear and could be influenced by the popularity of the artist):

$$\text{sim}(A, B) = \cos \theta = \frac{\sum_t A(t) \times B(t)}{\sqrt{\sum_t A(t)^2} \times \sqrt{\sum_t B(t)^2}}. \quad (26.2)$$

Another approach to calculating similarity is to assume that the occurrence of two music tracks or artists within the same context indicates some kind of similarity. The context can be web pages (or page counts returned by a search engine), playlists, purchase histories, and usage patterns in peer-to-peer (P2P) networks. Collaborative filtering (CF) refers to a set of techniques that make recommendations to users based on preference information from many users. The most common variant is to assume that the purchase history of a particular user (or to some extent equivalently their personal music collections) is characteristic of their taste in music. As an example of how co-occurrence can be used to calculate similarity, a search engine can be queried for documents that contain a particular artist  $A$  and  $B$ , as well as documents that contain both  $A$  and  $B$ . The artist similarity between  $A$  and  $B$  can then be found by:

$$\text{sim}(A, B) = \frac{co(A, B)}{\min(co(A), co(B))}, \quad (26.3)$$

where  $co(X)$  is the number of pages returned for query  $X$  or the co-occurrences of  $A$  and  $B$  in some context. A similar measure can be defined based on co-occurrences between tracks and artists in playlists

and compilation albums based on conditional probabilities:

$$\text{sim}(A, B) = \frac{1}{2} * \left( \frac{\text{co}(A, B)}{\text{co}(A)} + \frac{\text{co}(A, B)}{\text{co}(B)} \right). \quad (26.4)$$

Co-occurrences can also be defined in the context of peer-to-peer networks by considering the number of users that have both artists A and B in their shared collection. The popularity bias refers to the problem of popular artists appearing more similar than they should be due to them occurring in many contexts. A similarity measure can be designed to down weight the similarity between artists if one of them is very popular and the other is not (the right-hand part of the following equation):

$$\text{sim}(A, B) = \frac{C(A, B)}{C(B)} * \left( 1 - \frac{|C(A) - C(B)|}{C(\text{Max})} \right), \quad (26.5)$$

where  $C(\text{Max})$  is the number of times the most popular artist appears in a context.

### 1.26.5.1 Evaluation of similarity retrieval

One of the challenges in content-based similarity retrieval is evaluation. In evaluating mining systems ideally one can obtain ground truth information that is identical to the outcome of the mining algorithm. Unfortunately this is not the case in similarity as it would require manually sorting large collections of music in order of similarity to a large number of queries. Even for small collections and number of queries, collecting such data would be extremely time consuming and practically impossible. Instead the more common approach is to only consider the top  $K$  results for each query, where  $K$  is a small number, and have users annotate each result as relevant or not relevant. Sometimes a numerical discrete score is used instead of a binary relevance decision. Another possibility that has been used is to assume that tracks by the same artist or same genre should be similar and use such groupings to assign relevance values.

Evaluation metrics based on information retrieval can be used to evaluate the retrieved results for a particular query. They assume that each of the returned results has a binary annotation indicating whether or not it is relevant to the query. The most common one is the *F-measure* which is a combination of the simpler measures of *Precision* and *Recall*. *Precision* is the fraction of retrieved instances that are relevant. *Recall* is the fraction of relevant instances that are retrieved. As an example, consider a music similarity search in which relevance is defined by genre. If for a given query of Reggae music it returns 20 songs and 10 of them are also Reggae the precision for that query is  $10/20 = 0.5$ . If there are a total of 30 Reggae songs in the collection searched then the *Relevance* for that query is  $10/30 = 0.33$ . The *F-measure* is defined as the harmonic mean of *Precision P* and *Recall R*.

$$F = 2 \times \frac{P \times R}{P + R}. \quad (26.6)$$

These three measures are based on the list of documents returned by the system without taking into account the order they are returned. For similarity retrieval, a more accurate measure is the *Average Precision* which is calculated by computing the precision and recall at every position in the ranked sequence of documents, creating a precision-recall curve and computing the average. This is equivalent to the following finite sum:

$$AP = \frac{\sum_{k=1}^n P(k) \times \text{rel}(k)}{\#\text{relevant documents}}, \quad (26.7)$$

**Table 26.1** 20120 MIREX Music Similarity and Retrieval Results

	<b>FS</b>	<b>BS</b>	<b>P@5</b>	<b>P@10</b>	<b>P@20</b>	<b>P@50</b>
RND	17	0.2	8	9	9	9
TLN3	47	0.97	48	47	45	42
TLN2	47	0.97	48	47	45	42
TLN1	46	0.94	47	45	43	40
BWL1	50	1.08	53	51	50	47
PS1	55	1.22	59	57	55	51
PSS1	55	1.21	62	60	58	55
SSPK2	57	1.24	59	58	56	53

where  $P(k)$  is the precision at list position  $k$  and  $rel(k)$  is an indicator function that is 1 if the item at list position (or rank)  $k$  is a relevant document and 0 otherwise.

All of the measures described above are defined for a single query. They can easily be extended to multiple queries by taking their average across the queries. The most common way of evaluating similarity systems with binary relevance ground-truth is the *Mean Average Precision* (MAP) which is defined as the mean of the *Average Precision* across a set of queries.

The Music Information Retrieval Evaluation Exchange (MIREX) is an annual evaluation benchmark in which different groups submit algorithms to solve various MIR tasks and their performance is evaluated using a variety of subjective and objective metrics. Table 26.1 shows representative results of the music similarity and retrieval task from 2010. It is based on a dataset of 7000 30-second audio clips drawn from 10 genres. The objective statistics are the precision at 5, 10, 20, and 50 retrieved items without counting entries by the artist (artist filtering). The subjective statics are based on human evaluation of approximately 120 randomly selected queries and 5 results per query. Each result is graded with a fine score (between 0 and 100 with 100 being most similar) and a broad score (0 not similar, 1 somewhat similar, 2 similar) and the results are averaged. As can be seen all automatic music similarity systems perform significantly better than the random baseline (RND). The differ in terms of the type of extracted features utilized, the decision fusion strategy (such as simple concatenation of the different feature sets or empirical combinations of distances from the individual feature sets), and whether post-processing is applied to the resulting similarity matrix. There is also a strong correlation between the subjective and objective measures although it is not perfect (for example SSPK2 is better than PSS1 in terms of subjective measures but worst in terms of objective measures).

### 1.26.5.2 Cover song detection and audio fingerprinting

In addition to content-based similarity there are two related music mining problems. The goal of audio fingerprinting is to identify whether a music track is one of the recordings in a set of reference tracks. The problem is trivial if the two files are byte identical but can be considerably more challenging when various types of distortion need to be taken into account. The most common distortion is perceptual

audio compression (such as the one used for mp3 files) which can result in significant alterations to the signal spectrum. Although these alterations are not directly perceptible by humans they make the task of computer identification harder. Another common application scenario is music matching/audio fingerprinting for mobile applications. In this scenario the query signal is acquired through a low quality microphone on a mobile phone and contains significant amount of background noise and interference. At the same time the underlying signal is the same exact music recording which can help find landmark features and representations that are invariant to these distortions. Cover song detection is the more subtle problem of finding versions of the same song possibly performed by different artists, instruments, and tempo. As the underlying signals are completely different it requires the use of more high level representations such as chroma vectors that capture information about the chords and the melody of the song without being affected by timbral information. In addition it requires sophisticated sequence matching approaches such as dynamic time warping (DTW) or Hidden Markov Models (HMM) to deal with the potential variations in tempo. Although both of these problems can be viewed as content-based similarity retrieval problems with an appropriately defined notion of similarity they have some unique characteristics. Unlike the more classic similarity retrieval in which we expect the returned results to gradually become less similar, in audio fingerprinting and cover song detection there is a sharper cutoff defining what is correct or not. In the ideal case copies or cover versions of the same song should receive a very high similarity score and everything else a very low similarity score. This specificity is the reason why typically approaches that take into account the temporal evolution of features are more common.

Audio fingerprinting is a mature field with several systems being actively used in industry. As a representative example, we describe a landmark-based audio fingerprinting system based on the ideas used by Shazam, which is a music matching service for mobile phones. In this scheme, each audio track is represented by the location in time and frequency of prominent peaks of the spectrogram. Even though the actual amplitude of these peaks might vary due to noise and audio compression their actual location in the time frequency plane is preserved quite well in the presence of noise and distortion. The landmarks are combined into pairs and each pair is characterized by three numbers  $f_1$ ,  $f_2$ ,  $t$  which are the frequency of the first peak, the frequency of the second peak and the time between them. Both reference tracks and the query track are converted into this landmark representation. The triplets characterizing each pair are quantized with the basic idea being that if the query and a reference track have a common landmarks with consistent timing they are a match. The main challenge in an industrial strength implementation is deciding on the number of landmarks per second and the thresholds used for matching. The lookup of the query landmarks into the large pool of reference landmarks can be performed very efficiently using hashing techniques to effectively create an inverted index which maps landmarks to the files they originate.

To solve the audio cover song detection problem there are two issues that need to be addressed. The first issue is to compute a representation of the audio signal that is not affected significantly by the timbre of the instruments playing but still captures information about the melody and harmony (the combination of discrete pitches that are simultaneously sounding) of the song. The most common representation used in music mining for this purpose are chroma vectors (or pitch class profiles) which can be thought of as histograms showing the distribution of energy among different discrete pitches. The second issue that needs to be addressed is how to match two sequences of feature vectors (chroma vectors in this case) that have different timing and length as there is no guarantee that a cover song is played at the same tempo as the original and there might be multiple sections each with different timing.

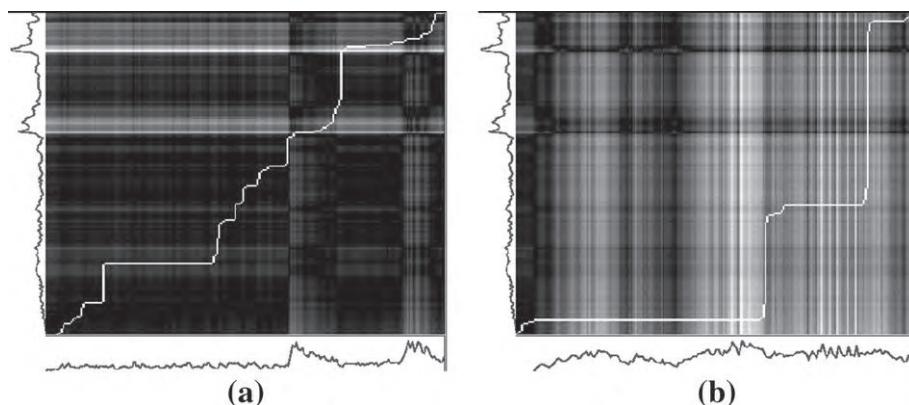

### 1.26.5.3 Sequence matching

Sequence matching algorithms are used for a variety of tasks in MIR including polyphonic audio and scores alignment, and real-time score following. More formally the problem is given two sequences of feature vectors with different lengths and timings find the optimal way of “elastically” transforming by the sequences so that they match each other. A common technique used to solve this problem, and also frequently employed in the literature for cover song detection, is dynamic time warping (DTW) a specific variant of dynamic programming. Given two time series of feature vectors  $X = (x_1, x_2, \dots, x_M)$  and  $Y = (y_1, y_2, \dots, y_N)$  with  $X, Y \in \mathbb{R}^d$  the DTW algorithm yields an optimal solution in  $O(MN)$  time where  $M$  and  $N$  are the lengths of the two sequences. It requires a local distance measure that can be used to compare individual feature vectors which should have small values when the vectors are similar and large values when they are different:

$$d : \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R} \geq 0. \quad (26.8)$$

The algorithm starts by building the distance matrix  $C \in \mathbb{R}^{M \times N}$  representing all the pairwise distances between the feature vectors of the two sequences. The goal of the algorithm is to find the **alignment or warping path** which is a correspondence between the elements of the two sequences with the boundary constraint that the first and last elements of the two sequences are assigned to each other. Intuitively for matching sequences the alignment path will be roughly diagonal and will run through the low-cost areas of the distance matrix. More formally the alignment is a sequence of points  $(p_i, p_j) \in [1 : M] \times [1 : N]$  for which the starting and ending points must be the first and last points of the aligned sequences, the points are time-ordered and each step size is constrained to either move horizontally, vertically or diagonally. The cost function of the alignment path is the sum of all the pairwise distances associated with its points and the alignment path that has the minimal cost is called the **optimal alignment path** and is the output of the DTW.

Figure 26.5 shows two distance matrices that are calculated based on energy contours of different orchestra music movements. The left matrix is between two performances by different orchestras of the

**FIGURE 26.5**

Similarity matrix between energy contours and alignment path using dynamic time warping. (a) Good alignment (b) bad alignment.

same piece. Even though the timing and duration of each performance is different they exhibit a similar overall energy envelope shown by the energy curves under the two axes. The optimal alignment path computed by DTW is shown imposed over the distance matrix. In contrast the matrix on the right shows the distance matrix between two unrelated orchestral movements where it is clear there is no alignment and the optimal alignment path deviates significantly from the diagonal.

Hidden Markov Models (HMM) are a probabilistic sequence modeling technique. The system is modeled as going through a set of discrete (hidden) states over time following Markov transitions, i.e., each state only depends on the value of previous state. In regular Markov models the only parameters are the state transition probabilities. In HMM the states are not directly visible but their probabilistic output is visible. Each state has an associated probability density function and the goal of HMM training is to estimate the parameters of both the transition matrix and the state-dependent observation matrix. For sequence matching the estimated sequence of hidden states can be used.

#### 1.26.5.4 Cover song detection

Cover song detection is performed by applying DTW between all the query song and all the references and returning as a potential match the one with the minimum total cost for the optimal alignment path. Typically the alignment cost between covers of the same song will be significantly lower than the alignment cost between two random songs. DTW is a relatively costly operation and therefore this approach does not scale to large number of songs. A common solution for large scale matching is to apply an audio fingerprinting type of approach with efficient matching to filter out a lot of irrelevant candidates and once a sufficient small number of candidate reference tracks have been selected apply pair-wise DTW between the query and all of them.

Table 26.2 shows the results of the audio cover song detection task of MIREX 2009 in the so called “mixed” collection which consists of 1000 pieces that contain 11 “cover song” each represented by 11 different versions. As can be seen the performance is far from perfect but it is still impressive given the difficulty of the problem. An interesting observation is that the objective evaluation measures are not consistent. For example the RE algorithm performs slightly worse than the SZA in terms of mean average precision but has better mean rank for the first correctly identified cover. Table 26.3 shows the results of the MIREX 2009 audio cover song detection task for the Mazurkas collection which consists 11 different performances/versions of 49 Chopin Mazurkas. As can be seen from the results this is a easier dataset to find covers probably due to the smaller size and more uniformity in timbre. The RE algorithm is based on the calculation of different variants of chroma vectors utilizing multiple feature sets. In contrast to the more common approach of scoring the references in a ranked list and setting up a threshold for identifying covers it follows a classification approach in which a pair is either classified as reference/cover or as

**Table 26.2** 2009 MIREX Audio Cover Song Detection-Mixed Collection

	RE	SZA	TA
Mean # of covers in top 10	6.20	7.35	1.96
Mean Average Precision	0.66	0.75	0.20
Mean Rank of first correct cover	2.28	6.15	29.90

**Table 26.3** 2009 MIREX Audio Cover Song Detection—Mazurkas

	<b>RE</b>	<b>SZA</b>	<b>TA</b>
Mean # of covers in top 10	8.83	9.58	5.27
Mean Average Precision	0.91	0.96	0.56
Mean Rank of first correct cover	1.68	1.61	5.49

reference/non-cover. The SZA algorithm is based on harmonic pitch class profiles (HPCP) which are similar to chroma vectors but computed over a sparse harmonic representation of the audio signal. The sequence of feature vectors of one song is transposed to the main tonality of the other song in consideration. A state space representation of embedding  $m$  and time delay  $z$  is used to represent the time series of HPCP with a recurrence quantification measure used for calculating cover song similarity.

## 1.26.6 Classification

Classification is the task of assigning each object (in our case a music track) to one of several pre-defined categories of interest. In data mining it refers to principled ways of building classification systems using as input a set of objects with associated ground truth classification labels which is called the training set. It is a subset of the more general concept of supervised learning in which an algorithm “learns” how to improve its performance over a particular task by analyzing the results on this task provided by humans during a training phase. One of the simplest classifiers is based on techniques such as the ones described in the similarity retrieval section. A new object represented by a vector of attributes/features is classified to the category of its nearest neighbor in the training set. A common variant is to consider the classification label of the majority of  $k$  nearest neighbors where  $k$  is an odd number. In addition a variety of techniques have been proposed specifically for this task. They include rule-based classifiers, decision trees, neural networks, support vector machines and various parametric classifiers based on Bayesian decision theory such as Naive Bayes and Gaussian Mixture Models. These techniques differ in terms of the assumptions they make, the time they take to train, and the amount of data they require to work well. Their goal is to fit as well as possible the relationship between the attributes or features that characterize the music tracks and the ground truth class label. The trained model should not only predict the class label of the tracks it has encountered in training but of new music tracks it has never encountered before.

Classification techniques can be grouped into two large families: generative and discriminative. In generative approaches the classification problem is recast, through Bayesian decision theory to the problem of estimating a probability density function from a set of samples (the feature vectors of a particular class in the training set). They are called generative because the estimated model can be used to generate new random samples (features). Given a classification task of  $M$  classes/categories,  $c_1, c_2, \dots, c_M$  and an unknown object (in our case music track) represented as a feature vector  $\mathbf{x}$  the goal is to calculate the  $M$  conditional probabilities (also referred to as a posteriori probabilities)  $P(c_i | \mathbf{x})$  where  $i = 1, 2, \dots, M$ . The predicted class label for the unknown vector  $\mathbf{x}$  will then be the  $c_i$  corresponding

to the maximum conditional probability. Using the *Bayes Rule* these conditional probabilities can be written as:

$$P(c_i|\mathbf{x}) = \frac{p(\mathbf{x}|c_i)P(c_i)}{p(\mathbf{x})}. \quad (26.9)$$

The prior probabilities  $P(c_i)$  can be calculated by simply counting the number of instances belonging to each class in the training set, so the main challenge is to estimate the probability density function of the feature vectors given the class  $p(\mathbf{x}|c_i)$ . Many classification algorithms solve this problem by assuming a particular parametric form for the probability density function and then estimating the parameters from the observed samples for the particular class. For example, the simple Naive Bayes classifier assumes that the probability density function corresponding to each feature is conditionally independent given the class. Therefore it can be expressed as the product of normal distributions (one for each feature). The parameters that need to be estimated are the means and variances of each feature for the particular class. It can be shown that these correspond to the statistical means and variances of the observed samples in the training set. In music mining the most common generative modeling technique used is *Gaussian Mixture Models* (GMM) in which each class is modeled as a weighted combination of samples from  $K$  Gaussian models.

The main insight behind discriminative approaches is that what is important in a classification problem is not to model the distribution of all the observed feature vectors, but rather to focus on the areas of the feature space in which the decision of which class the vector belongs is unclear. Essentially discriminative approaches try to directly solve the classification problem by making some assumptions about a discriminative function (i.e., a function that given as input an unknown feature vector returns a predicted class) and then optimizing the parameters of this function according to some criterion. For example, the assumption can be that the discriminant function is a linear combination of the features (geometrically corresponding to a hyperplane in the feature space) and the criterion might be the number of errors in the training set. In music mining the most common discriminative model used is *Support Vector Machines* (SVM). Another way of grouping classification algorithms is into parametric approaches in which each class is characterized by a small set of parameters (both the GMM and SVM classifiers are parametric methods) and non-parametric methods in which there is no explicit parameter representation. The canonical example of a non-parametric classifier is the *Nearest Neighbor* rule which simply classifies an unknown instance with the label associated with the training instance that is closest to it in the feature space. In many music mining classification problems the predicted labels form natural hierarchies. For example Folk Metal is a subgenre of Heavy Metal and Hostility is a subordinate emotion to Anger. A straightforward way of solving hierarchical classification problems is to apply standard classification techniques for the top level categories and then train classifiers for the subordinate categories separately for each top-level category. One issue with this approach is that by making a hard decision at each level errors can be propagated. An alternative is to view the hierarchy as a probabilistic graphical model and essentially compute conditional probabilities for the decisions at each level of the hierarchy using classifiers that output probabilities over all possible classes rather than a single classification decision.

### 1.26.6.1 Genre classification

Music can be grouped into categories in many different ways and most of them have been investigated in the literature. Probably the oldest classification task that was investigated was musical genre

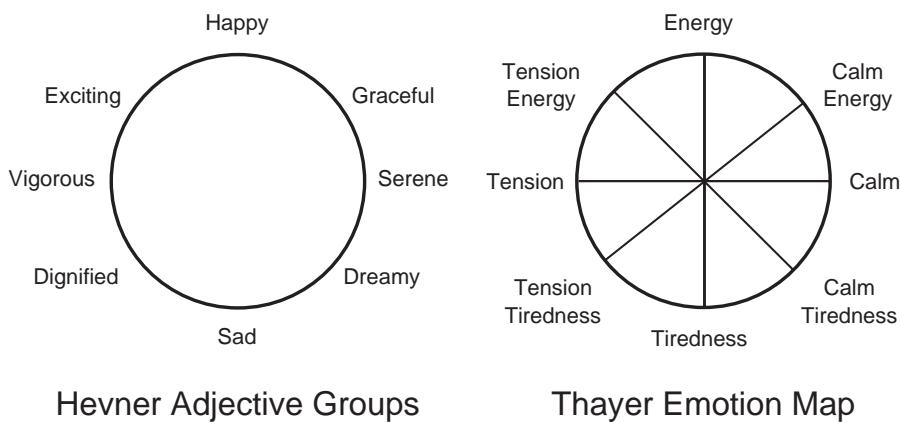

classification. Other tasks include artist/singer/performer classification, mood and emotion detection, instrument recognition and others. The boundaries between categories such as genre labels are fuzzy. Even though there is considerable agreement when listeners are asked to annotate an unknown piece of music with a genre label, there are also individual differences. Top-level genres such as classical or Reggae are more consistently identified, while more obscure genres such as folk metal or grime are meaningful only to smaller groups of listeners. Given the subjective nature of human genre annotations it is unreasonable to expect perfect computer genre classification performance (in fact the notion of perfect performance is only meaningful in relation to some ground truth which in this case will be inherently subjective). One fascinating finding is that average listeners are able to classify a music track with a label from a set of pre-defined top-level genres, with accuracy better than random with exposure to as little as 250 ms (1/4 of a second or approximately the time it takes to say the word “word”) and require only 3 s to reach their best classification performance. This indicates that low level audio-related features carry sufficient information for reliable genre classification. In a well-known user study (details can be found in the Further Reading section) a mean subject agreement of about 70% to the genres assigned by music companies was reported. Further studies have shown that on the same dataset computer classification achieves results comparable to some of the “worst” performing humans (69%) but not as good as the “best” performing humans (95%). In this case the ground-truth is defined as the genre labels that is assigned by the majority of the 27 users that participated in the study rather some external authority. Therefore the “worst” and “best” performance refer to subject agreement with the majority rather than any form of music knowledge. It also has been pointed out that listeners probably can be clustered into groups so that the perception of genres within a particular group is more consistent than across groups. In the majority of published work in automatic genre classification these issues are not considered and the ground truth is known and externally provided.

Automatic genre classification is one of the most popular topics in music mining to a large extent due to the simplicity of obtaining ground truth, the availability of datasets for which there are published results, and the direct mapping to classification techniques. It has also served as a good initial test-bed for experimenting with alternative audio and music feature sets. At the same time for a lot of music of interest the genre labels are already available (although for some cases like World music they are too generic to be useful).

### 1.26.6.2 Emotion and mood classification

Listeners can easily identify emotions and moods that are present in pieces of music. It is also known that music can induce emotions and moods to listeners. Therefore it is desirable to utilize emotion and mood related information in music retrieval systems. Unlike other types of audio classification such as genre in which the classification labels are to some extent pre-defined and readily available for particular music tracks, one of the challenges in emotion and mood classification is deciding what labels should be used and obtaining them for a particular set of music tracks.

Roughly speaking mood is a more persistent state of mind and can encompass different emotions whereas emotions are more instinctive. Most of the literature in emotion and mood classification relies on various schemes for describing emotions/moods from psychology. For example Hevner experimentally found eight adjective groups for describing music based on a user study of 450 subjects listening to 26 pieces of classical music. These groups are: dignified, sad, dreamy, serene, graceful, happy, exciting,

**FIGURE 26.6**

Different ways of organizing emotions.

vigorous and were arranged in a circle in the order they were listed such that the changes are gradual. Figure 26.6 shows this representation.

Schemes of describing emotion can be roughly divided into two general families: models based on hierarchies of words describing the different emotions and two dimensional (or sometimes even three dimensional) continuous emotion spaces where each axis corresponds to a pair of adjectives having opposite meanings (for example, happy and sad). A particular emotion is characterized as a point in the emotional space. The use of words to represent emotion (or affect) can be problematic as multiple emotions can be experienced at the same time and there is individual variability in how a particular experience is assessed. Figure 26.6 shows an example of emotion grouping and an example of an emotion space.

In terms of data mining techniques, standard classification approaches as the ones described above can be used. The most common sources of training data in the literature are either audio features, text features based on analyzing lyrics, or more generally tags which are described below. Hierarchical classification techniques can also be employed to deal with multiple levels of classification. In order to deal with the fact that multiple emotion/mood words might apply to the same music track a multi-label classification approach can be employed. In traditional classification there is a single ground truth label (from a predefined set of categories) for each training instance and a single predicted label (from the same set of categories) for each testing instance. In multi-label classification there are multiple labels (still from a predefined set of categories) associated with each instance. One can categorize multiple-label classification approaches into two broad families. The first family consists of problem transformation methods that convert a multi-label classification problem to a set of standard classification problems. For example each label can be treated separately as a binary classification problem with instances that are annotated with the label being positive examples and instances that do not contain the label as negative examples. This approach requires training  $K$  binary classifiers where  $K$  is the number of distinct labels. The second family consists of classification approaches that can be directly applied to

multi-label classification problems. A simple example is the *Nearest Neighbor* classifier in which a new instance is annotated by all the labels that are associated with the training instance that is closest to it in the feature space.

When dealing with a continuous emotional space both the ground truth and the predicted outcome are continuous rather than categorical. In data mining, regression refers to the prediction of a continuous output label from a set of continuous attributes. There is a large variety of regression algorithms which similarly to classification algorithms can be categorized as parametric and non-parametric. In many cases they are based on similar ideas to classification algorithms. For example support vector regression (SVR) is a counterpart to support vector machines (SVMs) and ensemble boosting regression (AdaBoost.RT) is the counterpart of the AdaBoost ensemble classification algorithm.

### 1.26.6.3 Evaluating classifier performance

The goal of a classifier is to be able to classify objects it has not encountered before. Therefore in order to get a better estimate of its performance on unknown data it is necessary to use some of the instances labeled with ground truth for testing purposes and not take them into account when training. The most common such evaluation scheme is called  $K$ -fold cross-validation. In this scheme the set of labeled instances is divided into  $K$  distinct subsets (folds) of approximately equal sizes. Each fold is used for testing once with the  $K - 1$  remaining folds used for training. As an example if there are 100 feature vectors then each fold will contain 10 feature vectors with each one of them being used one time for testing and  $K - 1$  times for training. The most common evaluation metric is classification accuracy which is defined as the percentage of testing feature vectors that were classified correctly based on the ground truth labels. When classifying music tracks a common post-processing technique that is applied is the so-called artist filter which ensures that the feature vectors corresponding to tracks from the same artist are not split between training and testing and are exclusively allocated only to one of them. The rationale behind artist filtering is that feature vectors from the same artist will tend to be artificially related or correlated due to similarities in the recording process and instrumentation. Such feature vectors will be classified more easily if included in both training and testing and maybe inflate the classification accuracy. Similar considerations apply to feature vectors from the same music track if each track is represented by more than one feature vector, in which case a similar track filter should be applied.

The most common evaluation metric for automatic classification is accuracy which is simply defined as the number of correctly classified instances in the testing data. It is typically expressed as a percentage. Additional insight can be provided by examining the confusion matrix which is a matrix that shows the correct classifications in the diagonal and shows how the misclassification are distributed among the other class labels.

Table 26.4 shows classification results from MIREX 2010. The classification results are shown as percentage accuracy. They are sorted based on the performance on the largest of the datasets considered (the Genre column). This dataset consists of 7000 clips each 30 s long. The following ten genres are all equally represented (700 clips for each genre): blues, jazz, country, baroque, classical, romantic, electronica, hiphop, rock, metal. The mood dataset consists of 600 30-second clips classified into 5 mood clusters. The labeling was done by human judges. Table 26.5 shows the 5 mood clusters used. The Latin dataset consists of 322 audio files representing 10 Latin music genres (axe, bachata, bolero, forro, gaucha, merengue, pagode, sertaneja, tango) sourced from Brazil and labeled by music experts. These genres are

Cluster 5	Aggressive	Fiery	Tense	Intense	Volatile	Visceral

more differentiated by rhythmic characteristics than the other datasets considered. For computing these classification accuracies, for all datasets, a three-fold cross-validation with artist filter (i.e., all songs of an artists are either part of the training or testing) approach was used. The algorithms differ in terms of the exact details of the feature extraction and the type of supervised learning classifier they utilize.

#### 1.26.6.4 Clustering

Clustering is the problem of partitioning a finite set of objects (music tracks in our case) into groups called clusters such that objects belonging to the same cluster are similar to each other, and objects belonging to different clusters are dissimilar. Similarly to classification, this is a well investigated problem in the area of data mining for which several algorithms have been proposed. In music mining it can be used to automatically organize a music collection into coherent groups, or identify users with different musical interest as well as automatically construct hierarchies of music tags. Similarly to classification typically some combination of audio features and text such as lyrics is utilized in music clustering. One of the classic algorithms for clustering is *K*-means which partitions  $N$  instances into  $K$  clusters such that each instance belongs to the “nearest” cluster and clusters are characterized by the mean of the instances that are assigned to them. The most common algorithm for *K-Means* clustering uses an iterative refinement technique consisting of two steps. In the first assignment step each instance is assigned to the cluster with the closest mean. The initial means can be either random or somehow spread in the feature space. In the second update step the means characterizing each cluster are updated to reflect the instances that have been assigned to them. The two steps are repeated with this new set of cluster means until the assignments no longer change. A somewhat similar approach can be used with the so called *EM algorithm* for finding clusters based on a Gaussian Mixture Model.

---

#### 1.26.7 Tag annotation

The term “tag” refers to any keyword associated to an article, image, video, or piece of music on the web. In the past few years there has been a gradual shift from manual annotation into fixed hierarchical taxonomies, to collaborative social tagging where any user can annotate multimedia objects with tags (so called folksonomies) without conforming to a fixed hierarchy and vocabulary. For example, Last.fm is a collaborative social tagging network which collects roughly 2 million tags (such as “saxophone,” “mellow,” “jazz,” “happy”) per month and uses that information to recommend music to its users. Another source of tags are “games with a purpose” where people contribute tags as a by-product of doing a task that they are naturally motivated to perform, such as playing casual web games. For example TagATune is a game in which two players are asked to describe a given music clip to each other using tags, and then guess whether the music clips given to them are the same or different.

Tags can help organize, browse, and retrieve items within large multimedia collections. As evidenced by social sharing websites including Flickr, Picasa, Last.fm, and You Tube, tags are an important component of what has been termed as “Web 2.0.” The goal of automatic tag annotation is to automatically predict tags by analyzing the musical content without requiring any annotation by users. Such systems typically utilize signal processing and supervised machine learning techniques to “train” autotaggers based on analyzing a corpus of manually tagged multimedia objects. Music classification can be viewed as a specialized restricted form of tag annotation where there is fixed vocabulary and only one tag applies to each music track.

There has been considerable interest for automatic tag annotation in multimedia research. Automatic tags can help provide information about items that have not been tagged yet or are poorly tagged. This avoids the so called “cold-start problem” in which an item can not be retrieved until it has been tagged. Addressing this problem is particularly important for the discovery of new items such as recently

released music pieces in a social music recommendation system. Another also automatic approach is to use text mining techniques to associate tags to particular music tracks.

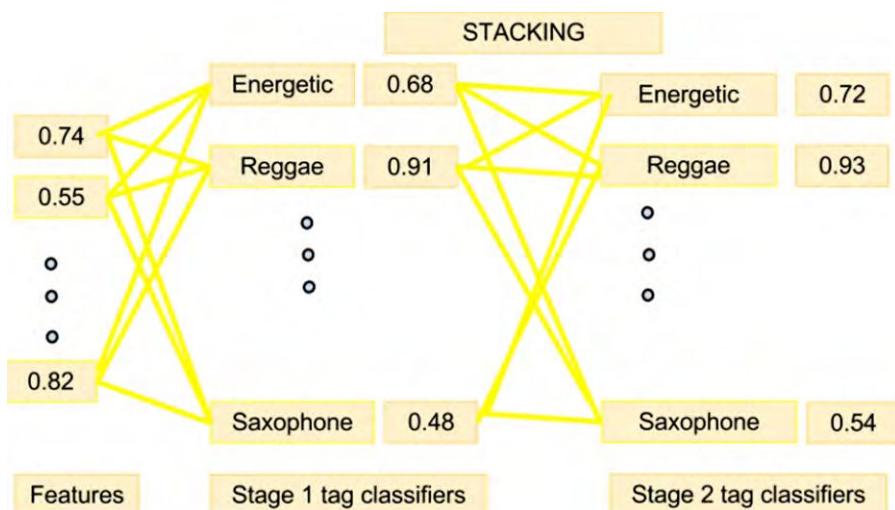

The training data for an automatic tag annotation system is typically represented as a *tag-track* matrix  $X$  where each element  $x[t, s]$  represents the strength of association between a particular tag  $t$ , and a particular song  $s$ . For example, the strength of association for a particular entry in the matrix can be the number of users that annotated that particular song with a particular tag.

From a machine learning perspective automatic tag annotation can be viewed as a variation of multi-label classification. In contrast to traditional classification in which each item is assigned one of  $k$  mutually exclusive class labels, in multi-label classification each item can be assigned to multiple labels (tags). Many different approaches to multi-label classification have been proposed in the literature. They leverage feature information computed from a training set of examples annotated with multiple labels to train models that can subsequently be used to predict labels for new examples. There are some unique characteristics and related challenges when the ground truth tag data is obtained from the web. The ground truth training data is *noisy* in the sense that the tags can contain synonyms (“calm” and “mellow”), misspellings (“chello”) and hierarchical relations (“symphony” and “classical”). In addition the data is *sparse* meaning that there can be few training examples for a given tag. Finally, the absence of a tag cannot always be taken to mean that the tag is not applicable, as it might be the case that the users have simply not yet considered that tag for the particular multimedia item. This phenomenon has been termed weak labeling in contrast to regular strong labeling.

A common straightforward approach to auto-tagging is to train  $K$  binary classifiers that classify each of the  $K$  tags independently. Instances that contain a tag are considered positive, and instances that do not contain it are considered negative. A new instance is annotated with all the tags that the binary classifiers predict as positive. Topic models such as *Latent Dirichlet Allocation* (LDA) make the assumption that tags can be grouped into an unknown number of higher level groups and build a probabilistic model around this assumption. Pre-processing and post-processing techniques that take into account semantic similarities between tags can also be used to improve the results. For example misspellings can be merged in a preprocessing step. A data driven approach that attempts to capture some of the dependencies between tags directly from the data is called *stacking*.

*Stacking* is a method of combining the outputs of multiple independent classifiers for multi-label classification. The first step of using stacking for multi-label classification is to train  $|V|$  individual tag classifiers using a training set  $(\mathbf{x}_i, \mathbf{y}_i)$ , where  $\mathbf{x}_i$  denotes the feature vector for instance  $i$  and  $\mathbf{y}_i$  is the associated set of labels. The output of these classifiers (binary or probabilistic)  $f_1(\mathbf{x}), f_2(\mathbf{x}), \dots, f_{|V|}(\mathbf{x})$  where  $\mathbf{x}$  is the input feature vector that can then be used as a feature to form a new feature set. Let the new feature set be  $z_1, z_2, \dots, z_{|V|}$ . This feature set, together with the original ground truth labels  $(\mathbf{z}_i, \mathbf{y}_i)$ , is then used for training a second stage of stacking classifiers. The goal is to have the stacking classifiers make use of information like the correlation between tags and the accuracy of the first stage classifiers to improve the annotation performance. For example suppose that the stage 1 performance for the tag “opera” is not very good but that most of the examples with the tag “opera” receive high probabilities for the tags “classical” and “voice” at stage 1. The stacking stage 2 can take into account this information from other tags and improve annotation performance: something not possible during stage 1, in which each tag is treated independently. Figure 26.7 shows this process as a block diagram.

Evaluation of automatic tagging systems is not trivial. In general, the evaluation metrics used are generalizations of commonly used evaluation metrics for single label classification. An annotated “training”

**FIGURE 26.7**

Stacking for automatic music tag annotation.

set of instances is used to “train” the classifier, and then used to “predict” the tags for a set of instances in a “test” set. We can also distinguish between evaluation metrics that are based on a predicted set of discrete tags (sometimes referred to as the annotation task) and ones that are based on a predicted set of tag affinities/probabilities (sometimes referred to as the ranking task) for each instance in the testing set. A common approach is to treat any classification decision equally and simply count the number of true positives (TP), true negatives (TN), false positives (FP), and false negatives (FN) to derive well-known measures such as precision, recall and F-measure. In the case of probabilistic output, multiple score thresholds can be considered as possible boundaries for binarization, in which case it is common to use *Receiver operating characteristic* (ROC) curves. An ROC curve is a plot of the true positive rate as a function of the false positive rate. The ROC curve can be summarized by the area under curve (AUC-ROC) which can be found by integrating the ROC curve and is upper bound by 1.0. Random guessing in a retrieval task results in an AUC-ROC of 0.5. Different tag annotation methods can have different operating point characteristics in terms of the trade-off between true positives and false positives. A final complication is that calculating metrics over the entire set of tags can be misleading as good performance on “popular” tags that appear in many instances will dominate. However, typically a more balanced response where all tags are considered is desired. In order to address this concern, evaluation metrics averaged across tags are used. Finally it is important to note that in most cases evaluation metrics based on annotated ground truth underestimate what the true performance of the system would be if evaluated by humans. The reason is that frequently, predicted tags that humans would consider applicable are not present in the ground truth and therefore evaluated as mistakes.

Table 26.6 shows both binary (F-measure) and affinity (AUC-ROC) evaluation metrics for automatic tag annotation from MIREX 2009 using the MajorMiner data-set. This data-set consists of 2300 clips

**Table 26.6** MIREX 2009 Tag Annotation Results (MajorMiner, Mood)

Measure	BP2	CC4	GP	GT2	HBC	LWW2
MajorMiner						
F-measure	0.29	0.26	0.01	0.29	0.04	0.31
AUC-ROC	0.76	0.75	—	0.79	0.74	0.80
Mood						
F-measure	0.19	0.18	0.08	0.21	0.06	0.70
AUC-ROC	0.63	0.64	—	0.65	0.66	0.80

selected at random from 3900 tracks. Each clip is 10 s long. The clips represent a total of 1400 different tracks on 800 different albums by 500 artists. To give a sense of the diversity of the music collection, the following genre tags have been applied to these artists, albums, and tracks on Last.fm: electronica, rock, indie, alternative, pop, britpop, idm, new wave, hiphop, singer-songwriter, trip-hop, post-punk, ambient, jazz. The MajorMiner game has collected a total of about 73,000 taggings, 12,000 of which have been verified by at least two users. In these verified taggings, there are 43 tags that have been verified at least 35 times, for a total of about 9000 verified uses. These are the tags are used in this task. The table also shows the results in the Mood dataset which consists of 3469 unique songs and 135 mood tags organized into 18 mood tag groups which where used as tags. The songs are Western pop songs mostly from the USPOP collection. Each song may belong to multiple mood tag groups. The main rationale on songs selection is: if more than one tag in a group were applied to a song, or if one tag in a group was applied more than once to a song, this song is marked as belonging to this group.

In this task, the participating groups submitted variants of the same algorithm. Due to space constraints we only show the top performing variant of each group. The evaluation was performed using 3-fold cross validation using artist filtering, i.e., the training and test sets contained different artists. The results are averaged across tags. The BP2 system is based on spectral and chroma features and for classification applies both feature selection and model selection. For model selection instead of using classification accuracy, as is common, they use a custom measure designed to deal better with unbalanced data-sets and over-fitting. Each tag is classified separately. The CC4 system is based on MFCC and delta-MFCC that are then transformed into a super-vector using a universal background approach. In this approach, a Gaussian Mixture Model is trained using a large corpus of music that is separate from the files considered for tag annotation. This universal background model is then adapted to better fit the data of the tag dataset. The parameters of the adapted GMM are then used as features and an ensemble classifier consisting of a linear support vector machine and AdaBoost classifier is utilized for classification. Each tag is treated separately. The GPP system uses spectral and chroma features followed by GMM modeling both at the frame level and track level. Each tag is treated as a separate classification problem. GT2 also utilized spectral and chroma features followed by a layer of tag-specific linear support vector machines followed by a stacking layer of also linear support vector machines. The HBC system utilizes bag of codewords representation (basically an occurrence histogram of different codewords which are computed by  $k$ -means clustering-this approach is also known as vector quantization) with MFCC and

delta MFCC as the original feature vectors. For tag annotation a codeword bernoulli average approach is utilized. Unfortunately it is hard to draw any reliable conclusions from these results. The exact details of the features and tag annotation approach are not the same, so it is hard to tell if the observed differences between algorithms are due to the feature set used or the tag annotation algorithm.

### 1.26.8 Visualization

Visualization is the display of information in such a way that relationships among data items and attributes can be analyzed and understood. It takes advantage of the strong pattern recognition properties of the human visual system. Traditional visualizations of music, such as the time domain waveforms and spectrograms, popular in audio editors convey very little information about the musical content and are focused on single music tracks. In this section we focus on visualizations of audio collections and associated information about them with specific emphasis on visualizing large collections of music. As we have already discussed a common approach in automatic analysis of music is to represent each track as a feature vector of fixed dimensionality (typical numbers range from 10 to 1000 dimensions). Dimensionality reduction methods try to transform these feature vectors to either 2 or 3 dimensions so that they can be visualized in a natural way by considering the transformed feature vector as a coordinate/point in a visual space. One of the most common technique for dimensionality reduction that can be used for visualization is Principal Component Analysis (or PCA). An alternative is the use of self-organizing maps (SOM) which attempt to perform both dimensionality reduction and clustering. These two methods underlie the majority of proposed music collection visualization systems. In this section we describe these two algorithms and describe generic visualization interfaces that can be built using them. Additional details such as how the user interacts with the generated visualization, the ability to zoom in and out, display hierarchies, etc. can be found in the further reading section.

Principal component analysis (PCA) converts a set of feature vectors with possibly correlated attributes into a set of feature vectors where the attributes are linearly uncorrelated. These new transformed attributes are called the principal components and when the method is used for dimensionality reduction their number is less than the number of original attributes. Intuitively this transformation can be understood as a projection of the original feature vectors to a new set of orthogonal axes (the principal components). The projection is such that each succeeding axis explains the highest variance of the original dataset possible, with the constraint that it is orthogonal to the preceding component. In a typical application scenario, where each song is represented by a 70 dimensional feature vector, the application of PCA to these feature vectors can then be used to convert them to 3 dimensional feature vectors which can be visualized as points in a 3D space. A common way of calculating PCA is based on the covariance matrix which is defined as:

$$C = \frac{1}{N} \sum B \times B^T, \quad (26.10)$$

where  $T$  denotes the transpose operator and  $B$  is the matrix resulting from subtracting the empirical mean of each dimension of the original data matrix consisting of the  $N$  feature vectors. The eigenvectors and eigenvalues of this covariance matrix are then computed and sorted in order of decreasing eigenvalue and the first  $K$  where  $K$  is the desired number of reduced dimensions are selected as the new basis

vectors. The original data can then be projected into the new space spanned by these basis functions, i.e., the principal components. PCA is a standard operation in statistics and it is commonly available in software package dealing with matrices.

One of the potential issues with PCA for music visualization is that, because it tries to preserve as much as possible the distances between points from the original feature space to the transformed feature space, it might leave large areas of the available visualized space empty of points. This is particularly undesirable in touch based interfaces, such as tablets, where in the ideal case, everywhere a user might press should trigger some music. Self-organizing maps are an approach that attempts to perform both dimensionality reduction and clustering while mostly preserving topology but not distances. It can result in more dense transformed feature spaces that are also discrete in nature in contrast to PCA which produces a transformed continuous space that needs to be discretized.

The SOM is a type of neural network used to map a high dimensional input feature space to a lower dimensional representation. It facilitates both similarity quantization and visualization. It was first documented in 1982 and since then it has been applied to a wide variety of diverse clustering tasks. The SOM maps the original  $d$ -dimensional feature vectors  $X \in \mathbb{R}^d$  to two discrete coordinates  $I \in [1 \dots M]$  and  $J \in [1 \dots N]$  on a rectangular grid.

The traditional SOM consists of a 2D grid of neural nodes each containing a  $n$ -dimensional vector,  $\mathbf{x}(t)$  of data. The goal of learning in the SOM is to cause different neighboring parts of the network to respond similarly to certain input patterns. This is partly motivated by how visual, auditory and other sensory information is handled in separate parts of the cerebral cortex in the human brain. The network must be fed a large number of example vectors that represent, as closely as possible, the kinds of vectors expected during mapping. The data associated with each node is initialized to small random values before training. During training, a series of  $n$ -dimensional vectors of sample data are added to the map. The “winning” node of the map known as the *best matching unit* (BMU) is found by computing the distance between the added training vector and each of the nodes in the SOM. This distance is calculated according to some pre-defined distance metric which in our case is the standard Euclidean distance on the normalized feature vectors.

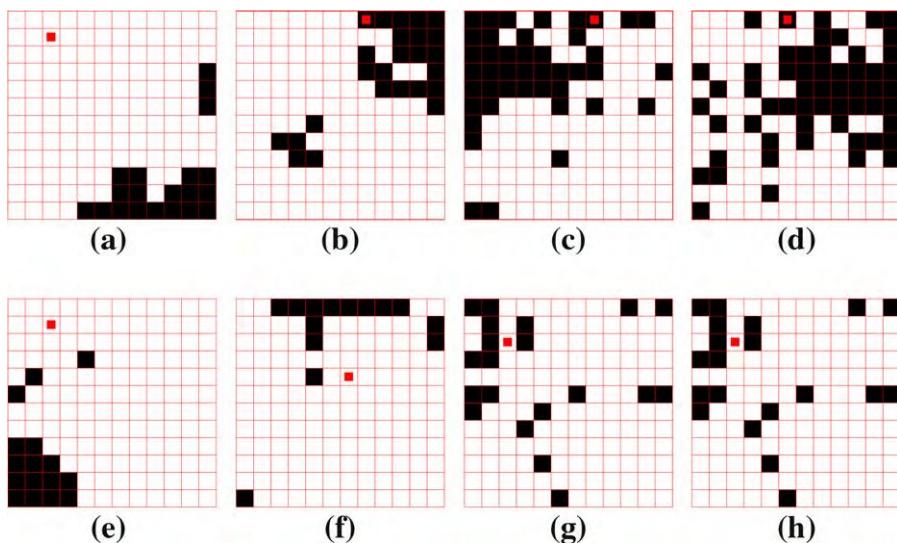

Once the winning node has been defined, it and its surrounding nodes reorganize their vector data to more closely resemble the added training sample. The training utilizes competitive learning. The weights of the BMU and neurons close to it in the SOM lattice are adjusted towards the input vector. The magnitude of the change decreases with time and with distance from the BMU. The time-varying learning rate and neighborhood function allow the SOM to gradually converge and form clusters at different granularities. Once a SOM has been trained, data may be added to the map simply by locating the node whose data is most similar to that of the presented sample, i.e., the winner. The reorganization phase is omitted when the SOM is not in the training mode.

The update formula for a neuron with representative vector  $\mathbf{N}(t)$  can be written as follows:

$$\mathbf{N}(t+1) = \mathbf{N}(t) + \Theta(v, t)\alpha(t)(\mathbf{x}(t) - \mathbf{N}(t)), \quad (26.11)$$

where  $\alpha(t)$  is a monotonically decreasing learning coefficient and  $x(t)$  is the input vector. The neighborhood function  $\Theta(v, t)$  depends on the lattice distance between the BMU and neuron  $v$ .

Figure 26.8 illustrates the ability of the automatically extracted audio features and the SOM to represent musical content. The top subfigures (a)–(d) show how different musical genres are mapped to different regions of the SOM grid (the black squares are the ones containing one or more songs from

**FIGURE 26.8**

Topological mapping of musical content by the self-organizing map. (a) Classical, (b) metal, (c) hiphop, (d) rock, (e) Bob Marley, (f) radiohead, (g) Led Zappelin (h) Dexter Gorden.

each specific genre). As can be seen Classical, Heavy Metal and HipHop are well-localized and distinct whereas Rock is more spread out reflecting its wide diversity. The SOM is trained on a collection of 1000 songs spanning 10 genres. The bottom subfigures (e)–(h) show how different artists are mapped to different regions of the SOM grid. The SOM in this case is trained on a diverse personal collection of 3000 songs spanning many artists and genres. It is important to note that in all these cases the only information used is actual audio signal that is automatically analyzed and no meta data. The locations of the genres/artists are emergent properties of the SOM and demonstrate how it organizes semantically the data.

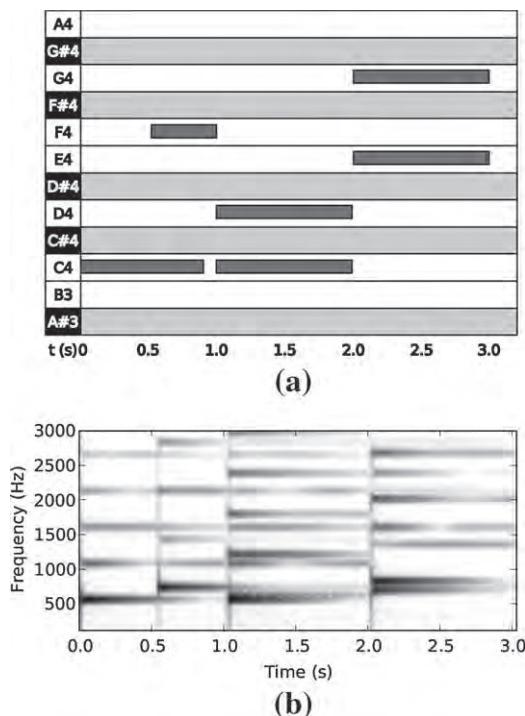

### 1.26.9 Advanced music mining

In addition to the music mining tasks that have been presented in this chapter, there are several additional topics and tasks that are more briefly described in this section. The decision to not cover them in more detail, had more to do with the limited amount of published work related to them and their usage of more recent and complex mining algorithms, rather than their importance. In many cases, they also lack commonly available data-sets and agreed upon evaluation methodologies. Multiple instance learning is a classification technique in which ground truth is provided for sets (bags) of instances rather than individual instances. A classic example in music mining is that frequently it is possible to obtain classification or retrieval ground truth for artists but the desired classification granularity is for songs. As multiple songs correspond to the same artist and the ground truth labeling does not necessarily apply to all of them, this problem is a natural fit for multiple instance learning. Semi-supervised learning is

a type of machine learning that makes use of both labeled and unlabeled data for training. It useful in scenarios where there is a limited amount of ground truth data available but large amounts of data that are unlabeled are also available.

### 1.26.9.1 Symbolic music mining

Music especially classical and to some extent popular music can be represented symbolically using representations that are similar to a music score, i.e., they encode which notes are played and at what time. A score is an abstract and structured representation. It can be interpreted in different ways by varying timing or even instrumentation depending on the performer. It can be viewed as a platonic ideal of a song that is normalized with respect to many details such as timbre, pitch and timing variations that complicate audio analysis. At the same time, because the information is discrete and structured it enables types of processing that are very difficult to perform with audio signals. For example it is possible to search efficiently for melodic patterns in large collections of symbolic data. There are several possible symbolic representations for music. The simplest form consists of simply the start and duration of a set of discrete notes or pitches. *MIDI* (Music Interface for Digital Instruments) files mostly contain this information. More expressive formats, such as *Music XML* can express additional information

**FIGURE 26.9**

Piano roll symbolic representation (a) and associated spectrogram (b).

such as graphic characteristics of the musical scores. Figure 26.9 relates a spectrogram representation with a corresponding symbolic representation using the so called piano roll notation. Algorithms from text mining, discrete mathematics and theoretical computer science are used in this research. It is also frequently driven by musicological considerations.

In the same way that the canonical example of music mining for audio signals is automatic genre classification, the canonical example of symbolic music information is searching for a particular monophonic melodic sequence in a database of melodies. This task has, for example, applications in *Query-by-humming* (QBH) systems where the user sings a melody and the best match is returned as a music file that can be played. Even though some systems only check for exact matches, in most cases, some form of approximate matching is utilized. Melodies are represented as one dimensional strings of characters, where each character represents either a discrete pitch or interval between succeeding pitches. The large literature on string matching algorithms such as editing distances, finding the longest common subsequence, or finding occurrences of one string in another can then be utilized for symbolic music mining. When melody matching needs to be performed in polyphonic audio or the query itself is polyphonic more sophisticated techniques based on computational geometry are utilized. Finally most of the music mining tasks described for audio signals can also be applied to symbolic music signals provided an appropriate feature representation is used. For example features computed from *MIDI* file such as average interval size, highest note, lowest note, etc. can be used as a feature representation for classification tasks.

### 1.26.9.2 Bridging symbolic and audio music mining

*Automatic transcription* refers to the process of essentially converting an audio recording to a symbolic representation. Figure 26.9 shows this process graphically. As can be seen the overlapping harmonic structure of notes makes it harder to separate them in a polyphonic context. Automatic transcription is a hard problem, and although significant progress has been made, it is still not very accurate for real world recordings. There are various simpler tasks related to bridging audio and symbolic representations that have been investigating with more successful results. Audio chord and key detection compute an abstract symbolic representation, i.e., a list of chord symbols for a music track. As an example application, using dynamic time warping (DTW) over chroma representations it is possible to find the correspondence between a symbolic representation and an audio recording. This problem is termed *Polyphonic audio alignment* or score following when it is performed in a real-time fashion. Combinations of symbolic and audio representations can also be used to enable new forms of querying musical data. For example in query-by-humming systems, the user sings or hums a melody and an audio recording that contains the melody is returned. It is also possible to analyze the internal structure of a music piece in terms of repeated sections such as the chorus or a bridge. This process has been termed *structure analysis*. By combining symbolic and audio representations we gain more insight in the complexity and structure of music. In turn, this can inform the more general music mining tasks we have described in this chapter. A task that has received some attention in the popular press but for which there has been no convincing demonstration is hit song science or popularity prediction. The idea is that somehow by analyzing audio and text features one might be able to predict whether a song will be a hit or how popular it will be before it is released on the market.

## 1.26.10 Software and datasets

Although frequently researchers implement their own audio feature extraction algorithms, there are several software collections that are freely available that contain many of the methods described in this chapter. They have enabled researchers more interested in the data mining and machine learning aspects of music analysis to build systems more easily. They differ in the programming language/environment they are written, the computational efficiency of the extraction process, their ability to deal with batch processing of large collections, their facilities for visualizing feature data, and their expressiveness/flexibility in describing complex algorithms.

Table 26.7 summarizes information about some of the most commonly used software resources as of the year 2012. The list is by no means exhaustive but does provide reasonable coverage of what is available in 2012. Some of these links contains collections of code and others more integrated frameworks. Most of the toolkits support some form of audio feature extraction. Some also include music mining algorithms but in many cases researchers rely on other general purpose machine learning and data mining software. Several of the figures in this chapter were created using *Marsyas* and some using custom MATLAB code. In general, although there are exceptions, software in MATLAB tends to be less efficient and more suited for prototyping than C/C++ software that is more efficient for large scale problems. An alternative to using a software toolkit is to utilize audio features provided by a web service such as the Echonest API.

Over time, several audio datasets and their associated ground truth have been collected and used to evaluate different music mining tasks. For more mature music mining tasks they have enabled, to some degree, comparison of different systems and reproducibility of results. Table 26.8 summarizes information about some of the common datasets used and their characteristics as available in 2012. Almost all of the datasets can be used for experiments in mining especially for tasks that can be performed

without ground truth such as similarity retrieval. In addition, several of them provide ground truth for one or more tasks. In many cases, they also contain computed audio features which is particular useful for researchers coming from the more general data mining research. The academic music information retrieval community has been fortunate to have help from industry in creating datasets. For example, the *Magnatagatune* (MGTTUNE) dataset was created with help from the *Magnatune* recording label. Another example of a dataset created with help from industry (EchoNest) is the recent and impressive in scope *Million Song Dataset* (MSD). It is a freely-available collection of audio features and metadata for a million popular music tracks. It also contains additional data such as sets of cover songs, lyrics, song-level tags and similarity and user data. Several datasets are also associated with MIREX tasks. In many cases, they are not accessible for experimentation and participants have to submit their algorithms which are executed by the MIREX organizers in order to get evaluation results.

### 1.26.11 Open problems and future trends

Music information retrieval and more specifically music mining are relatively new emerging research areas so there are many unexplored directions with significant challenges that can be investigated. Music information is multi-faceted, multi-disciplinary, multi-cultural, multi-modal and all these aspects complicate music mining. In this section some open problems and future trends are briefly described. In many of the music mining tasks that have been described in this chapter the assumptions they make are at the extremes of more nuanced differences encountered in the real world. For example music recommendation systems are either general in the sense that for a particular query they recommend the same set of similar tracks independently of who the user is, or they are highly personalized. Similarly, human genre annotations are not consistent but at the same time are not completely personalized. The reality is that probably listeners form social groups/clusters with similar taste. There is a lot of interesting work that can be done to leverage this group membership for more effective recommendations. There is a lot of context information that can also be taken into account. Typical listeners have different listening

preferences depending on the time of the day or the activity they are performing. Given the ubiquity of mobile devices that have geolocation capabilities can we leverage this information to adjust music recommendation to particular activities for a particular user? Recent advances in neuro-imaging have also made possible the monitoring of brain activity while listening to music. The resulting data is high dimensional and difficult to interpret but maybe in the future it will help lead to a better understanding of how our brain interprets music. Such understanding might radically change how we think about music mining.

A big area of future research is audio feature extraction. Existing features are rather crude, low level statistical descriptions that clearly do not capture a lot of the structure and complexity of music. A particularly interesting area that is receiving a lot of attention at the moment in the machine learning community is *Deep Belief Networks (DBN)*. They are a family of machine learning algorithms that are able to learn higher level abstract representations from lower level input signals in the context of classification problems. Another interesting challenge is that music unfolds over time at multiple levels. Many existing approaches to audio feature extraction and music mining ignore this temporal evolution or approximate it using rather crude models of dynamics. The majority of existing systems utilize one source of information and even in the cases where multiple source of information are utilized, their fusion is performed simply and directly. The integration of information from multiple facts at many different time scales is a big challenge for existing mining algorithms.

Another big limiting assumption that the majority of existing algorithm for music mining make is that the music is characterized statistically as a mixture without taking into account that it is composed of individual sound sources. At the same time, it is clear that as humans we pay a lot of attention and are able, to a large extent, to characterize and follow these individual sound sources in complex mixtures over time. This is true for both musically trained listeners and ones that are not. Separating a complex mixture of sounds to the individual components is called sound source separation and is a problem with a lot of existing literature but still far away from being solved. Even if it is solved it is unclear how all these individual sound sources, and their corresponding information can be combined for higher level music mining tasks.

Historically MIR originated from work in digital libraries and text retrieval. Therefore it has retained this focus on processing of large archives of existing music. However, new music is created, performed every day and increasingly computers are used for its production, distribution and consumption. There is a lot of potential in using MIR techniques in the context of music creation and especially live music performance. However, many of the developed techniques are not designed to work in real-time and be interactive.

The amount of data that needs to be processed constantly poses scalability challenges. For example if we expand the scope of research from recorded music by labels to all the amateur video and audio recordings uploaded on the web it will increase the number of files to be processed by one or maybe even two orders of magnitude. As audio signal processing and machine learning techniques become more sophisticated they became more computationally demanding. Important issues of scalability and parallel implementation will continue to arise making techniques that are practical in a few thousand tracks obsolete or practically infeasible in collections of a million music tracks. As collections get bigger an important consideration is music and recording quality. To most existing music mining systems a piece performed by the same combination of instruments by professional musicians and a high school cover band essentially have the same representation.

The way listeners react to music is constantly changing and varies among different age groups and cultures. Even though western popular music has been dominating music listening around the world, there is a lot of interesting work that can be done in applying music mining techniques to analyze other types of music from around the world. Such work falls under the area of computational ethnomusicology. The large diversity of music cultures can lead to specific mining problems that are variations of existing ones or completely new.

To conclude, mining music information is a complex, challenging and fascinating area of data mining. The challenges of scalability, time evolution, heterogeneous structured and unstructured representations, and personalization among others pose significant challenges to existing mining algorithms. Progress in music mining has the potential to lead to significant advances to data mining in general and the converse is also probably true. Finally music mining has already and will probably continue to affect the way music is produced, distributed, and consumed.

---

### 1.26.12 Further reading

In this section a number of pointers to relevant material to this chapter are provided. The list is not comprehensive but is a good representation of activity in the field. Music Information Retrieval is a relative new field with a history of a little bit more than 10 years [1]. Currently there is no comprehensive textbook that covers it fully. However, there are several related books and overview articles that are great starting points for learning more about the field. Orio [2] is an excellent, although somewhat outdated, tutorial and review of the field of MIR. A more recent collection of articles mostly focusing on music data management and knowledge discovery can be found in Shen et al. [3]. Many of the music mining tasks described in this chapter are covered in more detail in a recent collection of articles on music mining edited Li et al. [4]. The chapters on audio feature extraction, mood and emotional classification, web-based and community-based music information extraction, human computation for music classification, and indexing music with tags are particularly relevant.

The basic types of audio feature extraction, i.e., timbre, pitch and rhythm appear in a classic early paper on automatic genre classification [5]. Tempo induction refers to the specific problem of estimating a global tempo for a piece of music but the basic algorithms used are common to any type of rhythm analysis. Gouyon et al. [6] provide an experimental investigation of different tempo induction algorithms. Various types of pitch representations have been investigated especially in the context of chord and key detection [7]. An early seminal work showing how to combine text and audio features for extracting music information is Whitman and Smaragdis [8] and subsequent work has explored the text analysis of lyrics [9], web-based data [10] and microblogs [11].

The strategies and challenges of ground truth acquisition have been explored for music similarity [12], genre classification [13], and tag annotation [14]. An overview of the Music Information Retrieval eXchange (MIREX) for the years 2005–2007 can be found in Downie [15]. An early critical review of content-based music similarity approaches can be found in Aucouturier and Pachet [16]. It has been followed by many publications mostly focusing on how music similarity can be improved with better audio features, integration with text and context features, and design of better similarity metrics [16, 17]. High level overviews of audio fingerprinting systems have been provided by Wang [18] and Haitsma and Kalker [19], and a good review of different algorithms can be found in Cano et al. [20]. Two well

known cover song detection systems are Ellis and Poliner [21] and Serra et al. [22]. A comparative study of different component choices for cover song retrieval systems can be found in Liem and Hanjalic [23].

Classification, clustering, and regression are standard problems in data mining and pattern recognition and therefore well covered in many textbooks [24,25]. There is a large literature in automatic genre classification [5,26,27], in many cases showing that feature sets based on different musical aspects such as harmony and rhythm are all important and their combination gives better results than they do in isolation. Hierarchical classification can be performed by modeling the hierarchy as a Bayesian network [28]. A user study investigating the perception of top-level music genres by average listeners can be found in [29] and a comparison between automatic classification and annotation by users can be found in Lippens et al. [13]. An overview and critical discussion of genre classification can be found in McKay and Fujinaga [30]. Representative examples of emotion spaces that have been used in music mining are the groupings of adjectives used to describe classical music pieces by Hevner [31] as well as the 2D emotional space described by Theyer [32]. Emotion/mood recognition [33] using audio and text features has been covered in [9,34] among others. Regression can also be used for automatic emotion analysis of music [35]. Li et al. propose a clustering algorithm that combines both lyrics and audio features to perform bimodal learning [36].

Work on associating music with text using audio content analysis and machine learning started as early as 2002 [8], not using tags per se, but using keywords extracted from web-pages that ranked highly in search engine results for particular artists. Around 2007–2008, as social tag annotation became more common, some of the first papers that focused on automatic tag annotation for music started appearing in the literature, using different classification approaches and audio feature sets. For example, AdaBoost was used for tag prediction in Eck et al. [37]. A Gaussian Mixture Model over the audio feature space is trained for each word in a vocabulary in the seminal paper on semantic annotation by Turnbull et al. [38]. This work also provided the *CAL500* dataset that since then has frequently been used to evaluate tag annotation systems. Stacking for music tag annotation was originally proposed in [39]. The user evaluation of automatic tag annotation system as well as an machine learning approach that works with an open tag vocabulary has been described by Law et al. [40].

Various approaches to visualization in audio-based music information retrieval are surveyed in Cooper et al. [41]. The use of self-organizing maps in music visualization was popularized by the Islands of Music system that rendered the resulting self-organized map as a set of islands (areas of the grid where many songs were mapped) surrounded by ocean (areas of the grid where fewer songs were mapped) [42]. A number of music mining tasks have been formulated as multiple instance learning by Mandel and Ellis [43]. Symbolic music information retrieval can be done using polyphonic queries and references using a variety of methods based on string and geometric approaches [44]. Structure analysis is typically performed using self-similarity matrices [45]. The most common approach for polyphonic audio score alignment is based on calculating the distance (or similarity) matrix between two sequences typically of chroma vectors and performing dynamic time warping [46,47]. A excellent overview of signal processing methods for music transcription has been edited by Klapuri and Davy [48]. A critical view on hit song science can be found in Pachet and Roy [49]. The problem of identifying similar artists using both lyrics and acoustic data has been explored using a semi-supervised learning approach in which a small set of labeled samples are supplied for the seed labeling and then used to build classifiers that improve themselves using unlabeled data [50].

---

## Glossary

AdaBoost	a family of classification algorithms
Artist Filter	a preprocessing technique used in music mining task that ensures that tracks of the same artist are either part of the training set or the testing set but not both
Audio Fingerprinting	an algorithm for determining whether two digital audio files correspond to the same underlying recording
Beat Histogram (Spectrum)	a representation of the rhythmic content of a piece of music in terms of the amount of energy in different rhythm-related periodicities that are present
Chroma	a representation of the pitch content of a piece of music
Chromagram	a sequence of chroma vectors that can be visualized as an image
Collaborative Filtering	a technique for recommending items based on the purchase history of users
Cosine Similarity	a method of computing similarity between two vectors based on the cosine of the angle between them
Discriminatory Classifiers	a family of classification algorithms in which the goal is to discriminate between the classes directly without modeling the distribution of all the sample feature vectors but only the ones that affect the decision boundary
EM-algorithm	a algorithm for training Gaussian Mixture Models
Emotion Space	a multi-dimensional representation that maps different human emotions and their relations
F-Measure	a performance measure for retrieval algorithms
Games with a Purpose (GWAP)	computer games that in addition to being engaging and entertaining provide useful information for training computers
Gaussian Models	a parametric family of probability density functions
Gaussian Mixture Model	a method for modeling a probability density function as a combination of Gaussian components
Generative Classifiers	a family of classification algorithms in which the training data is modeled by estimating probability density functions that can generate new sample feature vectors
Genre	a categorical label that characterizes a particular type of music
Ground Truth	the information needed for training and evaluating a mining algorithm
Harmonic Pitch Class Profiles	a representation of pitch content for audio signals similar in nature to Chroma
Harmony	the structure of piece of music in terms of combinations of discrete notes or pitches

Hidden Markov Models (HMM)	a probabilistic techniques for modeling sequence of feature vectors
ISMIR	the annual International conference of the Society for Music Information Retrieval
K-Fold Cross Validation	a methodology for evaluating classification performance
K-Means	a standard clustering algorithm
Last.fm	an internet music recommendation service
Mean Average Precision:	a performance measure for retrieval algorithms across multiple queries
Mel-Frequency Cepstral Coefficients (MFCC)	a set of audio features frequently used in MIR that originated in speech processing
Musical Instrument Digital Interface (MIDI)	a symbolic format for transmitting and storing music related information
Music Information Retrieval (MIR)	the research area dealing with all aspects of retrieving information from music signals that are stored digitally
Music Information Retrieval Evaluation Exchange (MIREX)	an annual campaign for evaluating different algorithms on a variety of MIR tasks
Music XML	a symbolic format for representation all aspects of notated music
Naive Bayes	a family of parametric classification algorithms
Nearest Neighbor Classifier	a family of non-parametric classification algorithms
Pandora	an internet personalized radio station
Pitch Class Profiles	a representation of the pitch content of a piece of music
Precision	a performance measure for retrieval algorithms
Principle Component Analysis	a technique for dimensionality reduction
Query-by-Humming (QBH)	the task of matching a sung melody to a database of music tracks in either symbolic, or audio format
Recall	a performance measure for retrieval algorithms
Receiver Opeating Characteristic (ROC)	a graphical representation used to characterize retrieval systems
Rhythm	the structure of a piece of music over time
Self-Organizing Maps (SOM)	a dimensionality reduction and clustering techniques that maps high dimensional feature vectors into a discrete set of locations
Short Time Fourier Transfrom (STFT)	a transformation of a time varying signal to a time-frequency representation
Similarity Retrieval	a music mining task where a query music track is provided by the user and a set of tracks that are similar to it are returned by the system
Spectrum	a representation of a signal in terms of the amounts of different frequencies
Stacking	a methodology for combining binary classifiers for multi-label classification
Support Vector Machines	a family of discriminative classification algorithms

Tags	words from an open vocabulary supplied by users to characterize multimedia objects such as music tracks, images, and videos
Term Weighting	a technique from text mining in which different words get assigned different weights when considering the similarity of documents
Timbre	the properties that characterize a particular sound source when compared with other sound sources of the same pitch and loudness

---

## Acknowledgments

The author would like to thank Tiago Fernandes Tavares and Steven Ness for help with preparing the figures for this chapter. Moreover, the author would like to thank the many researchers from a variety of disciplines who have helped music information retrieval and, more specifically, music mining grow and evolve. Their efforts have made the work described in this chapter possible and the author is proud to have been a part of this amazing community from its inception.

*Relevant Theory:* Signal Processing Theory and Machine Learning

 subsampling, 474

Wavelet transform  
 applications, 514  
 classical 2-D function, 533–534  
 continuous signal, 477  
 dilations and translations, 473–474  
 dimensionality reduction, 478  
 dyadic sampling, 517  
 8-tap orthogonal filter, 448  
 filter banks, 444–445  
 5-/3-tap symmetric filter, 447  
 4-tap orthogonal filter, 447  
 Laplacian pyramid, 522

lifting step, 448  
 local cosine bases, 485  
 lowpass filter, 545  
 mathematical properties, 467  
 multiscale analysis, 476  
 9-/7-tap symmetric filter, 448  
 packet bases, 486  
 properties, 481  
 reconstruction formula, 476  
 smoothness, 481  
 spectral factorization, 444, 446  
 symmetry, 482  
 trous algorithm, 516  
 vanishing moments, 481

Weight-error, covariance matrix, 693–694  
 Weyl-Heisenberg or Gabor frame, 575  
 Whiteness, 1161  
 Widely-linear complex  
 filter, 663  
 least-mean squares, 662  
 Wirtinger's Calculus, 672  
 application, 926–927  
 in complex LMS, 925–926  
 in Pure Complex KLMS (PCKLMS), 928

Wirtinger derivatives  
 Cauchy-Riemann conditions, 671–672  
 minimization problem, 670–671  
 quadratic function, 674  
 real functions of complex variables, 672

**Z**

Zero and non-zero mean variables, 655  
 extended regressor, 656–657  
 extended weight vector, 656–657  
 z-transform, polyphase decomposition, 472
