# Introduction

## Signal Processing at Your Fingertips!

Let us flash back to the 1970s when the editors-in-chief of this e-reference were graduate students. One of the time-honored traditions then was to visit the libraries several times a week to keep track of the latest research findings. After your advisor and teachers, the librarians were your best friends. We visited the engineering and mathematics libraries of our Universities every Friday afternoon and poured over the IEEE Transactions, Annals of Statistics, the Journal of Royal Statistical Society, Biometrika, and other journals so that we could keep track of the recent results published in these journals. Another ritual that was part of these outings was to take sufficient number of coins so that papers of interest could be xeroxed. As there was no Internet, one would often request copies of reprints from authors by mailing postcards and most authors would oblige. Our generation maintained thick folders of hard-copies of papers. Prof. Azriel Rosenfeld (one of RC's mentors) maintained a library of over 30,000 papers going back to the early 1950s!

Another fact to recall is that in the absence of Internet, research results were not so widely disseminated then and even if they were, there was a delay between when the results were published in technologically advanced western countries and when these results were known to scientists in third world countries. For example, till the late 1990s, scientists in US and most countries in Europe had a lead time of at least a year to 18 months since it took that much time for papers to appear in journals after submission. Add to this the time it took for the Transactions to go by surface mails to various libraries in the world. Scientists who lived and worked in the more prosperous countries were aware of the progress in their fields by visiting each other or attending conferences.

Let us race back to 21st century! We live and experience a world which is fast changing with rates unseen before in the human history. The era of Information and Knowledge societies had an impact on all aspects of our social as well as personal lives. In many ways, it has changed the way we experience and understand the world around us; that is, the way we learn. Such a change is much more obvious to the younger generation, which carries much less momentum from the past, compared to us, the older generation. A generation which has grew up in the Internet age, the age of Images and Video games, the age of IPAD and Kindle, the age of the fast exchange of information. These new technologies comprise a part of their "real" world, and Education and Learning can no more ignore this reality. Although many questions are still open for discussions among sociologists, one thing is certain. Electronic publishing and dissemination, embodying new technologies, is here to stay. This is the only way that effective pedagogic tools can be developed and used to assist the learning process from now on. Many kids in the early school or even preschool years have their own IPADs to access information in the Internet. When they grow up to study engineering, science, or medicine or law, we doubt if they ever will visit a library as they would by then expect all information to be available at their fingertips, literally!

Another consequence of this development is the leveling of the playing field. Many institutions in lesser developed countries could not afford to buy the IEEE Transactions and other journals of repute. Even if they did, given the time between submission and publication of papers in journals and the time it took for the Transactions to be sent over surface mails, scientists and engineers in lesser developed countries were behind by two years or so. Also, most libraries did not acquire the proceedings of conferences and so there was a huge gap in the awareness of what was going on in technologically advanced

countries. The lucky few who could visit US and some countries in Europe were able to keep up with the progress in these countries. This has changed. Anyone with an Internet connection can request or download papers from the sites of scientists. Thus there is a leveling of the playing field which will lead to more scientist and engineers being groomed all over the world.

The aim of Online Reference for Signal Processing project is to implement such a vision. We all know that asking any of our students to search for information, the first step for him/her will be to click on the web and possibly in the Wikipedia. This was the inspiration for our project. To develop a site, related to the Signal Processing, where a selected set of reviewed articles will become available at a first “click.” However, these articles are fully refereed and written by experts in the respected topic. Moreover, the authors will have the “luxury” to update their articles regularly, so that to keep up with the advances that take place as time evolves. This will have a double benefit. Such articles, besides the more classical material, will also convey the most recent results providing the students/researchers with up-to-date information. In addition, the authors will have the chance of making their article a more “permanent” source of reference, that keeps up its freshness in spite of the passing time.

The other major advantage is that authors have the chance to provide, alongside their chapters, any multimedia tool in order to clarify concepts as well as to demonstrate more vividly the performance of various methods, in addition to the static figures and tables. Such tools can be updated at the author’s will, building upon previous experience and comments. We do hope that, in future editions, this aspect of this project will be further enriched and strengthened.

In the previously stated context, the Online Reference in Signal Processing provides a revolutionary way of accessing, updating and interacting with online content. In particular, the Online Reference will be a living, highly structured, and searchable peer-reviewed electronic reference in signal/image/video Processing and related applications, using existing books and newly commissioned content, which gives tutorial overviews of the latest technologies and research, key equations, algorithms, applications, standards, code, core principles, and links to key Elsevier journal articles and abstracts of non-Elsevier journals.

The audience of the Online Reference in Signal Processing is intended to include practicing engineers in signal/image processing and applications, researchers, PhD students, post Docs, consultants, and policy makers in governments. In particular, the readers can be benefited in the following needs:

- To learn about new areas outside their own expertise.
- To understand how their area of research is connected to other areas outside their expertise.
- To learn how different areas are interconnected and impact on each other: the need for a “helicopter” perspective that shows the “wood for the trees.”
- To keep up-to-date with new technologies as they develop: what they are about, what is their potential, what are the research issues that need to be resolved, and how can they be used.
- To find the best and most appropriate journal papers and keeping up-to-date with the newest, best papers as they are written.
- To link principles to the new technologies.

The Signal Processing topics have been divided into a number of subtopics, which have also dictated the way the different articles have been compiled together. Each one of the subtopics has been coordinated by an AE (Associate Editor). In particular:

1. Signal Processing Theory (Prof. P. Diniz)
2. Machine Learning (Prof. J. Suykens)
3. DSP for Communications (Prof. N. Sidiropoulos)
4. Radar Signal Processing (Prof. F. Gini)
5. Statistical SP (Prof. A. Zoubir)
6. Array Signal Processing (Prof. M. Viberg)
7. Image Enhancement and Restoration (Prof. H. J. Trussell)
8. Image Analysis and Recognition (Prof. Anuj Srivastava)
9. Video Processing (other than compression), Tracking, Super Resolution, Motion Estimation, etc. (Prof. A. R. Chowdhury)
10. Hardware and Software for Signal Processing Applications (Prof. Ankur Srivastava)
11. Speech Processing/Audio Processing (Prof. P. Naylor)
12. Still Image Compression
13. Video Compression

We would like to thank all the Associate Editors for all the time and effort in inviting authors as well as coordinating the reviewing process. The Associate Editors have also provided succinct summaries of their areas.

The articles included in the current editions comprise the first phase of the project. In the second phase, besides the updates of the current articles, more articles will be included to further enrich the existing number of topics. Also, we envisage that, in the future editions, besides the scientific articles we are going to be able to include articles of historical value. Signal Processing has now reached an age that its history has to be traced back and written.

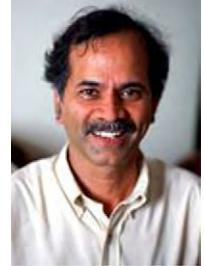

Last but not least, we would like to thank all the authors for their effort to contribute in this new and exciting project. We earnestly hope that in the area of Signal Processing, this reference will help level the playing field by highlighting the research progress made in a timely and accessible manner to anyone who has access to the Internet. With this effort the next breakthrough advances may be coming from all around the world.

The companion site for this work: <http://booksite.elsevier.com/9780124166165> includes multimedia files (Video/Audio) and MATLAB codes for selected chapters.

Rama Chellappa  
Sergios Theodoridis

# About the Editors

**Rama Chellappa** received the B.E. (Hons.) degree in Electronics and Communication Engineering from the University of Madras, India in 1975 and the M.E. (with Distinction) degree from the Indian Institute of Science, Bangalore, India in 1977. He received the M.S.E.E. and Ph.D. Degrees in Electrical Engineering from Purdue University, West Lafayette, IN, in 1978 and 1981, respectively. During 1981–1991, he was a faculty member in the department of EE-Systems at University of Southern California (USC). Since 1991, he has been a Professor of Electrical and Computer Engineering (ECE) and an affiliate Professor of Computer Science at University of Maryland (UMD), College Park. He is also affiliated with the Center for Automation Research, the Institute for Advanced Computer Studies (Permanent Member) and is serving as the Chair of the ECE department. In 2005, he was named a Minta Martin Professor of Engineering. His current research interests are face recognition, clustering and video summarization, 3D modeling from video, image and video-based recognition of objects, events and activities, dictionary-based inference, compressive sensing, domain adaptation and hyper spectral processing.

Prof. Chellappa received an NSF Presidential Young Investigator Award, four IBM Faculty Development Awards, an Excellence in Teaching Award from the School of Engineering at USC, and two paper awards from the International Association of Pattern Recognition (IAPR). He is a recipient of the K.S. Fu Prize from IAPR. He received the Society, Technical Achievement, and Meritorious Service Awards from the IEEE Signal Processing Society. He also received the Technical Achievement and Meritorious Service Awards from the IEEE Computer Society. At UMD, he was elected as a Distinguished Faculty Research Fellow, as a Distinguished Scholar-Teacher, received an Outstanding Innovator Award from the Office of Technology Commercialization, and an Outstanding GEMSTONE Mentor Award from the Honors College. He received the Outstanding Faculty Research Award and the Poole and Kent Teaching Award for Senior Faculty from the College of Engineering. In 2010, he was recognized as an Outstanding ECE by Purdue University. He is a Fellow of IEEE, IAPR, OSA, and AAAS. He holds four patents.

Prof. Chellappa served as the Editor-in-Chief of IEEE Transactions on Pattern Analysis and Machine Intelligence. He has served as a General and Technical Program Chair for several IEEE international and national conferences and workshops. He is a Golden Core Member of the IEEE Computer Society and served as a Distinguished Lecturer of the IEEE Signal Processing Society. Recently, he completed a two-year term as the President of the IEEE Biometrics Council.

**Sergios Theodoridis** is currently Professor of Signal Processing and Communications in the Department of Informatics and Telecommunications of the University of Athens. His research interests lie in the areas of Adaptive Algorithms and Communications, Machine Learning and Pattern Recognition, Signal Processing for Audio Processing and Retrieval. He is the co-editor of the book “Efficient Algorithms for Signal Processing and System Identification,” Prentice Hall 1993, the co-author of the best selling book “Pattern Recognition,” Academic Press, 4th ed. 2008, the co-author of the book “Introduction to Pattern Recognition: A MATLAB Approach,” Academic Press, 2009, and the co-author of three books in Greek, two of them for the Greek Open University. He is Editor-in-Chief for the Signal Processing Book Series, Academic Press and for the E-Reference Signal Processing, Elsevier.

He is the co-author of six papers that have received best paper awards including the 2009 IEEE Computational Intelligence Society Transactions on Neural Networks Outstanding paper Award. He has served as an IEEE Signal Processing Society Distinguished Lecturer. He was *Otto Monstead Guest Professor*, Technical University of Denmark, 2012, and holder of the *Excellence Chair*, Department of Signal Processing and Communications, University Carlos III, Madrid, Spain, 2011.

He was the General Chairman of EUSIPCO-98, the Technical Program co-Chair for ISCAS-2006 and ISCAS-2013, and co-Chairman and co-Founder of CIP-2008 and co-Chairman of CIP-2010. He has served as President of the European Association for Signal Processing (EURASIP) and as member of the Board of Governors for the IEEE CAS Society. He currently serves as member of the Board of Governors (Member-at-Large) of the IEEE SP Society.

He has served as a member of the Greek National Council for Research and Technology and he was Chairman of the SP advisory committee for the Edinburgh Research Partnership (ERP). He has served as Vice Chairman of the Greek Pedagogical Institute and he was for 4 years member of the Board of Directors of COSMOTE (the Greek mobile phone operating company). He is Fellow of IET, a Corresponding Fellow of the Royal Society of Edinburgh (RSE), a Fellow of EURASIP, and a Fellow of IEEE.

# Section Editors

## Section 1

**Paulo S. R. Diniz** was born in Niterói, Brazil. He received the Electronics Engineering degree (Cum Laude) from the Federal University of Rio de Janeiro (UFRJ) in 1978, the M.Sc. degree from COPPE/UFRJ in 1981, and the Ph.D. from Concordia University, Montreal, P.Q., Canada, in 1984, all in electrical engineering.

Since 1979 he has been with the Department of Electronic Engineering (the undergraduate department) UFRJ. He has also been with the Program of Electrical Engineering (the graduate studies department), COPPE/UFRJ, since 1984, where he is presently a Professor. He served as Undergraduate Course Coordinator and as Chairman of the Graduate Department. He has also received the Rio de Janeiro State Scientist award, from the Governor of Rio de Janeiro state.

From January 1991 to July 1992, he was a visiting Research Associate in the Department of Electrical and Computer Engineering of University of Victoria, Victoria, B.C., Canada. He also holds a Docent position at Helsinki University of Technology (now Aalto University). From January 2002 to June 2002, he was a Melchor Chair Professor in the Department of Electrical Engineering of University of Notre Dame, Notre Dame, IN, USA. His teaching and research interests are in analog and digital signal processing, adaptive signal processing, digital communications, wireless communications, multirate systems, stochastic processes, and electronic circuits. He has published several refereed papers in some of these areas and wrote the books *ADAPTIVE FILTERING: Algorithms and Practical Implementation*, Springer, NY, Fourth Edition 2013, *DIGITAL SIGNAL PROCESSING: System Analysis and Design*, Cambridge University Press, Cambridge, UK, Second Edition 2010 (with E. A. B. da Silva and S. L. Netto), and *Block Transceivers: OFDM and Beyond*, Morgan & Claypool, Fort Collins, CO, 2012, (with W. A. Martins and M. V. S. Lim). He has served as General co-Chair of ISCAS2011 and Technical Program Chair of the 1995 MWSCAS both held in Rio de Janeiro, Brazil. He was also the Technical Program co-Chair of SPAWC2008. He has been on the technical committee of several international conferences including ICASSP, ISCAS, ICECS, EUSIPCO, and MWSCAS. He has served as the Vice President for region 9 of the IEEE Circuits and Systems Society and as Chairman of the DSP technical committee of the same Society. He is also a Fellow of IEEE (for fundamental contributions to the design and implementation of fixed and adaptive filters and Electrical Engineering Education). He has served as Associate Editor for the following Journals: IEEE Transactions on Circuits and Systems II: Analog and Digital Signal Processing from 1996 to 1999, IEEE Transactions on Signal Processing from 1999 to 2002, and the Circuits, Systems and Signal Processing Journal from 1998 to 2002. He was a Distinguished Lecturer of the IEEE Circuits and Systems Society for the year 2000–2001. In 2004 he served as Distinguished Lecturer of the IEEE Signal Processing Society and received the 2004 Education Award of the IEEE Circuits and Systems Society.

## Section 2

**Johan A.K. Suykens** received the master degree in ElectroMechanical Engineering and the Ph.D. degree in Applied Sciences from the Katholieke Universiteit Leuven, in 1989 and 1995, respectively. In 1996 he has been a Visiting Postdoctoral Researcher at the University of California, Berkeley. He has been a Postdoctoral Researcher with the Fund for Scientific Research FWO Flanders and is currently a Professor (Hoogleraar) with KU Leuven. He is author of the books “Artificial Neural Networks for Modeling and Control of Non-linear Systems” (Kluwer Academic Publishers) and “Least Squares Support Vector Machines” (World Scientific), co-author of the book “Cellular Neural Networks, Multi-Scroll Chaos and Synchronization” (World Scientific), and editor of the books “Nonlinear Modeling: Advanced Black-Box Techniques” (Kluwer Academic Publishers) and “Advances in Learning Theory: Methods, Models and Applications” (IOS Press). He is a Senior IEEE member and has served as associate editor for the IEEE Transactions on Circuits and Systems (1997–1999 and 2004–2007) and for the IEEE Transactions on Neural Networks (1998–2009). He received an IEEE Signal Processing Society 1999 Best Paper (Senior) Award and several Best Paper Awards at International Conferences. He is a recipient of the International Neural Networks Society INNS 2000 Young Investigator Award for significant contributions in the field of neural networks. He has served as a Director and Organizer of the NATO Advanced Study Institute on Learning Theory and Practice (Leuven 2002), as a program co-chair for the International Joint Conference on Neural Networks 2004 and the International Symposium on Non-linear Theory and its Applications 2005, as an organizer of the International Symposium on Synchronization in Complex Networks 2007 and a co-organizer of the NIPS 2010 workshop on Tensors, Kernels and Machine Learning. He has been awarded an ERC Advanced Grant 2011.

# Authors Biography

## CHAPTER 1

**Isabela Ferrão Apolinário** was born in Brasília, Brazil. She is currently studying Electronics Engineering in the Federal University of Rio de Janeiro (UFRJ) and will soon join an M.Sc. course in the same university.

Since 2010 she has been a member of the Audio Processing Group (GPA) from the Signal Processing Laboratory (LPS) and has been studying audio processing. She has worked as an undergraduate teaching assistance in Calculus II and Digital Signal Processing.

She is currently a student member of the IEEE Circuits and Systems Society. Her main interest is in digital audio signal processing, more specifically in Psychoacoustics and Audio 3D.

## CHAPTER 2

**José Antonio Apolinário** Junior graduated from the Military Academy of Agulhas Negras (AMAN), Brazil, in 1981 and received the B.Sc. degree from the Military Institute of Engineering (IME), Brazil, in 1988, the M.Sc. degree from the University of Brasília (UnB), Brazil, in 1993, and the D.Sc. degree from the Federal University of Rio de Janeiro (COPPE/UFRJ), Rio de Janeiro, Brazil, in 1998, all in electrical engineering. He is currently an Adjoint Professor with the Department of Electrical Engineering, IME, where he has already served as the Head of Department and as the Vice-Rector for Study and Research. He was a Visiting Professor at the em Escuela Politécnica del Ejército (ESPE), Quito, Ecuador, from 1999 to 2000 and a Visiting Researcher and twice a Visiting Professor at Helsinki University of Technology (HUT), Finland, in 1997, 2004, and 2006, respectively. His research interests comprise many aspects of linear and nonlinear digital signal processing, including adaptive filtering, speech, and array processing. He has organized and has been the first Chair of the Rio de Janeiro Chapter of the IEEE Communications Society. He has recently edited the book "QRDRRLS Adaptive Filtering" (Springer, 2009) and served as the Finance Chair of IEEE ISCAS 2011 (Rio de Janeiro, Brazil, May 2011). He is a senior member of the IEEE.

**Carla Liberal Pagliari** received the Ph.D. degree in electronic systems engineering from the University of Essex, UK, in 2000. Since 1993 she has been with the Department of Electrical Engineering at the Military Institute of Engineering (IME), Rio de Janeiro, Brazil. She took part in the team that worked toward the development of the Brazilian Digital Television System. Her research interests include image processing, digital television, image and video coding, stereoscopic and multiview systems, and computer vision. She is a senior member of the IEEE and served as the Local Arrangements Chair

of IEEE ISCAS 2011 (Rio de Janeiro, Brazil, May 2011). She is currently an Associate Editor of the journal Multidimensional Systems and Signal Processing.

## CHAPTER 3

**Leonardo Gomes Baltar** received his B.Sc. and M.Sc. degrees in Electrical Engineering from the Federal University of Rio de Janeiro (UFRJ), Brazil, in 2004 and 2006, respectively. Since 2006, he is with the Chair of Circuit Theory and Signal Processing at the Technical University of Munich (TUM), Germany, as a research and teaching assistant pursuing a Ph.D. degree. His activities are mainly in the area of digital signal processing techniques applied to wired and wireless communications systems including multirate systems, filter banks, block transforms, digital filters design, and efficient processing structures. He has been involved in the European FP7 project PHYDYAS and in projects with industrial partners.

**Josef A. Nossek** received his Dipl.-Ing. and Dr. techn. degrees from the Technical University of Vienna, Austria, in 1974 and 1980, respectively. He was for 15 years with Siemens AG, Munich, in the field of communications, including the position of Head of Radio Systems Design for digital communications. In 1989 he joined the Technical University of Munich (TUM), Germany, where he is full Professor and Head of the Chair for Circuit Theory and Signal Processing. He is a Fellow of IEEE since 1993 for his contributions to the design of discrete-time networks and technical leadership in the development of radio communication systems. He was the Editor-in-Chief of the IEEE Transactions on Circuits and Systems (1993–1995). He was President-Elect, President, and Past President of the IEEE Circuits and Systems Society (2001/02/03). In 1998 he received the Innovations Award of the Vodafone Foundation for excellent research in mobile communications. In 2008 he received the Education Award of the IEEE Circuits and Systems Society. In 2011 he received the IEEE Guillemin-Cauer Best Paper Award. Since 2009 he is member of acatech (National Academy of Science and Engineering). He is author or co-author of numerous publications and has given a number of invited plenary lectures. He was the President of VDE (2007–2008), the German Association of Electrical, Electronics and Information Engineering, and Vice-President of VDE (2009–2010).

## CHAPTER 4

**Luiz W. P. Biscainho** was born in Rio de Janeiro, Brazil, in 1962. He received the Electronics Engineering degree (magna cum laude) from the EE (now Poli) at Universidade Federal do Rio de Janeiro (UFRJ), Brazil, in 1985, and the M.Sc. and D.Sc. degrees in Electrical Engineering from the COPPE at UFRJ in 1990 and 2000, respectively. Having worked in the telecommunication industry between 1985 and 1993, Dr. Biscainho is now Associate

Professor at the Department of Electronics and Computer Engineering (DEL) of Poli and the Electrical Engineering Program (PEE) of COPPE (serving as Academic Coordinator in 2010), at UFRJ. His research area is digital signal processing, particularly audio processing and adaptive systems. He is currently a member of the IEEE (Institute of Electrical and Electronics Engineers), the AES (Audio Engineering Society), the SBrT (Brazilian Telecommunications Society), and the SBC (Brazilian Computer Society).

## CHAPTER 5

**Håkan Johansson** received the Master of Science degree in computer science and the Licentiate, Doctoral, and Docent degrees in Electronics Systems from Linkoping University, Sweden, in 1995, 1997, 1998, and 2001, respectively. During 1998 and 1999 he held a postdoctoral position at Signal Processing Laboratory, Tampere University of Technology, Finland. He is currently Professor in Electronics Systems at the Department of Electrical Engineering of Linkoping University. His research encompasses design and implementation of efficient and flexible signal processing (SP) systems, mainly for communication applications. During the past decade, he has developed many different SP algorithms for various purposes, including filtering, sampling rate conversion, signal reconstruction, and parameter estimation. He has developed new estimation and compensation algorithms for errors in analog circuits such as compensation of mismatch errors in time-interleaved analog-to-digital converters and mixers. He is one of the founders of the company Signal Processing Devices Sweden AB that sells this type of advanced signal processing. He is the author or co-author of four books and some 160 international journal and conference papers. He is the co-author of three papers that have received best paper awards and he has authored one invited paper in IEEE Transactions and four invited chapters. He has served as Associate Editor for IEEE Trans. on Circuits and Systems I and II, IEEE Trans. Signal Processing, and IEEE Signal Processing Letters, and he is currently an Area Editor of the Elsevier Digital Signal Processing journal and a member of the IEEE Int. Symp. Circuits. Syst. DSP track committee.

## CHAPTER 6

**Lars Wanhammar** was born in Vansbro, Sweden, on August 19, 1944. He has received the following degrees: Teknisk magister (teknisk fysik) in 1970, civilingenjör in 1980, teknisk doktor in 1981, and docent in 1986, in electrical engineering from Linköping University, Sweden. During 1964–1970 he worked at Televerket (Royal Swedish Telephone Board), Division of Communication and during 1970–1971 as a Lecturer at the technical college in Norrköping. Since 1971 he has been working at Linköping University, Department of Electrical Engineering, Division of Applied Electronics, as Assistant, Research Assistant, and from 1982 as Associate Professor (universitetslektor) and from 1997 as full Professor and Head of the Division of Electronics Systems, at the Department of Electrical Engineering, Linköping University, Sweden. From 2011 he is currently Professor Emeritus.

## **xxxviii Authors Biography**

In addition, from 1995 to 2004 he worked as Adjunct Professor at the Norwegian Institute of Technology (NTNU) at the departments of Physical Electronics and Telecommunications.

His research interests are primary theory and design of digital signal processing and telecommunication systems, particularly analog and digital filters, and discrete transforms as well as computational properties of DSP algorithms, bit-serial, digit-serial and distributed arithmetic, CAD tools, and globally asynchronous locally synchronous techniques for ULSI.

He is the author or co-author of five books in analog and digital filters, one in parallel processing in industrial real-time applications, and one in DSP integrated circuits.

**Ya Jun Yu** received the B.Sc. and M.Eng. degrees in biomedical engineering from Zhejiang University, Hangzhou, China, in 1994 and 1997, respectively, and the Ph.D. degree in electrical and computer engineering from the National University of Singapore, Singapore, in 2004.

From 1997 to 1998, she was a Teaching Assistant with Zhejiang University. She joined the Department of Electrical and Computer Engineering, National University of Singapore as a Post Master Fellow in 1998 and remained in the same department as a Research Engineer until 2004. She joined the Temasek Laboratories at Nanyang Technological University as a Research Fellow in 2004. Since 2005, she has been with the School of Electrical and Electronic Engineering, Nanyang Technological University, Singapore, where she is currently an Assistant Professor. Her research interests include digital signal processing and VLSI circuits and systems design.

He has served as an associate editor for Circuits Systems and Signal Processing and IEEE TRANSACTIONS ON CIRCUITS AND SYSTEMS II since 2009 and 2010, respectively.

## **CHAPTER 7**

**Fred Harris** holds the Signal Processing Chair of the Communication Systems and Signal Processing Institute at San Diego State University where since 1967 he has taught courses in Digital Signal Processing and Communication Systems. He holds 20 patents on digital receiver and DSP technology and lectures throughout the world on DSP applications. He consults for organizations requiring high-performance, cost-effective DSP solutions. He is an adjunct member of the IDA-Princeton Center for Communications Research.

Fred Harris has written over 200 journal and conference papers, the most well known being his 1978 paper “On the use of Windows for Harmonic Analysis with the Discrete Fourier Transform”. He is the author of the book **Multirate Signal Processing for Communication Systems** and he has contributed to a number of other books on DSP applications including the “Source Coding” chapter in Bernard Sklar’s 1988 book, **Digital Communications** and the “Multirate FIR Filters for Interpolation and Resampling” and the “Time Domain Signal Processing with the DFT” chapters in Doug Elliot’s 1987 book **Handbook of Digital Signal Processing**, and “A most Efficient Digital Filter: The Two-Path Recursive All-Pass Filter” Chapter and the “Ultra Low Phase Noise DSP Oscillator” Chapter in Rick Lyon’s 2012 book **Streamlining Digital Signal Processing**. He is also co-author of the book **Software Radio Sampling Rate Selection, Design and Synchronization**.

In 1990 and 1991 he was the Technical and then the General Chair of the Asilomar Conference on Signals, Systems, and Computers and was Technical Chair of the 2003 Software Defined Radio Conference and of the 2006 Wireless Personal Multimedia Conference. He became a Fellow of the IEEE in 2003, cited for contributions of DSP to communications systems. In 2006 he received the Software Defined Radio Forum's "Industry Achievement Award". His paper at the 2006 SDR conference was selected for the best paper award as was his paper at the 2010 Autotestcon conference and again his paper at the 2011 Wireless Personal Mobile Communications Conference and once again the 2011 SDR conference. He is the former Editor-in-Chief of the Elsevier DSP Journal.

The spelling of my name with all lower case letters is a source of distress for typists and spell checkers. A child at heart, I collect toy trains and old slide-rules.

**Elettra Venosa** received the "Laurea" (BS/MS) degree, summa cum laude, in Electrical Engineering in January 2007 from Seconda Università degli Studi di Napoli, Italy. From January 2007 to November 2007 she was a researcher at the Italian National Inter-University Consortium for Telecommunications. In January 2011, she received the Ph.D. in Telecommunication/DSP from Seconda Università degli Studi di Napoli. From June 2008 to September 2008 she worked as a project manager for Kiranet –ICT Research Center – to develop an advanced radio identification system for avionics, in collaboration with the Italian Center for Aerospace Research (CIRA). From April 2009 to September 2009 she worked as associate researcher at Communications and Signal Processing Laboratory (CSPL) in the Department of Electrical and Computer Engineering at Drexel University, Philadelphia, where she worked on Sparse Sampling Techniques for Software Defined Radio Receivers. From January 2011 to July 2012 she worked as principal system engineer in IQ-Analog, CA, developing algorithms for digital correction in TI-ADCs. From August 2012 to December 2013 she was associate researcher in Qualcomm, CA. Her focus was to improve the current commercial modem architectures. Currently, she is working, as a postdoctoral researcher, on Multirate Signal Processing for Software Defined Radios in the Department of Electrical Engineering at San Diego State University, San Diego, CA, USA where she also teaches graduate and undergraduate courses. She is also working as a software defined radio engineer in Space Micro, CA. She is the author of more than 40 scientific publications on SDR and of the book "Software Radio: Sampling Rate Selection Design and Synchronization".

**Xiaofei** Chen received the Bachelor's degree in Electrical Engineering in June 2006 from Xi'an University of Posts & Telecommunications, China. In December 2008, he received the Master's degree at Electrical & Computer Engineering department, San Diego State University, USA. In March 2009, he joined the Joint Doctoral Program between San Diego State University and University of California, San Diego. His current research interests are in the area of multirate signal processing and software defined radio.

## CHAPTER 8

**Trac D. Tran** (S'94–M'98–SM'08) received the B.S. and M.S. degrees from the Massachusetts Institute of Technology, Cambridge, in 1993 and 1994, respectively, and the Ph.D. degree from the University of Wisconsin, Madison, in 1998, all in electrical engineering.

In July 1998, he joined the Department of Electrical and Computer Engineering, The Johns Hopkins University, Baltimore, MD, where he currently holds the rank of Professor. His research interests are in the field of signal processing, particularly in sparse representation, sparse recovery, sampling, multirate systems, filter banks, transforms, wavelets, and their applications in signal analysis, compression, processing, and communications. His pioneering research on integer-coefficient transforms and pre-/post-filtering operators has been adopted as critical components of Microsoft Windows Media Video 9 and JPEG XR—the latest international still-image compression standard ISO/IEC 29199–2. He is currently a regular consultant for the US Army Research Laboratory, Adelphi, MD.

He was the codirector (with Prof. J. L. Prince) of the 33rd Annual Conference on Information Sciences and Systems (CISS'99), Baltimore, in March 1999. In the summer of 2002, he was an ASEE/ONR Summer Faculty Research Fellow at the Naval Air Warfare Center Weapons Division (NAWCWD), China Lake, CA. He has served as Associate Editor of the IEEE TRANSACTIONS ON SIGNAL PROCESSING as well as the IEEE TRANSACTIONS ON IMAGE PROCESSING. He was a former member of the IEEE Technical Committee on Signal Processing Theory and Methods (SPTM TC) and is a current member of the IEEE Image Video and Multidimensional Signal Processing (IVMSP) Technical Committee. He received the NSF CAREER award in 2001, the William H. Huggins Excellence in Teaching Award from The Johns Hopkins University in 2007, and the Capers and Marion McDonald Award for Excellence in Mentoring and Advising in 2009.

## CHAPTER 9

**Yufang Bao** has been an Assistant Professor in the Department of Mathematics and Computer Science at UNC Fayetteville State University (UNCFSU) since 2007. She is also a scholar of the Center of Defense and Homeland Security (CDHS) at UNCFSU. She received her first Ph.D. degree in probability/statistics from Beijing Normal University (BNU), Beijing, China, and her second Ph.D. degree in Electrical Engineering from North Carolina State University (NCSU), Raleigh, NC. Her research focus was in probability/statistics. She subsequently directed her research into the area of applying mathematics in signal/image processing and analysis. Her contributions in signal/image processing included algorithm development that bridged stochastic diffusion and multi-scale wavelet theory with scale space analysis methods for image denoising and segmentation. Between 2002 and 2007, she has worked at the VA Center, UCSF, CA and then at the University of Miami, School of Medicine, FL, both as a research scientist focusing on statistical image reconstruction in Frequency domain with MR spectroscopy imaging, and with parallel

MR image reconstruction using mathematical modeling. Currently, her research interests are in applying mathematics to statistical digital signal/image processing and analysis, mathematical modeling, and their applications.

**Hamid Krim** (ahk@ncsu.edu) received his degrees in ECE from University of Washington and Northeastern University. He was a Member of Technical Staff at *AT&T Bell Labs*, where he has conducted research and development in the areas of telephony and digital communication systems/subsystems. Following an NSF postdoctoral fellowship at Foreign Centers of Excellence, LSS/University of Orsay, Paris, France, he joined the *Laboratory for Information and Decision Systems*, Massachusetts Institute of Technology, Cambridge, MA as a Research Scientist and where he was performing and supervising research.

He is presently Professor of Electrical Engineering in the ECE Department, North Carolina State University, Raleigh, leading the *Vision, Information and Statistical Signal Theories and Applications group*. His research interests are in statistical signal and image analysis and mathematical modeling with a keen emphasis on applied problems in classification and recognition using geometric and topological tools.

## CHAPTER 10

**Lisandro Lovisolo** was born in Neuquen, Argentina, but considers himself brazilian. He received the Electronics Engineering degree from Universidade Federal do Rio de Janeiro, in 1999, the M.Sc. degree in Electrical Engineering in 2001, and the D.Sc. degree in Electrical Engineering both from Universidade Federal do Rio de Janeiro (COPPE/UFRJ). Since 2003 he has been with the Department of Electronics and Communications Engineering (the undergraduate department), UERJ. He has also been with the Postgraduate in Electronics Program, since 2008. His research interests lie in the fields of digital signal and image processing and communications.

**Eduardo A. B. da Silva** was born in Rio de Janeiro, Brazil. He received the Electronics Engineering degree from Instituto Militar de Engenharia (IME), Brazil, in 1984, the M.Sc. degree in Electrical Engineering from Universidade Federal do Rio de Janeiro (COPPE/UFRJ) in 1990, and the Ph.D. degree in Electronics from the University of Essex, England, in 1995. In 1987 and 1988 he was with the Department of Electrical Engineering at Instituto Militar de Engenharia, Rio de Janeiro, Brazil. Since 1989 he has been with the Department of Electronics Engineering (the undergraduate department), UFRJ. He has also been with the Department of Electrical Engineering (the graduate studies department), COPPE/UFRJ, since 1996. His research interests lie in the fields of digital signal and image processing, especially signal compression, digital television, wavelet transforms, mathematical morphology, and applications to telecommunications.

## CHAPTER 11

**Suleyman Serdar Kozat** received the B.S. degree with full scholarship and high honors from Bilkent University, Turkey. He received the M.S. and Ph.D. degrees in Electrical and Computer Engineering from University of Illinois at Urbana Champaign, Urbana, IL, in 2001 and 2004, respectively.

After graduation, he joined IBM Research, T.J. Watson Research Center, Yorktown, NY as a Research Staff Member in Pervasive Speech Technologies Group, where he focused on problems related to statistical signal processing and machine learning. While doing his Ph.D., he was also working as a Research Associate at Microsoft Research, Redmond, WA, in Cryptography and Anti-Piracy Group. He holds several patent applications for his works performed in IBM Research and Microsoft Research. Currently, he is an Assistant Professor at the electrical and electronics engineering department, Koc University, Turkey. He coauthored more than 50 papers in refereed high impact journals and conference proceedings and has several patent applications. Overall, his research interests include intelligent systems, adaptive filtering for smart data analytics, online learning, and machine learning algorithms for signal processing.

He has been serving as an Associate Editor for the IEEE Transactions on Signal Processing and he is a Senior Member of the IEEE. He has been awarded IBM Faculty Award by IBM Research in 2011, Outstanding Faculty Award by Koc University in 2011, Outstanding Young Researcher Award by the Turkish National Academy of Sciences in 2010, ODTU Prof. Dr. Mustafa N. Parlar Research Encouragement Award in 2011 and holds Career Award by the Scientific Research Council of Turkey, 2009. He has won several scholarships and medals in international and national science and math competitions.

**Andrew C. Singer** received the S.B., S.M., and Ph.D. degrees, all in Electrical Engineering and Computer Science, from the Massachusetts Institute of Technology. Since 1998, he has been on the faculty of the Department of Electrical and Computer Engineering at the University of Illinois at Urbana-Champaign, where he is currently a Professor in the ECE department and the Coordinated Science Laboratory. During the academic year 1996, he was a Postdoctoral Research Affiliate in the Research Laboratory of Electronics at MIT. From 1996 to 1998, he was a Research Scientist at Sanders, A Lockheed Martin Company in Manchester, New Hampshire, where he designed algorithms, architectures, and systems for a variety of DOD applications. His research interests include signal processing and communication systems. He was a Hughes Aircraft Masters Fellow and was the recipient of the Harold L. Hazen Memorial Award for excellence in teaching in 1991. In 2000, he received the National Science Foundation CAREER Award, in 2001 he received the Xerox Faculty Research Award, and in 2002 he was named a Willett Faculty Scholar. He has served as an Associate Editor for the IEEE Transactions on Signal Processing and is a member of the MIT Educational Council, and of Eta Kappa Nu and Tau Beta Pi. He is a Fellow of the IEEE.

In 2005, he was appointed as the Director of the Technology Entrepreneur Center (TEC) in the College of Engineering. He also co-founded Intersymbol Communications, Inc., a venture-funded

fabless semiconductor IC company, based in Champaign Illinois. A developer of signal processing enhanced chips for ultra-high speed optical communications systems, Intersymbol was acquired by Finisar Corporation (NASD:FNSR) in 2007. He serves on the board of directors of a number of technology companies and as an expert witness for electronics, communications, and circuit-related technologies.

## CHAPTER 12

**Vítor H. Nascimento** was born in São Paulo, Brazil. He obtained the B.S. and M.S. degrees in Electrical Engineering from the University of São Paulo in 1989 and 1992, respectively, and the Ph.D. degree from the University of California, Los Angeles, in 1999. From 1990 to 1994 he was a Lecturer at the University of São Paulo, and in 1999 he joined the faculty at the same school, where he is now an Associate Professor. One of his papers received the 2002 IEEE SPS Best Paper Award. He served as an Associate Editor for the IEEE Signal Processing Letters from 2003 to 2005, for the IEEE Transactions on Signal Processing from 2005 to 2008, and for the EURASIP Journal on Advances in Signal Processing from 2006 to 2009, and was a member of the IEEE-SPS Signal Processing Theory and Methods Technical Committee from 2007 to 2012. Since 2010 he is the chair of the São Paulo SPS Chapter. His research interests include signal processing theory and applications, robust and nonlinear estimation, and applied linear algebra.

**Magno T. M. Silva** was born in São Sebastião do Paraíso, Brazil. He received the B.S., M.S., and Ph.D. degrees, all in electrical engineering, from Escola Politécnica, University of São Paulo, São Paulo, Brazil, in 1999, 2001, and 2005, respectively. From February 2005 to July 2006, he was an Assistant Professor at Mackenzie Presbyterian University, São Paulo, Brazil. Since August 2006, he has been with the Department of Electronic Systems Engineering at Escola Politécnica, University of São Paulo, where he is currently an Assistant Professor. From January to July 2012, he worked as a Postdoctoral Researcher at Universidad Carlos III de Madrid, Leganés, Spain. His research interests include linear and non-linear adaptive filtering.

## CHAPTER 14

**Ambuj Tewari** is with the Department of Statistics, University of Michigan, Ann Arbor. He has served on senior program committees of the conferences on Algorithmic Learning Theory (ALT), Conference on Learning Theory (COLT), and Neural Information Processing Systems (NIPS). His work has received both the student paper award (2005) and the best paper award (2011) at COLT. He received his M.A. in Statistics (2005) and Ph.D. in Computer Science (2007) from the University of California at Berkeley where his advisor was Peter Bartlett. He was a research Assistant Professor in Toyota Technological Institute at Chicago (2008–2010), an Assistant Professor

(part-time) in the Department of Computer Science, University of Chicago (2008–2010), and a postdoctoral fellow in the Institute for Computational Engineering and Sciences, University of Texas at Austin (2010–2012). He has also been a Visiting Researcher at Microsoft Research, Redmond.

**Peter L. Bartlett** is with the Division of Computer Science and Department of Statistics, University of California at Berkeley, and with the School of Mathematical Sciences, Queensland University of Technology. He is the co-author of the book “Learning in Neural Networks: Theoretical Foundations.” He has served as Associate Editor of the journals Machine Learning, Mathematics of Control Signals and Systems, the Journal of Machine Learning Research, the Journal of Artificial Intelligence Research, and the IEEE Transactions on Information Theory. He was awarded the Malcolm McIntosh Prize for Physical Scientist of the Year in Australia for his work in statistical learning theory. He was a Miller Institute Visiting Research Professor in Statistics and Computer Science at U.C. Berkeley in Fall 2001, and a Fellow, Senior Fellow, and Professor in the Research School of Information Sciences and Engineering at the Australian National University’s Institute for Advanced Studies (1993–2003).

## CHAPTER 15

**Barbara Hammer** received her Ph.D. in Computer Science in 1995 and her venia legendi in Computer Science in 2003, both from the University of Osnabrueck, Germany. From 2000 to 2004, she was a leader of the junior research group “Learning with Neural Methods on Structured Data” at University of Osnabrueck before accepting an offer as professor for Theoretical Computer Science at Clausthal University of Technology, Germany, in 2004. Since 2010, she is holding a professorship for Theoretical Computer Science for Cognitive Systems at the CITEC cluster of excellence at Bielefeld University, Germany. Several research stays have taken her to Italy, UK, India, France, the Netherlands, and the USA. Her areas of expertise include hybrid systems, self-organizing maps, clustering, and recurrent networks as well as applications in bioinformatics, industrial process monitoring, or cognitive science. She is leading the task force “Data Visualization and Data Analysis” of the IEEE CIS Technical Committee on Data Mining, and the Fachgruppe Neural Networks of the GI.

## CHAPTER 16

**John Shawe-Taylor** is a Professor at the Department of Computer Science, University College London (UK). His main research area is Statistical Learning Theory, but his contributions range from Neural Networks, to Machine Learning, to Graph Theory. He has published

over 150 research papers. He obtained a Ph.D. in Mathematics at Royal Holloway, University of London in 1986. He subsequently completed an M.Sc. in the Foundations of Advanced Information Technology at Imperial College. He was promoted to Professor of Computing Science in 1996. He moved to the University of Southampton in 2003 to lead the ISIS research group. He was appointed the Director of the Center for Computational Statistics and Machine Learning at University College, London in July 2006. He has coordinated a number of Europeanwide projects investigating the theory and practice of Machine Learning, including the NeuroCOLT projects. He is currently the scientific coordinator of a Framework VI Network of Excellence in Pattern Analysis, Statistical Modeling and Computational Learning (PASCAL) involving 57 partners.

**Shiliang Sun** received the B.E. degree in automatic control from the Department of Automatic Control, Beijing University of Aeronautics and Astronautics in 2002, and the Ph.D. degree in pattern recognition and intelligent systems from the State Key Laboratory of Intelligent Technology and Systems, Department of Automation, Tsinghua University, Beijing, China, in 2007. In 2004, he was entitled Microsoft Fellow. Currently, he is a Professor at the Department of Computer Science and Technology and the Founding Director of the Pattern Recognition and Machine Learning Research Group, East China Normal University. From 2009 to 2010, he was a Visiting Researcher at the Department of Computer Science, University College London, working within the Center for Computational Statistics and Machine Learning. He is a member of the PASCAL (Pattern Analysis, Statistical Modelling and Computational Learning) network of excellence, and on the editorial boards of multiple international journals. His research interests include machine learning, pattern recognition, computer vision, natural language processing, and intelligent transportation systems.

## CHAPTER 17

**Konstantinos Slavakis** received the M.E. and Ph.D. degrees in electrical and electronic engineering from Tokyo Institute of Technology (TokyoTech), Tokyo, Japan, in 1999 and 2002, respectively. For the period from 2004 to 2006, he was with TokyoTech as a JSPS PostDoc, and from 2006 to 2007, he was a Postdoc in the Department of Informatics and Telecommunications, University of Athens, Greece. From 2007 to 2012, he served as an Assistant Professor at the Department of Informatics and Telecommunications, University of Peloponnese, Tripolis, Greece. Currently, he is a Research Associate at the University of Minnesota, Digital Technology Center.

He serves as an Associate and Area Editor of the IEEE Transactions on Signal Processing. His research interests include applications of convex analysis and computational algebraic geometry to signal processing, machine learning, array, and multidimensional systems problems.

**Pantelis Bouboulis** received the M.Sc. and Ph.D. degrees in informatics and telecommunications from the National and Kapodistrian University of Athens, Greece, in 2002 and 2006, respectively. From 2007 till 2008, he served as an Assistant Professor in the Department of Informatics and Telecommunications, University of Athens. Since 2008, he teaches mathematics in Greek High Schools. His current research interests lie in the areas of machine learning, fractals, wavelets, and image processing.

## CHAPTER 18

**Franz Pernkopf** received his M.Sc. (Dipl. Ing.) degree in Electrical Engineering at Graz University of Technology, Austria, in summer 1999. He earned a Ph.D. degree from the University of Leoben, Austria, in 2002. In 2002 he was awarded the Erwin Schrödinger Fellowship. He was a Research Associate in the Department of Electrical Engineering at the University of Washington, Seattle, from 2004 to 2006. Currently, he is Associate Professor at the Laboratory of Signal Processing and Speech Communication, Graz University of Technology, Austria. His research interests include machine learning, discriminative learning, graphical models, feature selection, finite mixture models, and image- and speech processing applications.

**Robert Peharz** received his M.Sc. degree in Telematics at Graz University of Technology (TUG) in 2010. He currently pursues his Ph.D. studies at the SPSC Lab, TUG. His research interests include probabilistic graphical models, sparse coding, nonnegative matrix factorization, and machine learning in general, with applications to signal processing, audio engineering, and computer vision.

**Sebastian Tschiatschek** received the B.Sc. degree and M.Sc. degree in Electrical Engineering at Graz University of Technology (TUG) in 2007 and 2010, respectively. He conducted his Master thesis during a one-year stay at ETH Zürich, Switzerland. Currently, he is with the Signal Processing and Speech Communication Laboratory at TUG where he is pursuing the Ph.D. degree. His research interests include Bayesian networks, information theory in conjunction with graphical models and statistical pattern recognition.

## CHAPTER 19

**A. Taylan Cemgil** (M'04) received his Ph.D. (2004) from SNN, Radboud University Nijmegen, the Netherlands. Between 2004 and 2008 he worked as a postdoctoral researcher at Amsterdam University and the Signal Processing and Communications Laboratory, University of Cambridge, UK. He is currently an Associate Professor of Computer Engineering at Bogazici University, Istanbul, Turkey. He is a member of the IEEE MLSP Technical Committee and an Associate Editor of IEEE Signal Processing Letters and Digital Signal Processing. His research interests are in Bayesian statistical methods and inference, machine learning, and audio signal processing.

## CHAPTER 20

**Dao Lam** is a Ph.D. Candidate at Missouri University of Science and Technology, Rolla, MO. He received the B.S. degree from Post and Telecommunications Institute of Technology, Ho Chi Minh, Vietnam in 2003. He got his M.S. from Waseda University, Japan in 2008. His research interests are image processing, robotics, supervised and unsupervised learning, and computational intelligence.

**Donald Wunsch** is the Mary K. Finley Missouri Distinguished Professor at Missouri University of Science & Technology (Missouri S&T). Earlier employers were: Texas Tech University, Boeing, Rockwell International, and International Laser Systems. His education includes: Executive MBA—Washington University in St. Louis, Ph.D., Electrical Engineering—University of Washington (Seattle), M.S., Applied Mathematics (same institution), B.S., Applied Mathematics—University of New Mexico, and Jesuit Core Honors Program, Seattle University. Key research contributions are: Clustering; Adaptive Resonance and Reinforcement Learning architectures, hardware and applications; Neurofuzzy regression; Traveling Salesman Problem heuristics; Robotic Swarms; and Bioinformatics. He is an IEEE Fellow and previous INNS President, INNS Fellow and Senior Fellow 07—present, and served as IJCNN General Chair, and on several Boards, including the St. Patrick's School Board, IEEE Neural Networks Council, International Neural Networks Society, and the University of Missouri Bioinformatics Consortium. He has produced 16 Ph.D. recipients in Computer Engineering, Electrical Engineering, and Computer Science; has attracted over \$8 million in sponsored research; and has over 300 publications including nine books. His research has been cited over 6000 times.

## CHAPTER 21

**Andrzej Cichocki** received the M.Sc. (with honors), Ph.D. and Dr.Sc. (Habilitation) degrees, all in electrical engineering, from *Warsaw University of Technology* in Poland.

Since 1972, he has been with the *Institute of Theory of Electrical Engineering, Measurement and Information Systems, Faculty of Electrical Engineering* at the *Warsaw University of Technology*, where he obtained a title of a full Professor in 1995.

He spent several years at *University Erlangen-Nuerenberg* in Germany, at the Chair of Applied and Theoretical Electrical Engineering directed by Professor Rolf Unbehauen, as an Alexander-von-Humboldt Research Fellow and Guest Professor.

In 1995–1997 he was a team leader of the laboratory for Artificial Brain Systems, at Frontier Research Program RIKEN (Japan), in the Brain Information Processing Group.

He is currently senior team leader and the head of the *Cichocki Laboratory for Advanced Brain Signal Processing*, at *RIKEN Brain Science Institute* in Japan.

## CHAPTER 22

**Xueyuan Zhou** received his Ph.D. degree in computer science from the University of Chicago in 2011. His research interests include statistical machine learning theory and application in non-linear high dimensional data.

**Mikhail Belkin** is an Associate Professor in the Department of Computer Science and Engineering at the Ohio State University. He received his Ph.D. degree in mathematics from the University of Chicago in 2003. His research interests include a range of theoretical questions concerning the computational and statistical limits of learning and mathematical foundations of learning structure from data.

**Yannis Kopsinis** received the B.Sc. degree from the Department of Informatics and Telecommunications, University of Athens, Greece, in 1998 and his Ph.D. degree in 2003 from the same department. From January 2004 to December 2005 he has been a research fellow with the Institute for Digital Communications, School of Engineering and Electronics, the University of Edinburgh, UK. From January 2006 to September 2009 he was a senior researcher in the same department. From January 2012 to April 2013 he was a Ramon Y Cajal Fellow in the School of Applied Physics, University of Granada, Spain. He currently holds a Marie Curie Intra-European fellowship

on sparse online learning. His current research interests include adaptive signal processing, time-frequency analysis, and compressed sensing.

**Konstantinos Slavakis** received the M.E. and Ph.D. degrees in electrical and electronic engineering from Tokyo Institute of Technology (TokyoTech), Tokyo, Japan, in 1999 and 2002, respectively. For the period of 2004–2006, he was with TokyoTech as a JSPS PostDoc, and from 2006 to 2007, he was a Postdoc in the Department of Informatics and Telecommunications, University of Athens, Greece. From 2007 to 2012, he served as an Assistant Professor at the Department of Informatics and Telecommunications, University of Peloponnese, Tripolis, Greece. Currently, he is a Research Associate at the University of Minnesota, Digital Technology Center.

He serves as an Associate and Area Editor of the IEEE Transactions on Signal Processing. His research interests include applications of convex analysis and computational algebraic geometry to signal processing, machine learning, array, and multidimensional systems problems.

## CHAPTER 24

**José C. Principe** is currently a Distinguished Professor of Electrical and Biomedical Engineering at the University of Florida, Gainesville, USA. He is BellSouth Professor and Founder and Director of the University of Florida Computational Neuro-Engineering Laboratory (CNEL). He is an IEEE fellow and AIMBE fellow, and is the past Editor-in-Chief of the IEEE TRANSACTIONS ON BIOMEDICAL ENGINEERING, past President of the International Neural Network Society, former Secretary of the Technical Committee on Neural Networks of the IEEE Signal Processing Society, and a former member of the Scientific Board of the Food and Drug Administration. He is involved in biomedical signal processing, in particular, the electroencephalogram (EEG) and the modeling and applications of adaptive systems.

**Badong Chen** received his Ph.D. degree in Computer Science and Technology from Tsinghua University, Beijing, China, in 2008. He was a Postdoctoral Associate at the University of Florida Computational NeuroEngineering Laboratory (CNEL) during the period October, 2010 to September, 2012. He is currently a Professor at the Institute of Artificial Intelligence and Robotics, Xi'an Jiaotong University, Xi'an, China. His research interests are in statistical signal processing, information theoretic learning, online kernel learning, and their applications in cognition and neuroscience.

## I Authors Biography

**Luis G. Sanchez Giraldo** was born in 1983 in Manizales, Colombia. He received the B.S. in electronics engineering and M.Eng. in industrial automation from Universidad Nacional de Colombia in 2005 and 2008, respectively, and his Ph.D. in electrical and computer engineering from University of Florida in 2012. Between 2004 and 2008, he was appointed as a research assistant at the Control and Digital Signal Processing Group (GCPDS) at Universidad Nacional de Colombia. During his Ph.D. studies he worked as a research assistant at the Computational Neuro-Engineering Laboratory (CNEL) at University of Florida. His main research interests are in machine learning and signal processing.

## CHAPTER 25

**Enes Makalic** was born in 1980. He received the Bachelor of Computer Science (Honors) degree in 2002 and the Ph.D. degree in 2007, both from Monash University, Australia. His research interests include information theoretic model selection using Minimum Message Length (MML) and Minimum Description Length (MDL) theories of statistical inference. He currently holds a Postdoctoral position with The University of Melbourne, Australia.

**Daniel F. Schmidt** was born in 1980. He received the Bachelor of Digital Systems (Honors) degree in 2002 and the Ph.D. degree in 2008, both from Monash University, Australia. His research interests are primarily information theoretic approaches to statistical inference, model selection, and estimation. He currently holds a Postdoctoral position with The University of Melbourne, Australia.

**Abd-Krim Seghouane** received his Ph.D. degree from University of Paris sud (Paris XI) in 2003. His research interests are within statistical signal and image processing. He is currently a Senior Research Fellow within the department of Electrical and Electronic Engineering, The University of Melbourne.

## CHAPTER 26

**George Tzanetakis** is an Associate Professor and Canada Research Chair in Computer Analysis of Audio and Music at the Department of Computer Science with cross-listed appointments in ECE and Music at the University of Victoria, Canada. In 2011 he was a visiting scientist at Google Research. He received his Ph.D. in Computer Science at Princeton University in 2002 and was a Post-Doctoral fellow at Carnegie Mellon University in 2002–2003. His research spans all stages of audio content analysis such as feature extraction, segmentation, classification with specific emphasis on music information retrieval. He is also the primary designer and developer of Marsyas an open

source framework for audio processing with specific emphasis on music information retrieval applications. His pioneering work on musical genre classification received a IEEE signal processing society young author award and is frequently cited. More recently he has been exploring new interfaces for musical expression, music robotics, computational ethnomusicology, and computer-assisted music instrument tutoring. These interdisciplinary activities combine ideas from signal processing, perception, machine learning, sensors, actuators, and human-computer interaction with the connecting theme of making computers better understand music to create more effective interactions with musicians and listeners.

# Introduction to Signal Processing Theory

# 1

## 1.01.1 Introduction

Signal processing is a key area of knowledge that finds applications in virtually all aspects of modern life. Indeed the human beings are employing signal processing tools for centuries without realizing it [1]. In present days the younger generation might not be able to understand how one can live without carrying a mobile phone, traveling long distances without an almost self piloted airplane, exploring other planets without human presence, and utilizing a medical facility without a wide range of diagnostic and intervention equipments.

Signal processing consists of mapping or transforming information bearing signals into another form of signals at the output, aiming at some application benefits. This mapping defines a continuous or analog system if it involves functions representing the input and output signals. On the other hand, the system is discrete or digital if its input and output signals are represented by sequences of numbers.

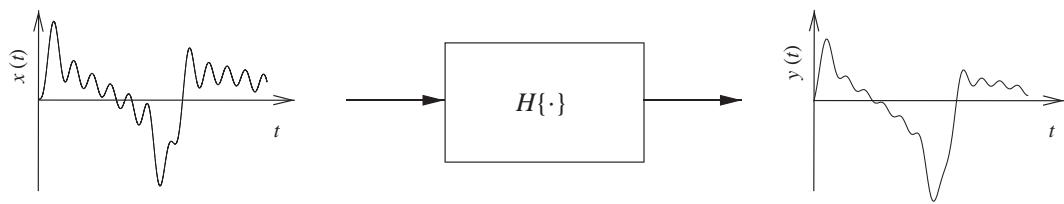

Signal processing theory is very rich and as a reward it has been finding applications in uncountable areas, among which we can mention bioengineering, communications, control, surveillance, environment monitoring, oceanography, and astronomy, just to mention a few. In particular, the enormous advance in digital integrated circuit technology, responsible for the computing and information revolutions that we are so used today, enabled the widespread use of Digital Signal Processing Systems. These systems allowed advances in fields such as: speech, audio, image, video, multirate processing, besides in several applications of wireless communications and digital control.

This chapter is an overview of the classical signal processing tools whose details are encountered in numerous textbooks such as: [1–15]. The topics treated in the following chapters entail the description of many signal processing tools, usually not covered in the classical textbooks available in the market. As a result, we believe that the readers can benefit from reading many of these chapters, if not all, in order to deepen and widen their current knowledge as well as to start exploiting new ideas.

---

## 1.01.2 Continuous-time signals and systems

The processing of signals starts by accessing the type of information we want to deal with. Many signals originating from nature are continuous in time and as such, the processing involved must include analog signal acquisition systems followed by the implementation of a continuous-time system if the processing

**FIGURE 1.1**

Continuous-time system.

remains analog all the way. Alternatively, assuming the original continuous-time signal contains limited spectral information, we can sample it in order to generate a sequence representing the continuous-time signal unambiguously<sup>1</sup>. In this latter form one can benefit from the advanced digital integrated circuit technology to process the signal. However, many real life applications still includes continuous-time signal processing at least at the acquisition and actuator phases of the processing.

A continuous-time system maps an analog input signal represented by  $x(t)$  into an output signal represented by  $y(t)$ , as depicted in Figure 1.1. A general representation of this mapping is

$$y(t) = \mathcal{H}\{x(t)\},$$

where  $\mathcal{H}\{\cdot\}$  denotes the operation performed by the continuous-time system. If the system is linear and time-invariant (LTI), as will be described in Chapter 2, there are several tools to describe the mapping features of the system. Typically, a general description of the systems consists of a differential equation which in turn can be solved and analyzed by employing the Laplace transform. A key feature of the LTI systems is their full representation through their impulse responses. The behavior of a nonlinear system is more complicated to analyze since it can not be fully characterized by its impulse response.

Another important tools to deal with the continuous-time signals which are periodic and non-periodic are the Fourier series and Fourier transform, respectively. As will be discussed in Chapter 2, the Fourier and Laplace transforms are closely related, being both essential tools to describe the behavior of continuous-time signals when applied to LTI systems.

The Laplace transform is suitable to represent a time-domain non-periodic function of a continuous and real (time) variable, resulting in a frequency-domain non-periodic function of a continuous and complex frequency variable. That is,

$$X(s) = \int_{-\infty}^{\infty} x(t)e^{-st} dt \iff x(t) = \frac{1}{2\pi} e^{\sigma t} \int_{-\infty}^{\infty} X(\sigma + j\omega)e^{j\omega t} d\omega.$$

The Fourier transform is employed to represent a time-domain non-periodic function of a continuous and real (time) variable with a frequency-domain non-periodic function of a continuous and imaginary

<sup>1</sup>As will be seen in Chapter 5, we can completely reconstruct a continuous-time band-limited signal  $x(t)$  from its sampled version  $x(n)$  if the sampling frequency is chosen correctly.

frequency variable. The Fourier transform is described by

$$X(\Omega) = \int_{-\infty}^{\infty} x(t) e^{-j\Omega t} dt \iff x(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} X(\Omega) e^{j\Omega t} d\Omega.$$

The representation of a time-domain periodic function of a continuous and real (time) variable is performed by the Fourier series. In the frequency-domain, the representation consists of a non-periodic function of a discrete and integer frequency variable, as following described:

$$X(k) = \frac{1}{T} \int_0^T x(t) e^{-j(2\pi/T)kt} dt \iff x(t) = \sum_{k=-\infty}^{\infty} X(k) e^{j(2\pi/T)kt}.$$

### 1.01.3 Discrete-time signals and systems

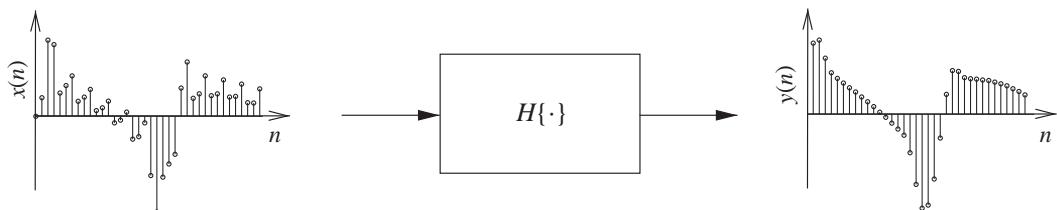

A discrete-time signal is represented by a sequence of numbers and can be denoted as  $x(n)$  with  $n \in Z$ , where  $Z$  is the set of integer numbers. The samples  $x(n)$  might represent numerically the amplitude of a continuous-time signal sample at every  $T$  seconds or can be originated from a discrete information. In many applications, the sampling period  $T$  represents the time interval between two acquired samples of the continuous-time signal. However, in other situations it might represent the distance between two sensors of two pixels of an image, or the separation between two antennas, just to mention a few examples.

Discrete-time systems map input sequences into output sequences. A general representation of this mapping is

$$y(n) = \mathcal{H}\{x(n)\},$$

where  $\mathcal{H}\{\cdot\}$  denotes the operation performed by the discrete-time system. Figure 1.2 depicts the input-to-output mapping of sequences. According to the properties of  $\mathcal{H}\{\cdot\}$ , the discrete-time system might be LTI. This way, it benefits from a number of analysis and design tools such as frequency-domain representations. However, there are many applications employing nonlinear, time-varying, and even non-causal systems [2,5,7,8,11,12,16].

If the system is linear and time-invariant, as will be described in Chapter 2, there are several tools to describe the mapping features of the system. Typically, a general description of discrete-time systems through a difference equation can be solved and analyzed by employing the  $z$  transform. Also a

**FIGURE 1.2**

Discrete-time signal representation.

discrete-time LTI system is fully described by its impulse response, whereas a nonlinear system can not be fully characterized by its impulse response.

The  $z$  transform is the key tool to represent a time-domain non-periodic function of a discrete and integer variable through a frequency-domain non-periodic function of a continuous and complex frequency variable. That is,

$$X(z) = \sum_{n=-\infty}^{\infty} x(n)z^{-n} \iff x(n) = \frac{1}{2\pi j} \oint_C X(z)z^{n-1} dz.$$

The discrete-time Fourier transform (DTFT) represents a time-domain non-periodic function of a discrete and integer variable by a periodic function of a continuous frequency variable in the frequency domain as follows:

$$X(e^{j\omega}) = \sum_{n=-\infty}^{\infty} x(n)e^{-j\omega n} \iff x(n) = \frac{1}{2\pi} \int_{-\infty}^{\infty} X(e^{j\omega})e^{j\omega n} d\omega.$$

Finally, the discrete Fourier transform (DFT) is the right tool to represent a time-domain periodic function of a discrete and integer variable through a periodic function of a discrete and integer frequency variable in the frequency domain. The DFT is defined as

$$X(k) = \sum_{n=0}^{N-1} x(n)e^{-j(2\pi/N)kn} \iff x(n) = \frac{1}{N} \sum_{k=0}^{N-1} X(k)e^{j(2\pi/N)kn}.$$

The DFT plays a key role in digital signal processing since it represents a finite-length sequence in the time domain through a finite-length sequence in the frequency domain. Since both domains utilize sequences, this feature makes the DFT a natural choice for time-frequency representation of information in a digital computer. A little mental exercise allows us to infer that the DFT is the perfect representation in the frequency domain of a finite-length sequence in the time domain, if we interpret the latter as a period of a periodic infinite-length sequence. In addition, by employing appropriate zero-padding in two finite-length sequences, the product of their DFTs represents the DFT of their linear convolution (see [Chapter 3](#)), turning the DFT a valuable tool for LTI system implementation. There is a plethora of applications for the DFT in signal processing and communications and some of them can be accessed in the references [2–13].

Often, whenever a DSP system is LTI, it can be described through a difference equation as follows:

$$\sum_{i=0}^N a_i y(n-i) + \sum_{l=0}^M b_l x(n-l) = 0.$$

The above description is suitable for implementation in digital computers. The difference equation represents a causal LTI system if its auxiliary conditions correspond to its initial conditions and those are zeros [2]. Assuming  $a_0 = 1$ , the above equation can be rewritten as

$$y(n) = - \sum_{i=1}^N a_i y(n-i) + \sum_{l=0}^M b_l x(n-l).$$

This class of system has infinite impulse response (i.e.,  $y(n) \neq 0$  when  $n \rightarrow \infty$ ) and, as such, it is called IIR system or filter.

The nonrecursive system generates the output signal from past input samples, that is,

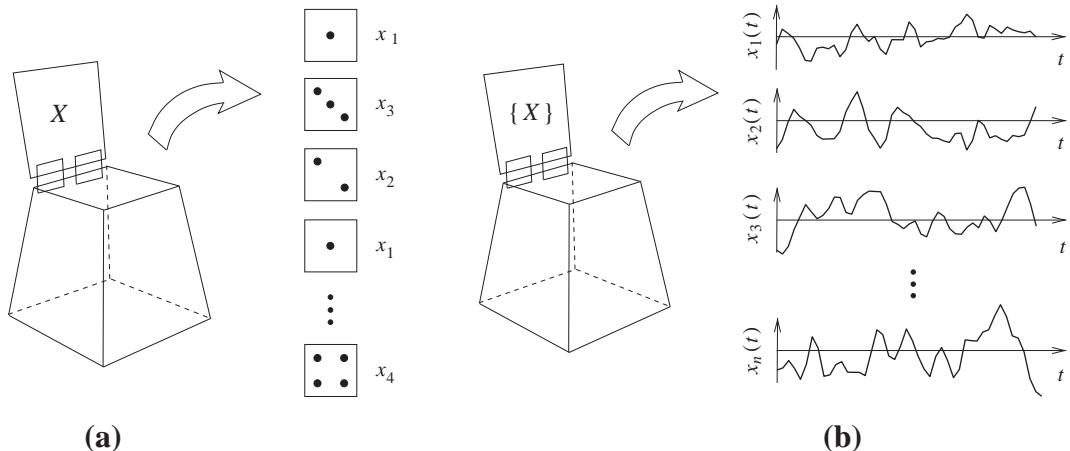

$$y(n) = \sum_{l=0}^M b_l x(n-l).$$

In this case, the resulting system has finite impulse response and is known as FIR systems or filters.

### 1.01.4 Random signals and stochastic processes

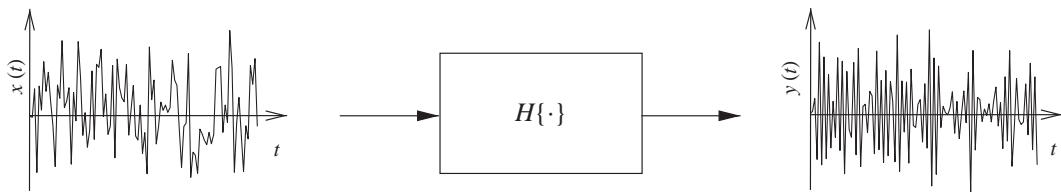

In most practical applications, we have to deal with signals that can not be described by a function of time, since their waveforms follow a random pattern [17,18]. Take, for example, the thermal noise inherent to any material. Despite the lack of exact knowledge of the signal values, it is possible to analyze and extract information the signals contain by employing the mathematical tools available to deal with random signals. Chapter 4 will present a compact and yet clarifying review of random signals and stochastic processes which are crucial to understand several concepts that will be discussed in the more advanced chapters.

The theory starts by defining a random variable as a mapping of the result of a random process experiment onto the set of numbers. A random variable  $X$  is a function that assigns a number  $x$  to every outcome of a random process experiment. An example is given in Figure 1.3(a), in which each outcome of a throw of a dice, numbers 1–6, corresponds to a determined value,  $x_1$ – $x_6$ , respectively.

**FIGURE 1.3**

Examples of random variable and stochastic process. (a) Random variable. (b) Stochastic process.

**FIGURE 1.4**

Filtering of a random signal.

The stochastic process is a rule to describe the time evolution of the random variable depending on the random process experiment, whereas the set of all experimental outcomes is its domain known as the ensemble. An example is given in Figure 1.3(b), in which, at any time instant  $t_0$ , the set formed by the output samples of the stochastic process  $\{X\}$ ,  $\{x_1(t_0), x_2(t_0), x_3(t_0), \dots, x_n(t_0)\}$ , represents a random variable. A single outcome  $x_i(t)$  of  $\{X\}$  is a random signal. Since random signals do not have a precise description of their waveforms, we have to characterize them either via measured statistics or through a probabilistic model. In general, the first- and second-order statistics (mean and variance, respectively) are sufficient for characterization of the stochastic process, particularly due to the fact that these statistics are suitable for measurements.

As an illustration, Figure 1.4 shows a random signal as an input of a highpass filter. We can observe that the output signal is still random, but clearly shows a faster changing behavior given that the low frequency contents of the input signal were attenuated by the highpass filter.

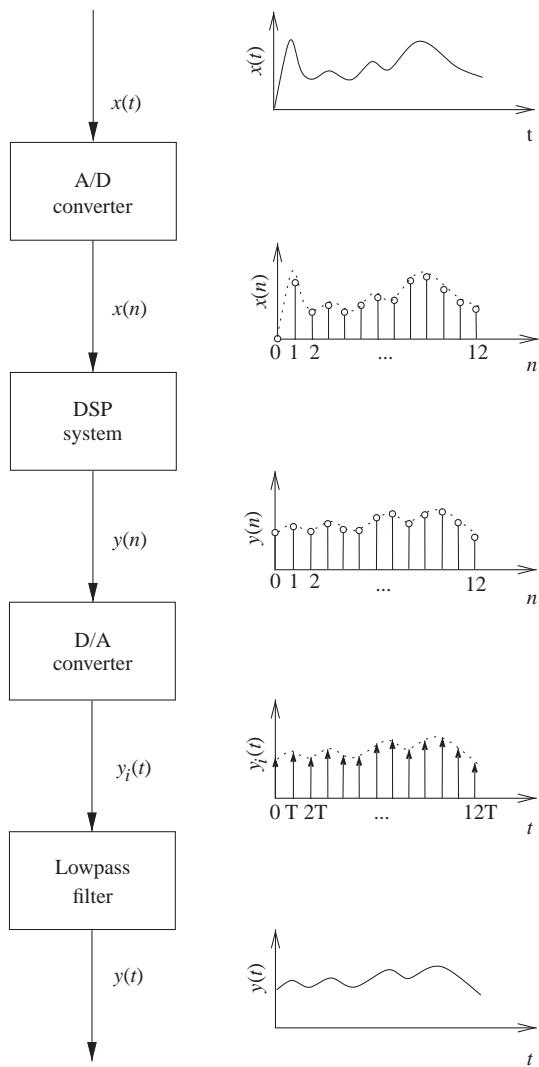

### 1.01.5 Sampling and quantization

A digital signal processing system whose signals originated from continuous-time sources includes several building blocks, namely: an analog-to-digital (A/D) converter; a digital signal processing (DSP) system; a digital-to-analog (D/A) converter; and a lowpass filter. Figure 1.5 illustrates a typical digital signal processing setup where:

- The A/D converter produces a set of samples in equally spaced time intervals, which may retain the information of the continuous-time signal in the case the latter is band limited. These samples are converted into a numeric representation, in order to be applied to the DSP system.
- The DSP performs the desired mapping between the input and output sequences.
- The D/A converter produces a set of equally spaced-in-time analog samples representing the DSP system output.
- The lowpass filter interpolates the analog samples to produce a smooth continuous-time signal.

[Chapter 5](#) will discuss in detail the conditions which a continuous-time signal must satisfy so that its sampled version retains the information of the original signal, dictated by the sampling theorem. This theorem determines that a band limited continuous-time signal can be theoretically recovered from its sampled version by filtering the sequence with an analog filter with prescribed frequency response.

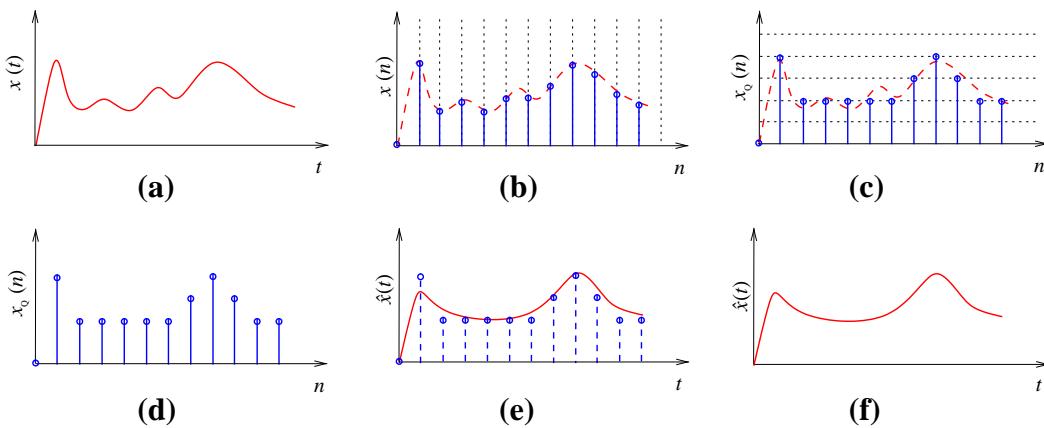

It is also important to mention that, while processing the signals in the digital domain, these are subject to quantization errors, such as: roundoff errors originated from internal arithmetic operations

**FIGURE 1.5**

DSP system.

performed in the signals; deviations in the filter response due to finite wordlength representation of the multiplier coefficients inherent to the signal processing operation; and errors due to representation of the acquired continuous-time signals with a set of discrete levels.

The actual implementation of a DSP system might rely on general purpose digital machines, where the user writes a computer software to implement the DPS tasks. This strategy allows fast prototyping and testing. Other mean is to use special-purpose commercially available CPUs, known as Digital Signal

**FIGURE 1.6**

A digital signal generation. (a) Original continuous-time signal. (b) A/D converter: sampling. (c) A/D converter: quantization. (d) Digital signal. (e) D/A converter.(f) Recovered continuous-time signal.

Processors, which are capable of implementing sum of product operations in a very efficient manner. Yet another approach is to employ special purpose hardware tailored for the given application.

Figure 1.6 depicts a continuous-time signal, its digitized version, and its recovered continuous-time representation. We can notice, from Figures 1.6(a) to 1.6(f), the effects of a low sampling frequency and a small number of quantization steps on the A/D and D/A processes.

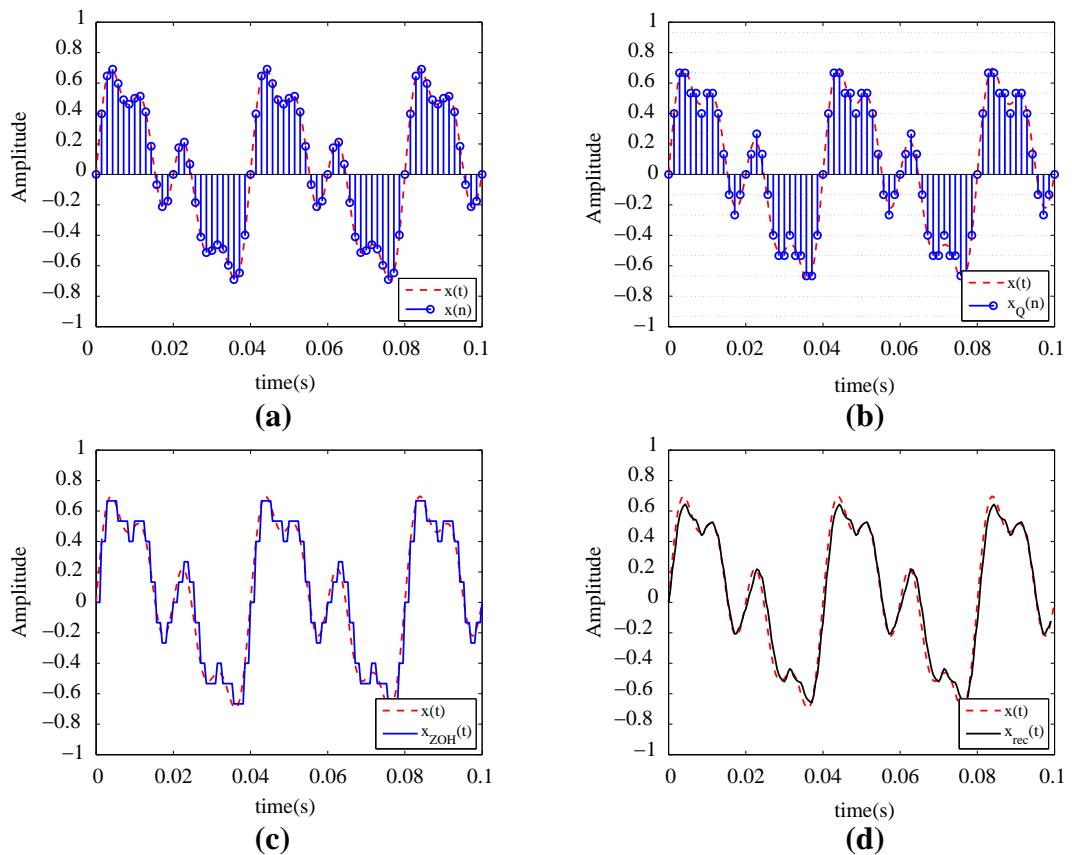

Figure 1.7 is a detailed example of the steps entailing an A/D and a D/A conversion, where in Figure 1.7(a) a continuous-time signal is depicted along with its equally spaced samples. These samples are then quantized as illustrated Figure 1.7(b). Assuming the quantized samples are converted into an analog signal through a zero-order hold, the output of the D/A converter becomes as illustrated in Figure 1.7(c). The sampled-and-held continuous-time signal is lowpass filtered in order to recover the original continuous-time signal. As can be observed in Figure 1.7(d), the recovered signal resembles the original where the difference originates from the quantization effects and the nonideal lowpass filter at the D/A converter output.

### 1.01.6 FIR and IIR filter design

The general form of an FIR transfer function is given by

$$H(z) = \sum_{l=0}^M b_l z^{-l} = H_0 z^{-M} \prod_{l=0}^M (z - z_l).$$

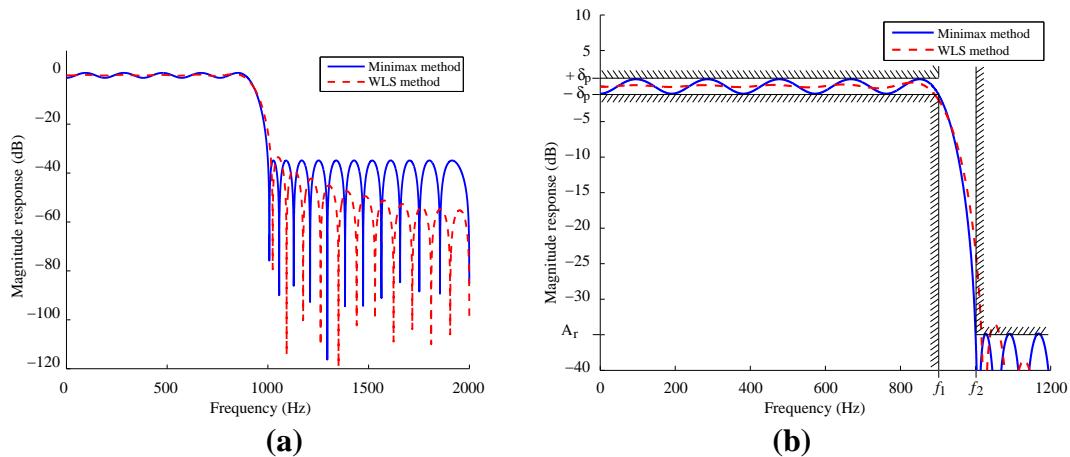

Since all the poles of the FIR transfer function are placed at  $z = 0$ , it is always stable. As a result, the transfer function above will always represent a stable filter. The main feature of the FIR filters is

**FIGURE 1.7**

A real digital signal generation. (a) A/D converter: sampling. (b) A/D converter: quantization. (c) D/A converter: zero-order hold. (d) D/A converter: lowpass filter.

the possibility of designing structurally induced linear-phase filters. On the other hand, an FIR filter requires a higher number of multiplications, additions and storage elements when compared to their IIR counterparts in order to satisfy a prescribed specification for the magnitude response.

There are many methods to design an FIR filter [19], ranging from the simple ones, such as the window and frequency sampling methods, to more efficient and sophisticated, that rely on some kind of optimization method [20–22]. The simple methods lead to solutions which are far from optimum in most practical applications, in the sense that they either require higher order or cannot satisfy prescribed specifications. A popular optimization solution is the minimax method based on the Remez exchange algorithm, which leads to transfer functions with minimum order to satisfy prescribed specifications.

**FIGURE 1.8**

Typical magnitude responses of FIR filters: Minimax and WLS. (a) Magnitude response. (b) Specifications for a lowpass filter using minimax design.

Nowadays, with the growing computational power, it is possible to design quite flexible FIR filters by utilizing weighted least squares (WLS) solutions. These filters are particularly suitable for multirate systems, since the resulting transfer functions can have decreasing energy in their stopband [2]. The WLS method enables the design of filters satisfying prescribed specifications, such as the maximum deviation in the passband and in part of the stopband, while minimizing the energy in a range of frequencies in the stopband. As can be observed in Figure 1.8, for a given filter order, the minimax design leads to lower maximum stopband attenuation, whereas the WLS solution leads to lower stopband energy. Note there are solutions in between where some maximum values of stopband ripples can be minimized while the energy of the remaining ones is also minimized. It is possible to observe that the WLS solution does not satisfy the prescribed specifications given that it has the same filter order as the minimax solution.

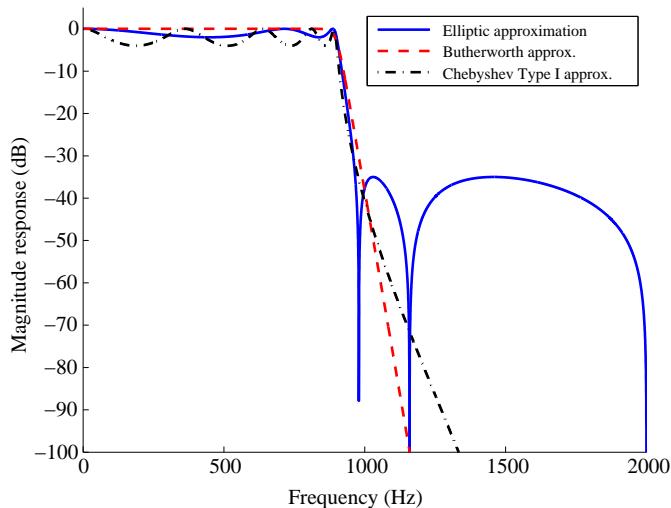

The typical transfer function of an IIR filter is given by

$$H(z) = \frac{Y(z)}{X(z)} = \frac{\sum_{l=0}^M b_l z^{-l}}{1 + \sum_{i=1}^N a_i z^{-i}},$$

which can be rewritten in a form explicitly showing the poles positions as

$$H(z) = H_0 \frac{\prod_{l=0}^M (1 - z^{-1} z_l)}{\prod_{i=0}^N (1 - z^{-1} p_i)} = H_0 z^{N-M} \frac{\prod_{l=0}^M (z - z_l)}{\prod_{i=0}^N (z - p_i)}.$$

IIR filters are usually designed by using well-established analog filter approximations, such as Butterworth, Chebyshev, and elliptic methods (Figure 1.9). The prototype analog transfer function is then

**FIGURE 1.9**

Typical magnitude response of an IIR filter.

transformed into a digital transfer function by using an adequate transformation method. The most widely used transformation methods are bilinear and the impulse invariance methods [2].

### 1.01.7 Digital filter structures and implementations

From a closer examination of the FIR and IIR transfer functions, one can infer that they can be realized with three basic operators: adder, multiplier and delay (represented by  $z^{-1}$ ).

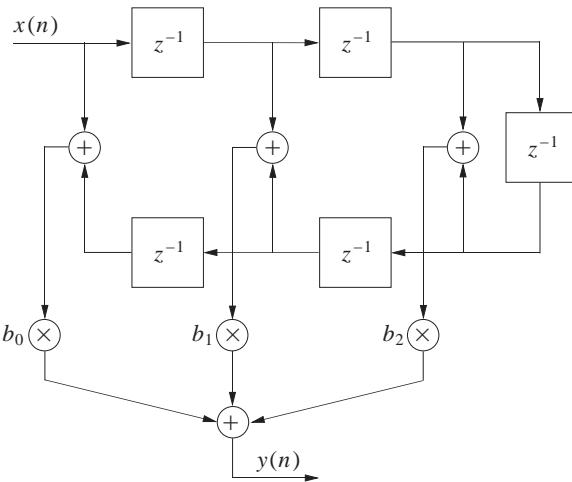

For example, Figure 1.10 shows a linear-phase FIR filter realization of odd order. Linear-phase filters have symmetric or anti-symmetric impulse response and the symmetry should be exploited in order to minimize the number of multipliers in the filter implementation, as illustrates Figure 1.10.

Figure 1.11 depicts a possible direct-form realization of an IIR transfer function. This realization requires the minimum number of multiplications, adders and delays to implement the desired IIR transfer function.

There are many alternative structures to implement the FIR and IIR filters. For example, IIR transfer functions can be implemented as a product or as a summation of lower order IIR structures by starting with their description as:

$$\begin{aligned} H(z) &= \prod_{k=1}^m \frac{\gamma_{0k} + \gamma_{1k}z^{-1} + \gamma_{2k}z^{-2}}{1 + m_{1k}z^{-1} + m_{2k}z^{-2}} \\ &= h_0^p + \sum_{k=1}^m \frac{\gamma_{1k}^p z + \gamma_{2k}^p}{z^2 + m_{1k}z + m_{2k}}, \end{aligned}$$

respectively. The right choice for a filter realization must take into consideration some issues, such as: modularity, quantization effects, design simplicity, power consumption, etc. [2]. Chapter 6 will address

**FIGURE 1.10**

Odd-order linear-phase FIR filter structure with  $M = 5$ .

advanced methods for FIR and IIR filter realization and implementation, where elegant and creative solutions are introduced in a clear manner. This chapter will also discuss strategies to implement digital filters efficiently.

### 1.01.8 Multirate signal processing

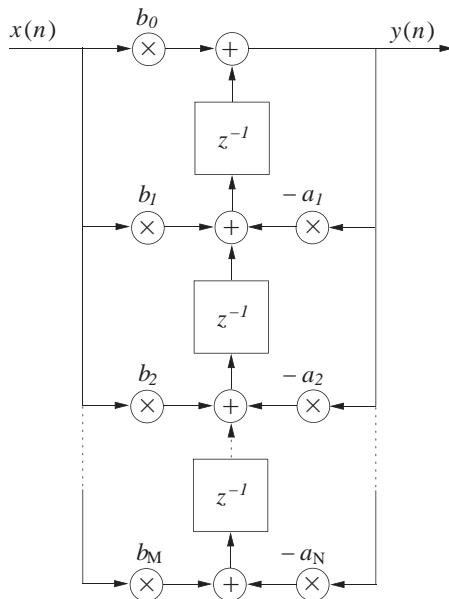

In digital signal processing it is easy to change the sampling rate of the underlying sequences by a ratio of integer values. This feature is highly desirable whenever we want to merge information of systems employing distinct sampling rates. In these cases, those rates should be made compatible [6,9,10].

Systems that internally employ multiple sampling rates are collectively referred to as multirate systems. In most cases, these systems are time-varying or, at most, periodically time-invariant.

The basic operations of the multirate systems are the decimation and interpolation. The right composition of these operations allows arbitrary rational sampling rate changes. If this sampling rate change is arbitrary and non-rational, the only solution is to recover the bandlimited continuous-time signal  $x(t)$  from its samples  $x(m)$ , and then re-sample it with a different sampling rate, thus generating a distinct discrete-time signal  $\bar{x}(n)$ .

If we assume that a discrete-time signal  $x(m)$  was generated from a continuous-time signal  $y(t)$  with sampling period  $T_1$ , so that  $x(m) = y(mT_1)$ , with  $m = \dots, 0, 1, 2, \dots$ , the sampling theorem requires that  $y(t)$  should be bandlimited to the range  $[-\frac{\pi}{T_1}, \frac{\pi}{T_1}]$ . The sampled continuous-time signal is given by:

$$y'(t) = \sum_{m=-\infty}^{\infty} x(m)\delta(t - mT_1).$$

**FIGURE 1.11**

Direct-Form IIR filter structure, for  $M = N$ .

The spectrum of the sampled signal is periodic with period  $\frac{2\pi}{T_1}$ . The original continuous-time signal  $y(t)$  can be recovered from  $y'(t)$  through an ideal lowpass filter. This interpolation filter, whose impulse response is denoted as  $h(t)$ , has ideal frequency response  $H(e^{j\omega})$  as follows:

$$H(e^{j\omega}) = \begin{cases} 1, & \omega \in [-\frac{\pi}{T_1}, \frac{\pi}{T_1}] \\ 0, & \text{otherwise,} \end{cases}$$

so that

$$y(t) = y'(t) * h(t) = \frac{1}{T_1} \sum_{m=-\infty}^{\infty} x(m) \operatorname{sinc} \frac{\pi}{T_1} (t - mT_1).$$

By re-sampling  $y(t)$  with period  $T_2$ , we obtain the discrete-time signal in the new desired sampling rate as follows:

$$\bar{x}(n) = \frac{1}{T_1} \sum_{m=-\infty}^{\infty} x(m) \operatorname{sinc} \frac{\pi}{T_1} (nT_2 - mT_1),$$

where  $\bar{x}(n) = y(nT_2)$ , with  $n = \dots, 0, 1, 2 \dots$

In this general equation governing sampling rate changes, there is no restriction on the values of  $T_1$  and  $T_2$ . However, if  $T_2 > T_1$  and aliasing is to be avoided, the interpolation filter must have a zero gain for  $\omega \notin [-\frac{\pi}{T_2}, \frac{\pi}{T_2}]$ .

In the case the sampling rate change corresponds to a ratio of integer numbers, all we need is simple decimation and interpolation operations. The decimation operation, or down-sampling, consists of retaining every  $M$ th sample of a given sequence  $x(m)$ . Since we are disposing samples from the original sequence, either the signal is sufficiently limited in band or the signal has to be filtered by a lowpass filter so that the decimated signal retains the useful information of the original signal. Decimation is a time-varying operation, since, if  $x(m)$  is shifted by  $m_0$ , the output signal will, in general, differ from the unshifted output shifted by  $m_0$ . Indeed, decimation is a periodically time-invariant operation, which consist of an extra degree of freedom with respect to the traditional time-invariant systems.

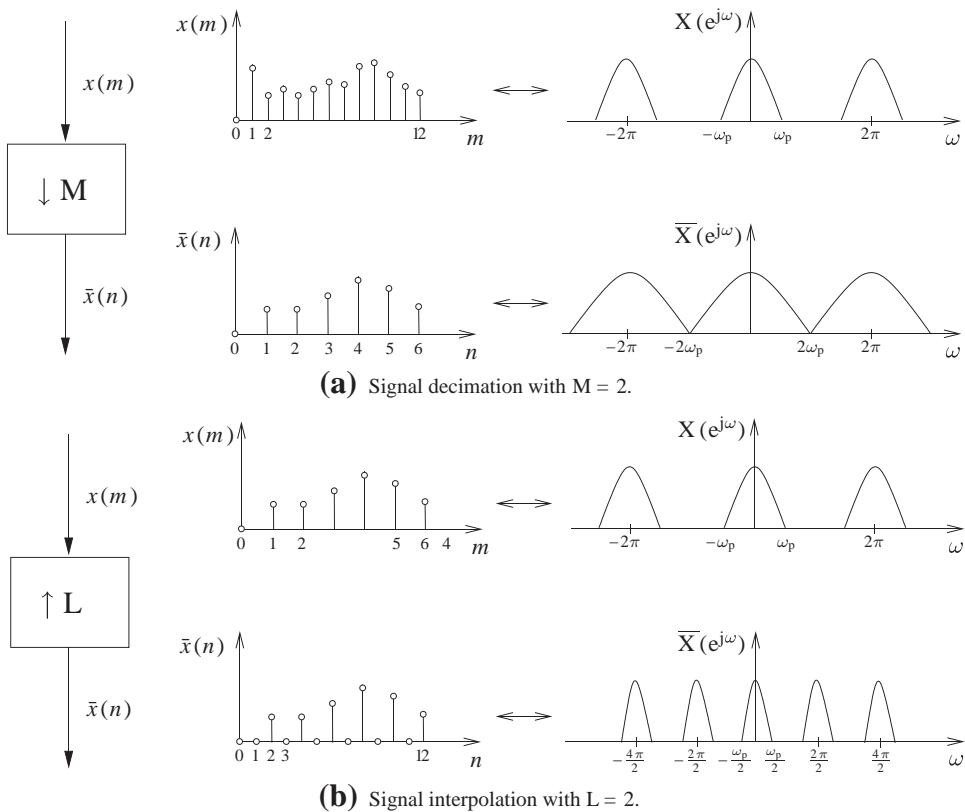

The interpolation, or up-sampling, of a discrete-time signal  $x(m)$  by a factor of  $L$  consists of inserting  $L - 1$  zeros between each of its samples. In the frequency domain, the spectrum of the up-sampled signal is periodically repeated. Given that the spectrum of the original discrete-time signal is periodic with period  $2\pi$ , the interpolated signal will have period  $\frac{2\pi}{L}$ . Therefore, in order to obtain a smooth interpolated version of  $x(m)$ , the spectrum of the interpolated signal must have the same shape of the spectrum of  $x(m)$ . This can be obtained by filtering out the repetitions of the spectra beyond  $[-\frac{\pi}{L}, \frac{\pi}{L}]$ . Thus, the up-sampling operation is generally followed by a lowpass filter. The interpolation is only periodically time-invariant and does not entail any loss of information.

Figure 1.12 illustrates discrete-time signal decimation and interpolation operations. As can be observed in Figure 1.12(a), the decimation factor of two widens the spectrum of the sampled signal in comparison to the new sampling rate. Figure 1.12(b) depicts the effect of increasing the sampling rate of a given sequence by two, where it can be seen that the frequency contents of the original signal repeats twice as often and appears narrower in the new sampling rate.

Chapter 7 will further discuss the theory and practice of multirate signal processing. This chapter will show how sophisticated real-life signal processing problems can be addressed starting from the basic theory. In particular, the authors address the design of flexible communications systems incorporating several advanced signal processing tools [4, 23–25].

### 1.01.9 Filter banks and wavelets

In many applications it is desirable to decompose a wideband discrete-time signal into several non-overlapping narrowband subsignals in order to be transmitted, quantized, or stored. In this case, each narrow-band channel can have its sampling rate reduced, since the subband signals have lower bandwidth than their originator signal. The signal processing tool that performs these tasks is the analysis filter bank. The analysis filters, represented by the transfer functions  $H_i(z)$ , for  $i = 0, 1, \dots, M - 1$ , consist of a lowpass filter  $H_0(z)$ , bandpass filters  $H_i(z)$ , for  $i = 1, 2, \dots, M - 2$ , and a highpass filter  $H_{M-1}(z)$ . Ideally, these filters have non-overlapping passbands, whereas their spectrum combination should cover the overall spectrum of the input signal. The outputs of the analysis filters, denoted as  $x_i(n)$ , for  $i = 0, 1, \dots, M - 1$ , have together  $M$  times the number of samples of the original signal  $x(n)$ . However, since each subband signal occupies a spectrum band  $M$  times narrower than the input signal, they can be decimated so the number of samples in the subbands does not increase. Indeed, if the input signal is uniformly split into subbands, we can decimate each  $x_i(n)$  by a factor of  $L$  smaller or equal to  $M$  without generating unrecoverable aliasing effects. Figure 1.13 shows the general configuration of a maximally (or critically) decimated analysis filter, where the decimation factor is equal to the number of subbands, i.e.,  $L = M$ .

**FIGURE 1.12**

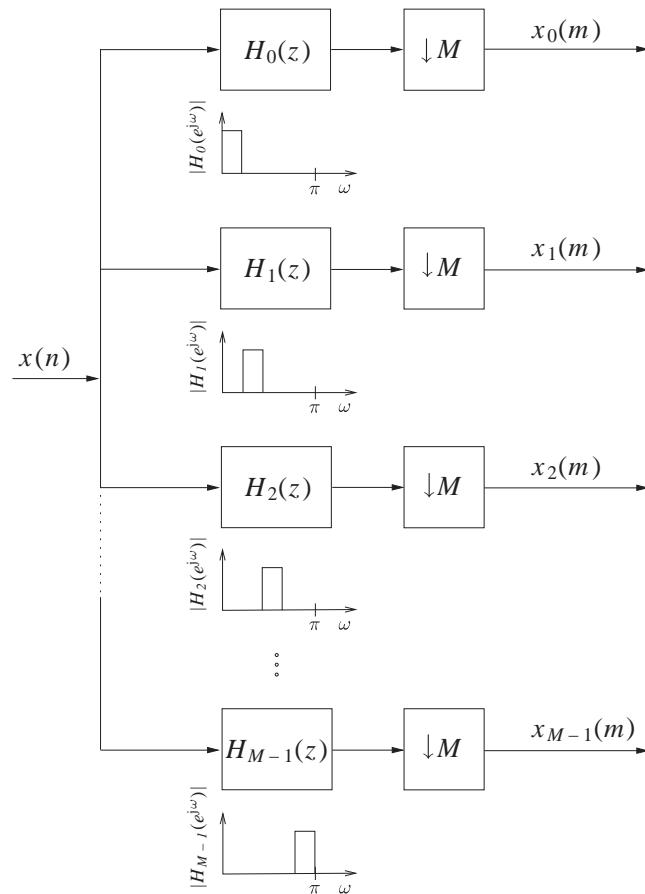

Signal decimation and interpolation. (a) Signal decimation with  $M = 2$ . (b) Signal interpolation with  $L = 2$ .

Whenever the input signal is split in subbands and decimated, if  $L \leq M$ , it is always possible to recover the input signal by properly designing the analysis filters in conjunction with the synthesis filters  $G_i(z)$ , for  $i = 0, 1, \dots, M - 1$ . The synthesis filters are placed after interpolators and they have the task of smoothing the up-sampled signals. Figure 1.14 illustrates the general configuration of the synthesis filter bank. A key feature of the synthesis filter bank is to cancel out or reduce the aliasing effects.

If the signals in the subbands are not modified, the filter bank output  $y(n)$  can be a delayed copy signal of  $x(n)$ . The cascade connection of the analysis and synthesis filter banks satisfying this condition is called a perfect reconstruction filter bank.

The cascade of an  $M$ -channel synthesis filter bank with an  $M$ -channel analysis filter bank gives rise to a transmultiplex system. The transmultiplex model is widely used in communications to model multiuser, multicarrier, and multiple access systems [4,23,24]. Chapter 7 will utilize multirate signal processing and transmultiplexers to discuss a design procedure to be applied in cognitive radio.

Chapter 8 will present several methods for designing the analysis filters  $H_i(z)$  and the synthesis filters  $G_i(z)$ , such that perfect reconstruction, as well as other features, are met. This chapter will also discuss

**FIGURE 1.13**

Analysis Filter Bank.

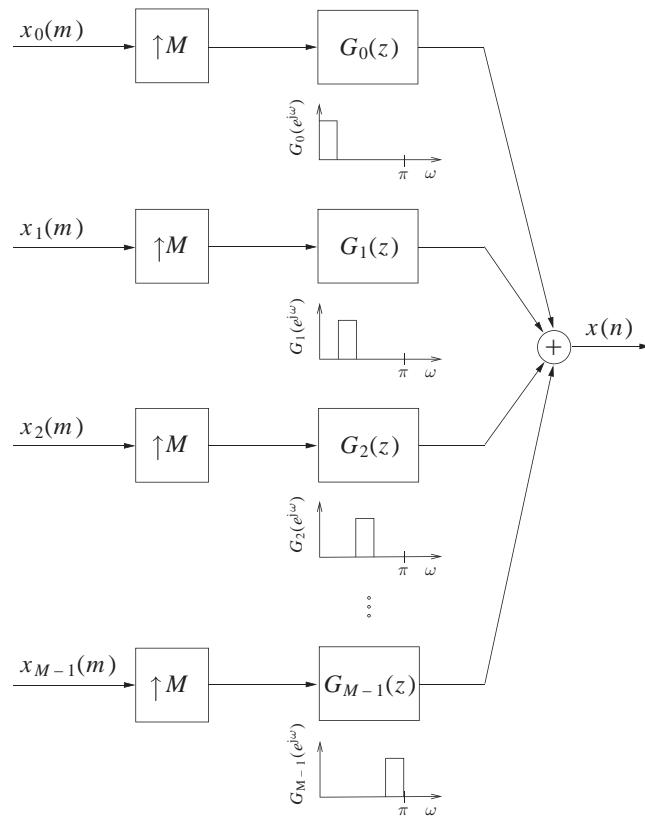

the design of filter banks with the subbands divided in octave bands, giving rise to the discrete-time wavelet series.

Figure 1.15 shows a four-band filter bank design and its effect in a composed signal.

Figure 1.16 illustrates how a four-band synthesis filter bank performs the recomposition of the input signal starting from the decimated subband signals.

### 1.01.10 Discrete multiscale and transforms

Discrete-time signals and systems can be characterized in the frequency domain by their Fourier transforms. One of the main advantages of discrete-time signals is that they can be processed and represented

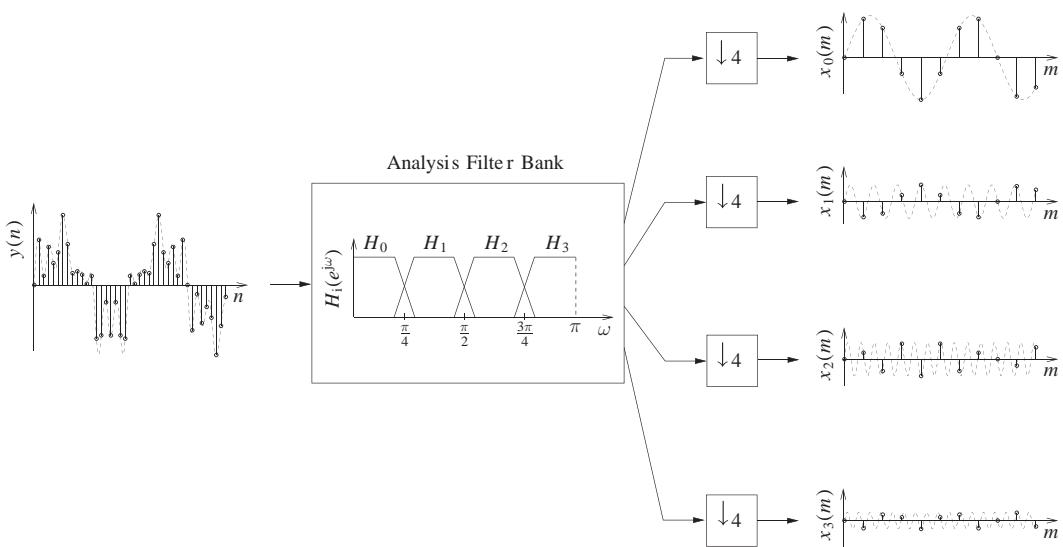

**FIGURE 1.14**

Synthesis Filter Bank.

in digital computers. However, when we examine the definition of the discrete-time Fourier transform,

$$X(e^{j\omega}) = \sum_{n=-\infty}^{\infty} x(n)e^{-j\omega n},$$

we notice that such a characterization in the frequency domain depends on the continuous variable  $\omega$ . This implies that the Fourier transform, as it is, is not suitable for the processing of discrete-time signals in digital computers. We need a transform depending on a discrete-frequency variable that, if possible, preserves the handy interpretations of the Fourier-based tools, which retains important information. This can be obtained from the Fourier transform itself in a very simple way, by sampling uniformly the continuous-frequency variable  $\omega$  as long as the input sequence has finite length, otherwise the time-domain signal will be affected by aliasing. Using this strategy it is possible to obtain a mapping of a signal depending on a discrete-time variable  $n$  to a transform depending on a discrete-frequency

**FIGURE 1.15**

Analysis filter bank design.

variable  $k$ , leading to another interpretation for the DFT. Unfortunately, the DFT has its limitations in representing more general class of signals as will be following discussed.

The wavelet transform of a function belonging to  $\mathcal{L}^2(\mathbb{R})$ , the space of the square integrable functions, is the function decomposition in a basis composed by expansions, compressions, and translations of a single mother function  $\psi(t)$ , called wavelet.

The wavelet transform can be defined as

$$x(t) = \sum_{m=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} c_{m,n} \overline{\psi}_{m,n}(t)$$

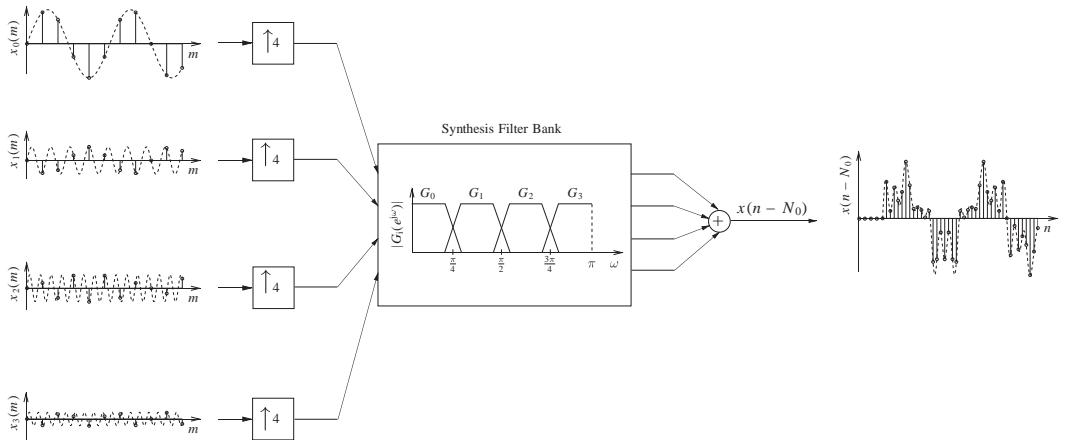

$$c_{m,n} = \int_{-\infty}^{\infty} x(t) \psi_{m,n}^*(t) dt,$$

where

$$\psi_{m,n}(t) = 2^{-m/2} \psi(2^{-m}t - n)$$

$$\overline{\psi}_{m,n}(t) = 2^{-m/2} \overline{\psi}(2^{-m}t - n).$$

This pair of equations defines a biorthogonal wavelet transform which are characterized by two wavelets: the analysis wavelet,  $\psi(t)$ , and the synthesis wavelet,  $\overline{\psi}(t)$ . Any function  $x(t) \in \mathcal{L}^2(\mathbb{R})$  can be

**FIGURE 1.16**

Synthesis filter bank design.

decomposed as a linear combination of contractions, expansions, and translations of the synthesis wavelet  $\bar{\psi}(t)$ . The weights of the expansion can be computed via the inner product of  $x(t)$  with expansions, contractions, and translations of the analysis wavelet  $\psi(t)$ .

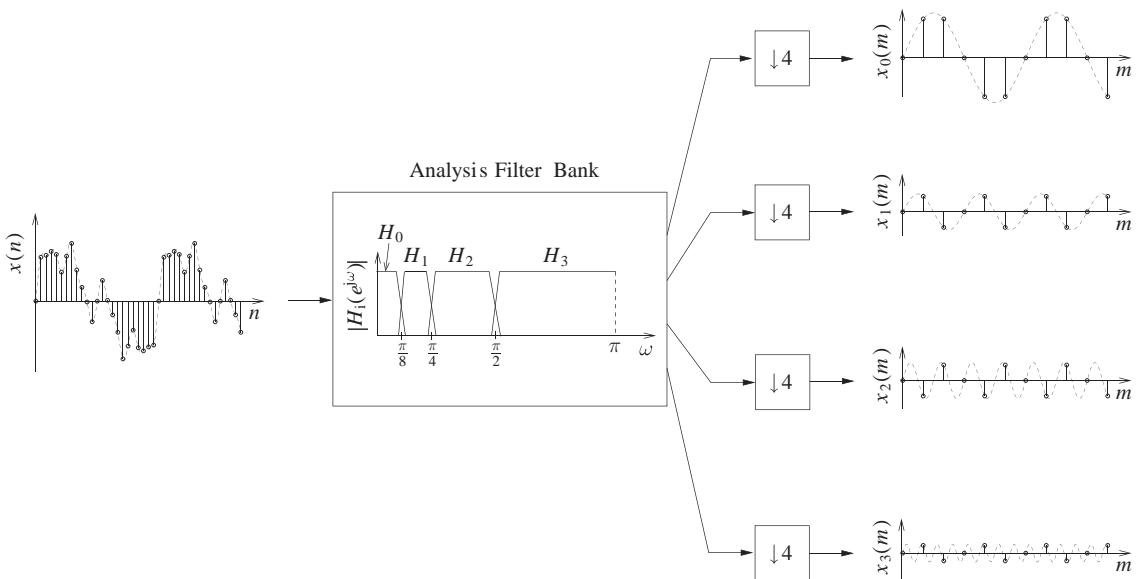

Functions  $\psi_{m,n}(t)$  do not comprise an orthogonal set, so neither do the functions  $\bar{\psi}_{m,n}(t)$ . However, functions  $\psi_{m,n}(t)$  are orthogonal to  $\bar{\psi}_{m,n}(t)$  so that

$$\langle \psi_{m,n}(t), \bar{\psi}_{k,l}(t) \rangle = \delta(m - k)\delta(n - l).$$

A byproduct of the development of the wavelet transforms is the so called wavelet series, allowing the representation of signals in the time and frequency domains through sequences. The cascade of two-band filter banks can produce many alternative maximally decimated decompositions. Of particular interest is the hierarchical decomposition achieving an octave-band decomposition, in which only the lowpass band is further decomposed. This configuration gives rise to the widely used wavelets series.

As will be discussed in Chapter 10, there are many transform-based tools in signal processing theory available to meet the requirement of different applications. The classical Fourier based transforms have been used for centuries, but their efficiency in dealing with nonstationary signals is limited. With wavelet series, for example, it is possible to obtain good resolution in time and frequency domains, unlike the Fourier-based analysis. Chapter 9 will include a myriad of transform solutions tailored for distinct practical situations.

Figure 1.17 illustrates a wavelet series representation of a composed signal, where the input signal is decomposed by an octave-band filter bank representing a wavelet series.

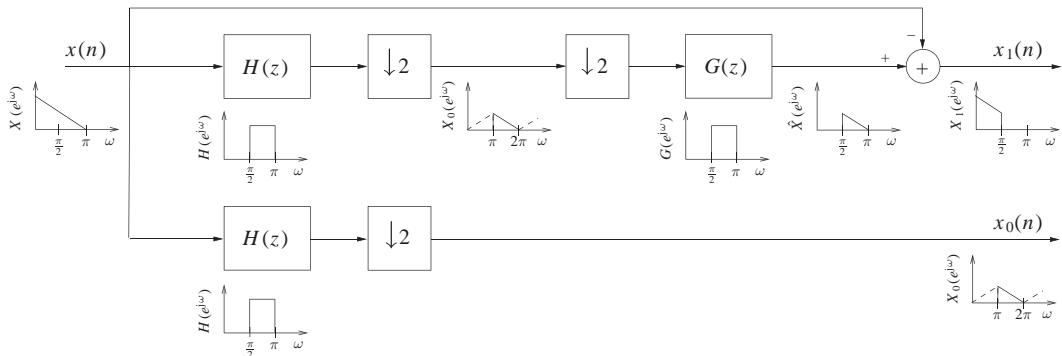

**FIGURE 1.17**

Wavelet series of a composed sinusoidal signal.

### 1.01.11 Frames

Frames consist of a set of vectors that enables a stable representation of a signal starting from an analysis operation whereby a set of coefficients is generated from the signal projection with the frame vectors, and a synthesis operation where the synthesis vectors are linearly combined to approximate the original signal. Chapter 10 will introduce the idea of frames by discussing the concepts of overcomplete representations, frames and their duals, frame operators, inverse frames and frame bounds. In particular, it will show how to implement signal analysis and synthesis employing frames generated from a fixed prototype signal by using translations, modulations and dilations; and analyzes frames of translates, Gabor frames and wavelet frames. The frames representation is usually redundant by requiring more coefficients than the minimum, where redundancy is measured by frame bounds [13]. The end result of employing the framework of frames is a set of signal processing tools such as: the Gabogram; time-frequency analysis; the matching pursuit algorithm, etc.

Figure 1.18 shows the representation of a composed signal into frames. As can be observed the representation of  $x(n)$  by  $x_1(n)$  and  $x_0(n)$  is redundant, since  $x_1(n)$  has the same rate as the input signal  $x(n)$ , whereas  $x_0(n)$  has half rate.

**FIGURE 1.18**

Frame representation.

## 1.01.12 Parameter estimation

In many signal processing applications it is crucial to estimate the power spectral density (PSD) of a given discrete-time signal. Examples of the use of PSD are vocal-track modeling, radar systems, antenna array, sonar systems, synthesis of speech and music, just to name a few. Usually, the first step in PSD estimation consists of estimating the autocorrelation function associated with the given data, followed by a Fourier transform to obtain the desired spectral description of the process.

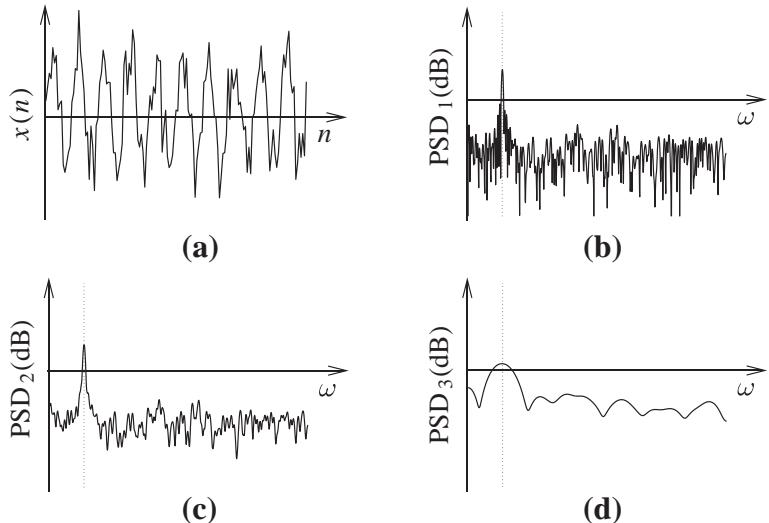

In the literature we can find a large number of sources dealing with algorithms for performing spectral estimation. The alternative solutions differ in their computational complexity, precision, frequency resolution, or other statistical aspects. In general, the spectral estimation methods can be classified as nonparametric or parametric methods. The nonparametric methods do not prescribe any particular structure for the given data, whereas parametric schemes assume that the provided process follows the pattern of a prescribed model characterized by a specific set of parameters [14].

Since the parametric approaches are simpler and more accurate, they will be emphasized in [Chapter 11](#). However, it should be mentioned that the parametric methods rely on some (a priori) information regarding the problem at hand.

[Figure 1.19](#) shows a noisy signal record and the estimated PSDs utilizing distinct methods. As can be observed, some of the resulting PSDs expose the presence of a sinusoid, not clearly observed in the time-domain signal.

## 1.01.13 Adaptive filtering

In many practical situations we can extract information from a signal by comparing it to another signal or a reference. For the cases where the specifications are neither known nor time-invariant, an adaptive filter is the natural solution. The coefficients of these filters are data driven and the resulting processing

**FIGURE 1.19**

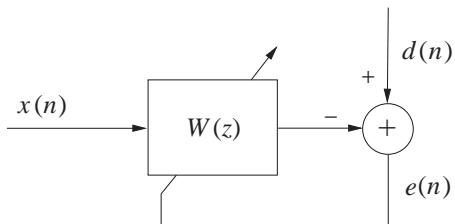

Spectral estimation. (a) Time-domain signal. (b) Estimated PSD1.(C) Estimated PSD2. (d) Estimated PSD3.

task does not meet the homogeneity and additive conditions of linear filtering. An adaptive filter is also time-varying since its parameters are continually changing in order to minimize a cost function.

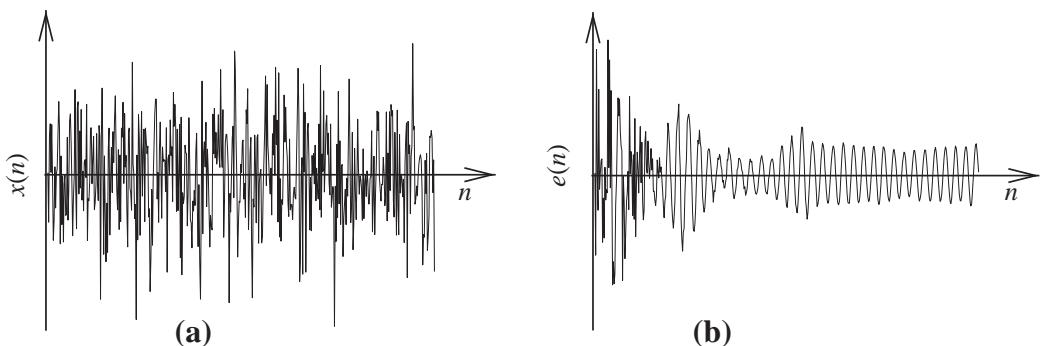

Adaptive filters are self-designing and perform the approximation step on-line. Starting from an initial condition, the adaptive filter searches an optimal solution in an iterative format. Since adaptive filters are nonlinear filters, the analysis of their performance behavior requires the solution of time-domain equations usually involving the second-order statistics of their internal and external quantities. Although the analysis of an adaptive filter is more complicated than for fixed filters, it is a simple solution to deal with unknown stationary and nonstationary environments. On the other hand, since the adaptive filters are self-designing filters, their design can be considered less involved than those of standard fixed digital filters [3]. An important topic related to adaptive filtering is neural networks and machine learning [26], not directly covered in this book.

Figure 1.20 depicts the general setup of an adaptive-filtering environment, where, for a given iteration  $n$ , an input signal  $x(n)$  excites the adaptive filter which will produce an output signal  $y(n)$  which is then compared with a reference signal  $d(n)$ . From this comparison, an error signal  $e(n)$  is formed according to  $d(n) - y(n)$ . The error signal is the argument of a cost (or objective) function whose minimization is achieved by properly adapting the adaptive filter coefficients. In Figure 1.21, it is shown a signal enhancement where it is recognized in the error signal that the input signal contained a sinusoidal component. In Figure 1.21 (a) it is difficult to observe the presence of a sinusoidal signal whereas the error signal clearly shows a nearly sinusoidal behavior.

Chapter 12 will present a comprehensive overview related to adaptive signal processing that unifies several concepts that go beyond the concepts covered in textbooks such as [3, 27, 28].

## 1.01.14 Closing comments

The theory of signal processing has been developing for over four decades at a fast pace. The following chapters will cover many of the classical tools widely employed in applications that we perceive in our daily life through the use of mobile phones, media players, medical equipments, transportation and so on. These chapters will also cover recent advances and describe many new tools which can potentially be utilized in new applications, as well as can be further investigated. The authors of the chapters are frequent and important contributors to the field of signal processing theory. The goal of each chapter is to provide an overview and a brief tutorial of important topic pertaining to the signal processing theory, including key references for further studies. The present chapter attempted to describe the context in which each family of tools is employed.

The rest of this book is organized as follows:

- [Chapter 2](#) covers the basic concepts of Continuous-Time Signals and Systems highlighting the main tools that can be employed to analyze and design such systems. Several examples are included to

illustrate the use of the tools in a full continuous-time environment. The content of this chapter is also essential to make the connection between the continuous-time and the discrete-time systems.

- [Chapter 3](#) addresses Discrete-Time Signals and Systems emphasizing the basic analysis tools that will be crucial to understand some more advanced techniques presented in the forthcoming chapters. This chapter shows how the powerful state-space representation of discrete-time systems can be employed as an analysis and design tool.
- [Chapter 4](#) on Random Signals and Stochastic Processes describes in a comprehensive way the basic concepts required to deal with random signals. It starts with the concept of probability useful to model chance experiments, whose outcomes give rise to the random variable. The time-domain signals representing non-static outcomes are known as stochastic processes where their full definition is provided. The chapter describes the tools to model the interactions between random signals and linear-time invariant systems.
- [Chapter 5](#) covers Sampling and Quantization where the basic concepts of properly sampling a continuous-time signal and its representation as a sequence of discrete-valued samples are addressed in detail. The chapter discusses a wide range of topics rarely found in a single textbook such as: uniform sampling and reconstruction of deterministic signals; the extension to sampling and reconstruction of stochastic processes; time-interleaved ADCs for high-speed A/D conversion. In addition, topics related to the correction to analog channel mismatches, principles of quantization, and over-sampled ADCs and DACs are briefly discussed. The chapter also includes the more advanced method for discrete-time modeling of mixed-signal systems employed in  $\Sigma\Delta$ -modulator-based ADCs.
- [Chapter 6](#) takes us to a tour on design of FIR and IIR transfer functions of fixed filters satisfying prescribed specifications, explaining their basic realizations and exploring more sophisticated realizations. For IIR filters, the chapter introduces the concept of wave digital filter in a concise and clear manner, providing the motivation for its conception from the analog filter structures. The resulting IIR filter realizations keep the low sensitivity properties of their analog originators. For FIR filter structures, the chapter covers the frequency masking approach that exploits redundancy in the impulse response of typical FIR filters with high selectivity, aiming at reducing the computational complexity. The chapter also explains in detail how to implement digital filters efficiently in specific hardware by properly scheduling the arithmetic operations.
- [Chapter 7](#) on Multirate Signal Processing for Software Radio Architecture applies several concepts presented in the previous chapters as tools to develop and conceive the implementation of radio defined by software, a subject of great interest in modern communications systems. Software defined radio entails implementing radio functionality into software, resulting in flexible radio systems whose main objective is to provide multi-service, multi-standard, multi-band features, all reconfigurable by software. From the signal processing perspective, several basic concepts of multirate systems such as, interpolation, decimation, polyphase decomposition, and transmultiplex play a central role. The chapter reviews the required concepts of signal processing theory and propose a software based radio architecture.
- [Chapter 8](#) on Modern Transform Design for Practical Audio/Image/Video Coding Applications addresses the design of several applications-oriented transform methods. Most signal processing textbooks present the classical transforms requiring large amount of multiplications, however the demand for low-power multimedia platforms requires the development of computationally efficient

transforms for coding applications. This chapter has the unique feature of presenting systematic procedures to design these transforms while illustrating their practical use in standard codecs.

- [Chapter 9](#) entitled Discrete Multi-Scale Transforms in Signal Processing presents a deeper high level exposition of the theoretical frameworks of the classical wavelets and the anisotropic wavelets. The aim is to enable the reader with enough knowledge of the wavelet-based tools in order to exploit their potential for applications in information sciences even further. Indeed the material covered in this chapter is unique in the sense that every discrete multi-scale transform is linked to a potential application.
- [Chapter 10](#) on Frames discusses the use of overcomplete signal representations employing frames and their duals, frame operators, inverse frames, and frame bounds. The signal analysis and synthesis using frame representation is also addressed in detail. In particular, the chapter emphasis is on frames generated from a fixed prototype signal by using translations, modulations and dilations, and analyzes frames of translates, Gabor frames and wavelet frames. The chapter also presents signal analysis techniques based on the Gaborgram and time-frequency analysis using frames and the matching pursuit algorithm.
- [Chapter 11](#) on Parametric Estimation exploits the key engineering concept related to modeling signals and systems, so that the model provides understanding of the underlying phenomena and possibly their control. This chapter emphasizes the parametric models leading to simple estimation of the parameters while exposing the main characteristics of the signals or systems under study. By employing both statistical and deterministic formulations, the chapter explains how to generate auto-regressive and moving average models which are then applied to solve problems related to spectrum estimation, prediction, and filtering.
- [Chapter 12](#) on Adaptive Filtering presents a comprehensive description of the current trends as well as some open problems in this area. The chapter discusses the basic building blocks utilized in adaptive filtering setup as well as its typical applications. Then, the chapter discusses what are the optimal solutions following by the derivation of the main algorithms. The authors confront for the first time two standard approaches to access the performance of the adaptive filtering algorithms. The chapter closes by discussing some current research topics and open problems for further investigation.

## Nomenclature

C	capacitance, in Faraday (F)
f	frequency, in cycles per second or Hertz (Hz)
L	inductance, in Henry (H)
R	resistance, in Ohms ( $\Omega$ )
t	time, in Second (s)
$x(t)$	input signal of a given continuous-time system, expressed in volt (V) when it corresponds to an input voltage; $y(t)$ is usually used as the output signal
$\Omega$	angular frequency, in radian per second (rad/s) (it is sometimes referred to as <i>frequency</i> although corresponding to $2\pi f$ )

---

### 1.02.1 Introduction

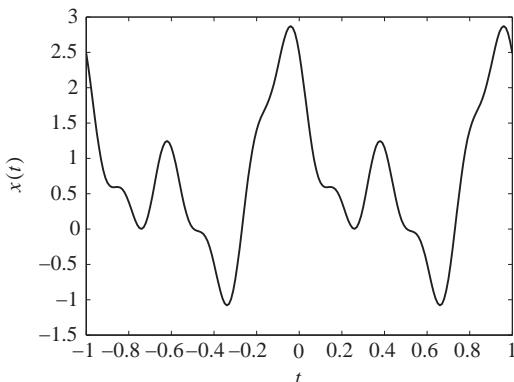

Most signals present in our daily life are continuous in time such as music and speech. A signal is a function of an independent variable, usually an observation measured from the real world such as position, depth, temperature, pressure, or time. Continuous-time signals have a continuous independent variable. The velocity of a car could be considered a continuous-time signal if, at any time  $t$ , the velocity  $v(t)$  could be defined. A continuous-time signal with a continuous amplitude is usually called an analog signal, speech signal being a typical example.

Signals convey information and are generated by electronic or natural means as when someone talks or plays a musical instrument. The goal of signal processing is to extract the useful information embedded in a signal.

Electronics for audio and last generation mobile phones must rely on universal concepts associated with the flow of information to make these devices fully functional. Therefore, a system designer, in order to have the necessary understanding of advanced topics, needs to master basic signals and systems theory. System theory could then be defined as the relation between signals, input and output signals.

---

<sup>1</sup> Authors thank Prof. Ney Bruno for his kind and competent review of this chapter.

**FIGURE 2.1**

Example of a continuous-time signal.

As characterizing the complete input/output properties of a system through measurement is, in general, impossible, the idea is to infer the system response to non-measured inputs based on a limited number of measurements. System design is a challenging task. However, several systems can be accurately modeled as linear systems. Hence, the designer has to create between the input and the output, an expected, or predictable, relationship that is always the same (time-invariant). In addition, for a range of possible input types, the system should generate a predictable output in accordance to the input/output relationship.

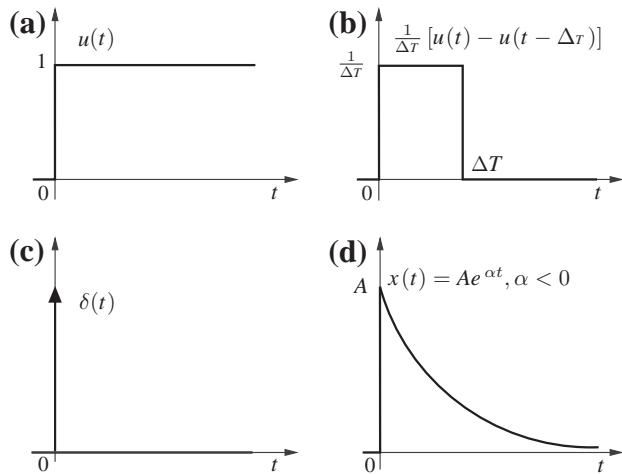

A continuous-time signal is defined on the continuum of time values as the one depicted in Figure 2.1,  $x(t)$  for  $t \in \mathbb{R}$ .

Although signals are real mathematical functions, some transformations can produce complex signals that have both real and imaginary parts. Therefore, throughout this book, complex domain equivalents of real signals will certainly appear.

Elementary continuous-time signals are the basis to build more intricate signals. The unit step signal,  $u(t)$ , displayed by Figure 2.2a is equal to 1 for all time greater than or equal to zero, and is equal to zero for all time less than zero. A step of height  $K$  can be made with  $Ku(t)$ .

A unit area pulse is pictured in Figure 2.2b; as  $\Delta\tau$  gets smaller, the pulse gets higher and narrower with a constant area of one (unit area). We can see the impulse signal, in Figure 2.2c, as a limiting case of the pulse signal when the pulse is infinitely narrow. The impulse response will help to estimate how the system will respond to other possible *stimuli*, and we will further explore this topic on the next section.

Exponential signals are important for signals and systems as eigensignals of linear time-invariant systems. In Figure 2.2d, for  $A$  and  $\alpha$  being real numbers,  $\alpha$  negative, the signal is a decaying exponential. When  $\alpha$  is a complex number, the signal is called a complex exponential signal. The periodic signals sine and cosine are used for modeling the interaction of signals and systems, and the usage of complex exponentials to manipulate sinusoidal functions turns trigonometry into elementary arithmetic and algebra.

**FIGURE 2.2**

Basic continuous-time signals: (a) unit-step signal  $u(t)$ , (b) unit-area pulse, (c) impulse signal (unit-area pulse when  $\Delta\tau \rightarrow 0$ ), and (d) exponential signal.

## 1.02.2 Continuous-time systems

We start this section by providing a simplified classification of continuous-time systems in order to focus on our main interest: a linear and time-invariant (LTI) system.

Why are linearity and time-invariance important? In general, real world systems can be successfully modeled by theoretical LTI systems; in an electrical circuit, for instance, a system can be designed using a well developed linear theory (valid for LTI systems) and be implemented using real components such as resistors, inductors, and capacitors. Even though the physical components, strictly speaking, do not comply with linearity and time-invariance for any input signals, the circuit will work quite well under reasonable conditions (input voltages constrained to the linear working ranges of the components).

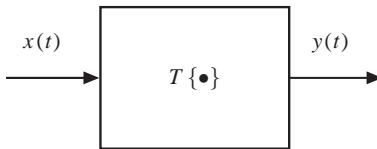

A system can be modeled as a function that transforms, or maps, the input signal into a new output signal. Let a continuous-time system be represented as in Figure 2.3 where  $x(t)$  is the input signal and  $y(t)$ , its output signal, corresponds to a transformation applied to the input signal:  $y(t) = \mathcal{T}\{x(t)\}$ .

The two following properties define a LTI system.

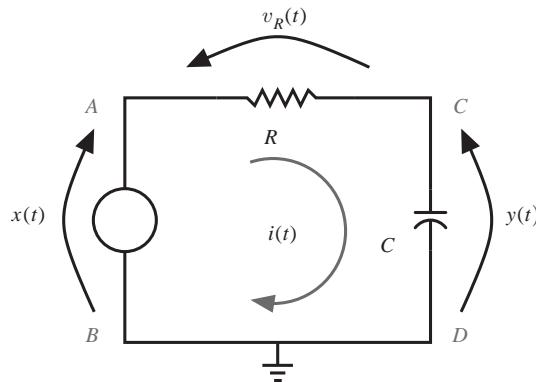

**Linearity:** A continuous-time system is said to be linear if a linear combination of input signals, when applied to this system, produces an output that corresponds to a linear combination of individual outputs, i.e.,

$$\begin{aligned} y(t) &= \mathcal{T}\{a_1x_1(t) + a_2x_2(t) + \dots\} \\ &= a_1\mathcal{T}\{x_1(t)\} + a_2\mathcal{T}\{x_2(t)\} + \dots \\ &= a_1y_1(t) + a_2y_2(t) + \dots, \end{aligned} \tag{2.1}$$

where  $y_i(t) = \mathcal{T}\{x_i(t)\}$ .

**FIGURE 2.3**

A generic continuous-time system representing the output signal as a transformation applied to the input signal:  $y(t) = T\{x(t)\}$ .

**FIGURE 2.4**

An example of an electric circuit representing a continuous-time system with input  $x(t)$  and output  $y(t)$ .

**Time-invariance:** A continuous-time system is said to be time-invariant when the output signal,  $y(t)$ , corresponding to an input signal  $x(t)$ , will be a delayed version of the original output,  $y(t - t_0)$ , whenever the input is delayed accordingly, i.e.,

$$\begin{aligned} &\text{if } y(t) = T\{x(t)\}; \\ &\text{then } y(t - t_0) = T\{x(t - t_0)\}. \end{aligned}$$

The transformation caused in the input signal by a linear time-invariant system may be represented in a number of ways: with a set of differential equations, with the help of a set of state-variables, with the aid of the concept of the impulse response, or in a transformed domain.

Let the circuit in Figure 2.4 be an example of a continuous-time system where the input  $x(t)$  corresponds to the voltage between terminals  $\mathcal{A}$  and  $\mathcal{B}$  while its output  $y(t)$  is described by the voltage between terminals  $\mathcal{C}$  and  $\mathcal{D}$ .

We know for this circuit that  $x(t) = y(t) + v_R(t)$  and that the current in the capacitor,  $i(t)$ , corresponds to  $C dy(t)/dt$ . Therefore,  $v_R(t) = Ri(t) = RC dy(t)/dt$ , and we can write

$$RC \frac{dy(t)}{dt} + y(t) = x(t), \quad (2.2)$$

which is an input-output (external) representation of a continuous-time system given as a differential equation.

Another representation of a linear system, widely used in control theory, is the state-space representation. This representation will be presented in the next section since it is better explored for systems having a higher order differential equation.

In order to find an explicit expression for  $y(t)$  as a function of  $x(t)$ , we need to solve the differential equation. The complete solution of this system, as shall be seen in the following section, is given by the sum of an homogeneous solution (zero-input solution or natural response) and a particular solution (zero-state solution or forced solution):

$$y(t) = \underbrace{y_h(t)}_{\text{homogeneous solution}} + \underbrace{y_p(t)}_{\text{particular solution}}. \quad (2.3)$$

The homogeneous solution, in our example, is obtained from (2.2) by setting  $RD dy_h(t)/dt + y_h(t) = 0$ . Since this solution and its derivatives must comply with the homogeneous differential equation, its usual choice is an exponential function such as  $Ke^{st}$ ,  $s$  being, in general, a complex number. Replacing this general expression in the homogeneous differential equation, we obtain  $RCs + 1 = 0$  (characteristic equation) and, therefore,  $s = -1/RC$ , such that the homogenous solution becomes

$$y_h(t) = Ke^{-\frac{t}{RC}}, \quad (2.4)$$

where  $K$  is a constant.

The particular solution is usually of the same form as the forcing function (input voltage  $x(t)$  in our example) and it must comply with the differential equation without an arbitrary constant. In our example, if  $x(t) = Me^{-mt}$ ,  $y_p(t)$  would be  $\frac{M}{1-mRC}e^{-mt}$ .

If we set  $x(t) = u(t)$ , the step function which can be seen as a DC voltage of 1 Volt switched at time instant  $t = 0$ , the forced solution is assumed to be equal to one when  $t \geq 0$ . For this particular input  $x(t) = u(t)$ , the output signal is given by  $y(t) = (Ke^{-\frac{t}{RC}} + 1)u(t)$ . Constant  $K$  is obtained with the knowledge of the initial charge of the capacitor (*initial conditions*); assuming it is not charged ( $v_c(t) = 0$ ,  $t \leq 0$ ), we have

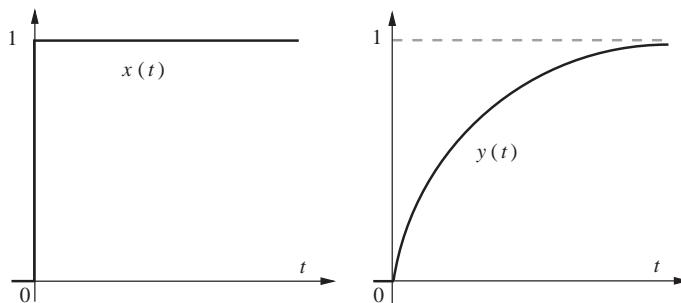

$$y(t) = (1 - e^{-\frac{t}{RC}})u(t), \quad (2.5)$$

which can be observed in Figure 2.5.

Note that, for this case where  $x(t) = u(t)$ , the output  $y(t)$  is known as the *step response*, i.e.,  $r(t) = y(t)|_{x(t)=u(t)}$ . Moreover, since the impulse  $\delta(t)$  corresponds to the derivative of  $u(t)$ ,  $\delta(t) = du(t)/dt$ , and the system is LTI (linear and time-invariant), we may write that  $dr(t)/dt = dT\{u(t)\}/dt$  which corresponds to  $T\{du(t)/dt\}$ , the transformation applied to the impulse signal leading to

$$h(t) = \frac{dr(t)}{dt}, \quad (2.6)$$

$h(t)$  known as the *impulse response* or  $h(t) = y(t)|_{x(t)=\delta(t)}$ .

**FIGURE 2.5**

Input and output signals of the system depicted in Figure 2.4. See [Video 1](#) to watch animation.

The impulse response is, particularly, an important characterization of a linear system. It will help to estimate how the system will respond to other *stimuli*. In order to show the relevance of this, let us define the unit impulse as

$$\delta(t) = \lim_{\Delta\tau \rightarrow 0} \frac{1}{\Delta\tau} [u(t) - u(t - \Delta\tau)], \quad (2.7)$$

such that we may see an input signal \$x(t)\$ as in Figure 2.6:

$$x(t) \approx \sum_{k=-\infty}^{\infty} x(k\Delta\tau) \underbrace{\left[ \frac{u(t - k\Delta\tau) - u(t - k\Delta\tau - \Delta\tau)}{\Delta\tau} \right]}_{\delta(t - k\Delta\tau) \text{ when } \Delta\tau \rightarrow 0} \Delta\tau. \quad (2.8)$$

The idea is to show that any signal, e.g., \$x(t)\$, can be expressed as a sum of scaled and shifted impulse functions.

In (2.8), making \$\Delta\tau \rightarrow 0\$ and representing the resulting continuous time by \$\tau\$ instead of \$k\Delta\tau\$, we can use the integral instead of the summation and find

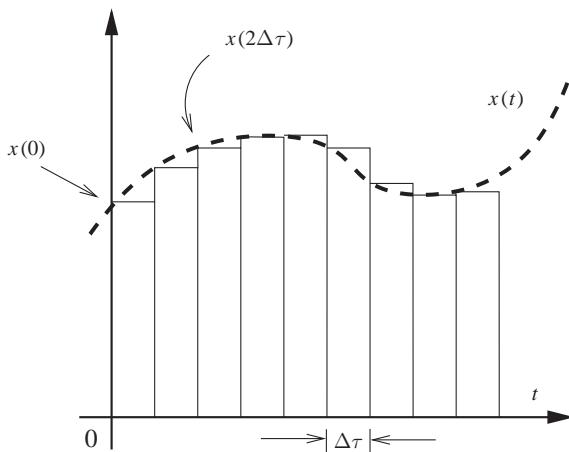

$$x(t) = \int_{-\infty}^{\infty} x(\tau) \delta(t - \tau) d\tau. \quad (2.9)$$

In a LTI system, using the previous expression as an input signal to compute the output \$y(t) = T\{x(t)\}\$, we obtain \$\int\_{-\infty}^{\infty} x(\tau) T\{\delta(t - \tau)\} d\tau\$ such that the output signal can be written as

$$y(t) = \int_{-\infty}^{\infty} x(\tau) h(t - \tau) d\tau. \quad (2.10)$$

This expression is known as the *convolution* integral between the input signal and the system impulse response, and is represented as

$$y(t) = x(t) * h(t). \quad (2.11)$$

**FIGURE 2.6**

A signal  $x(t)$  can be obtained from the pulses if we make  $\Delta\tau \rightarrow 0$ .

Please note that the output signal provided by the convolution integral corresponds to the zero-state solution.

From Figure 2.6, another approximation for  $x(t)$  can be devised, leading to another expression relating input and output signals. At a certain instant  $t = \tau$ , let the angle of a tangent line to the curve of  $x(t)$  be  $\theta$  such that  $\tan \theta = \frac{dx(\tau)}{d\tau}$ . Assuming a very small  $\Delta\tau$ , this tangent can be approximated by  $\frac{\Delta x(\tau)}{\Delta\tau}$  such that

$$\Delta x(\tau) = \frac{dx(\tau)}{d\tau} \Delta\tau. \quad (2.12)$$

Knowing each increment at every instant  $t = k\Delta\tau$ , we can visualize an approximation for  $x(t)$  as a sum of shifted and weighted step functions  $u(t - k\Delta\tau)$ , i.e.,

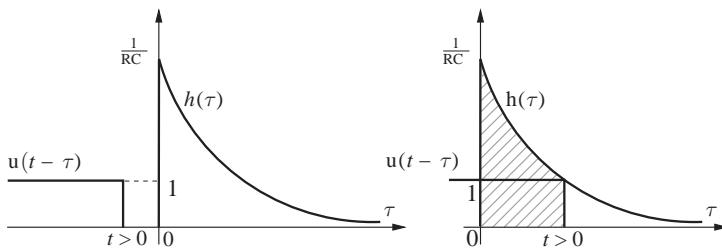

$$x(t) \approx \sum_{k=-\infty}^{\infty} \Delta x(k\Delta\tau) u(t - k\Delta\tau) = \sum_{k=-\infty}^{\infty} \frac{dx(k\Delta\tau)}{d\tau} u(t - k\Delta\tau) \Delta\tau. \quad (2.13)$$

From the previous expression, if we once more, as in (2.9), make  $\Delta\tau \rightarrow 0$  and represent the resulting continuous-time by  $\tau$  instead of  $k\Delta\tau$ , we can drop the summation and use the integral to obtain

$$x(t) = \int_{-\infty}^{\infty} \frac{dx(\tau)}{d\tau} u(t - \tau) d\tau. \quad (2.14)$$

Assuming, again, that the system is LTI, we use the last expression as an input signal to compute the output  $y(t) = \mathcal{T}\{x(t)\}$ , obtaining  $\int_{-\infty}^{\infty} \frac{dx(\tau)}{d\tau} \mathcal{T}\{u(t - \tau)\} d\tau$  which can be written as

$$y(t) = \int_{-\infty}^{\infty} \frac{dx(\tau)}{d\tau} r(t - \tau) d\tau \quad (2.15)$$

**FIGURE 2.7**

Graphical interpretation of the convolution integral. See [Video 2](#) to watch animation.

or,  $r(t)$  being the step-response, as

$$y(t) = \frac{dx(t)}{dt} * r(t). \quad (2.16)$$

In our example from Figure 2.4, taking the derivative of  $r(t) = (1 - e^{-t/RC})u(t)$ , we obtain the impulse response (the computation of this derivative is somehow tricky for we must bear in mind that the voltage in the terminals of a capacitor cannot present discontinuities; just as in the case of the current through an inductor) as:

$$h(t) = \frac{1}{RC}e^{-\frac{t}{RC}}. \quad (2.17)$$

In order to have a graphical interpretation of the convolution, we make  $x(t) = u(t)$  in (2.11) and use

$$r(t) = h(t) * u(t) = \int_{-\infty}^{\infty} h(\tau)u(t - \tau)d\tau; \quad (2.18)$$

we then compute this integral, as indicated in Figure 2.7, in two parts:

$$\begin{aligned} &\text{for } t < 0 : r(t) = 0; \\ &\text{for } t > 0 : r(t) = \int_0^t h(\tau)d\tau = \frac{1}{RC} \int_0^t e^{-\frac{\tau}{RC}}d\tau. \end{aligned} \quad (2.19)$$

Finally, from (2.19), we obtain  $r(t) = (1 - e^{-t/RC})u(t)$ , as previously known.

A few mathematical properties of the convolution are listed in the following:

- *Commutative*:  $x(t) * h(t) = h(t) * x(t)$ .
- *Associative*:  $[x(t) * h_1(t)] * h_2(t) = x(t) * [h_1(t) * h_2(t)]$ .
- *Distributive*:  $x(t) * [h_1(t) + h_2(t)] = x(t) * h_1(t) + x(t) * h_2(t)$ .
- *Identity element of convolution*:  $x(t) * \delta(t) = x(t)$ .

The properties of convolution can be used to analyze different system combinations. For example, if two systems with impulse responses  $h_1(t)$  and  $h_2(t)$  are cascaded, the whole cascade system will present the impulse response  $h_1(t) * h_2(t)$ . The commutative property allows the order of the systems of the cascade combination to be changed without affecting the whole system's response.

Two other important system properties are causability and stability.

*Causability:* A causal system, also known as non-anticipative system, is a system in which its output  $y(t)$  depends only in the current and past (not future) information about  $x(t)$ . A non-causal, or anticipative, system is actually not feasible to be implemented in real-life. For example,  $y(t) = x(t + 1)$  is non-causal, whereas  $y(t) = x(t - 1)$  is causal.

With respect to the impulse response, it is also worth mentioning that, for a causal system,  $h(t) = 0$  for  $t < 0$ .

*Stability:* A system is stable if and only if every bounded input produces a bounded output, i.e., if  $|x(t)| < B_x$  then  $|y(t)| < B_y$  for all values of  $t$ .

More about stability will be addressed in a forthcoming section, after the concept of poles and zeros is introduced.

The classic texts for the subjects discussed in this section include [1–5].

### 1.02.3 Differential equations

In many engineering applications, the behavior of a system is described by a differential equation. A differential equation is merely an equation with derivative of at least one of its variables. Two simple examples follow:

$$a \frac{d^2x}{dt^2} + b \frac{dx}{dt} + c = \sin(t), \text{ and} \quad (2.20)$$

$$\frac{\partial^2 z}{\partial x^2} + \frac{\partial^2 z}{\partial y^2} = x^2 + y^2 \quad (2.21)$$

where  $a$ ,  $b$ , and  $c$  are constants.

In (2.20), we observe an *ordinary differential equation*, i.e., there is only one independent variable and  $x = f(t)$ ,  $t$  being the independent variable. On the other hand, in (2.21), we have a *partial differential equation* where  $z = f(x, y)$ ,  $x$  and  $y$  being two independent variables. Both examples have *order 2* (highest derivative appearing in the equation) and *degree 1* (power of the highest derivative term).

This section deals with the solution of differential equations usually employed to represent the mathematical relationship between input and output signals of a linear system. We are therefore most interested in linear differential equations with constant coefficients having the following general form:

$$a_0 y + a_1 \frac{dy}{dt} + \cdots + a_N \frac{d^N y}{dt^N} = b_0 x + b_1 \frac{dx}{dt} + \cdots + b_M \frac{d^M x}{dt^M}. \quad (2.22)$$

The expression on the right side of (2.22) is known as *forcing function*,  $f(t)$ . When  $f(t) = 0$ , the differential equation is known as *homogeneous* while a non-zero forcing function corresponds to a nonhomogeneous differential equation such as in

$$a_0 y + a_1 \frac{dy}{dt} + \cdots + a_N \frac{d^N y}{dt^N} = f(t). \quad (2.23)$$

As mentioned in the previous section, the general solution of a differential equation as the one in (2.22) is given by the sum of two expressions:  $y_H(t)$ , the solution of the associated homogeneous differential equation

$$a_0 y + a_1 \frac{dy}{dt} + \cdots + a_N \frac{d^N y}{dt^N} = 0, \quad (2.24)$$

and a particular solution of the nonhomogeneous equation,  $y_P(t)$ , such that

$$y(t) = y_H(t) + y_P(t). \quad (2.25)$$

*Solution of the homogeneous equation:* The natural response of a linear system is given by  $y_H(t)$ , the solution of (2.24). Due to the fact that a linear combination of  $y_H(t)$  and its derivatives must be equal to zero in order to comply with (2.24), it may be postulated that it has the form

$$y_H(t) = e^{st}, \quad (2.26)$$

where  $s$  is a constant to be determined.

Replacing the assumed solution in (2.24), we obtain, after simplification, the characteristic (or auxiliary) equation

$$a_0 + a_1 s + \cdots + a_N s^N = 0. \quad (2.27)$$

Assuming  $N$  distinct roots of the polynomial in (2.27),  $s_1$  to  $s_N$ , the homogeneous solution is obtained as a linear combination of  $N$  exponentials as in

$$y_H(t) = k_1 e^{s_1 t} + k_2 e^{s_2 t} + \cdots + k_N e^{s_N t}. \quad (2.28)$$

Two special cases follow.

1. *Non-distinct roots:* if, for instance,  $s_1 = s_2$ , it is possible to show that  $e^{s_1 t}$  and  $t e^{s_2 t}$  are independent solutions leading to

$$y_H(t) = k_1 e^{s_1 t} + k_2 t e^{s_2 t} + \cdots.$$

2. *Characteristic equation with complex roots:* it is known that, for real coefficients ( $a_0$  to  $a_N$ ), all complex roots will occur in complex conjugate pairs such as  $s_1 = \alpha + j\beta$  and  $s_2 = \alpha - j\beta$ ,  $\alpha$  and  $\beta$  being real numbers. Hence, the solution would be

$$\begin{aligned} y_H(t) &= k_1 e^{(\alpha+j\beta)t} + k_2 e^{(\alpha-j\beta)t} + \cdots \\ &= [(k_1 + k_2) \cos \beta t + j(k_1 - k_2) \sin \beta t] e^{\alpha t} + \cdots \\ &= (k_3 \cos \beta t + k_4 \sin \beta t) e^{\alpha t} + \cdots, \end{aligned}$$

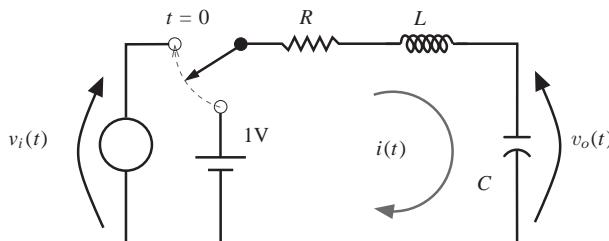

$k_3$  and  $k_4$  being real numbers if we make  $k_1 = k_2^*$ . In that case, we will have

$$y_H(t) = k_5 \cos(\beta t - \theta) e^{\alpha t} + \cdots,$$

with  $k_5 = \sqrt{k_3^2 + k_4^2}$  and  $\theta = \arctan \frac{k_4}{k_3}$ . Also note from the last expression that, in order to have a stable system (bounded output),  $\alpha$  should be negative (causing a decaying exponential).

**Table 2.1** Assumed Particular Solutions to Common Forcing Functions

Forcing function $f(t)$	Assumed $y_P(t)$
$K$	$A_0$
$Kt$	$A_0 t + A_1$
$Kt^n$	$A_0 t^n + A_1 t^{n-1} + \dots + A_{n-1} t + A_n$
$K e^{-\alpha t}$	$A_0 e^{-\alpha t}$
$\sin \Omega t$ or $\cos \Omega t$	$A_0 \sin \Omega t + A_1 \cos \Omega t$
$e^{-\alpha t} \sin \Omega t$ or $e^{-\alpha t} \cos \Omega t$	$e^{-\alpha t} (A_0 \sin \Omega t + A_1 \cos \Omega t)$

**FIGURE 2.8**

RLC series circuit with a voltage source as input and the voltage in the capacitor as output.

*Solution of the nonhomogeneous equation:* A (any) forced solution of the nonhomogeneous equation must satisfy (2.23) containing no arbitrary constant. A usual way to find the forced solution is employing the so called method of undetermined coefficients: it consists in estimating a general form for  $y_P(t)$  from  $f(t)$ , the forcing function. The coefficients ( $A_0, A_1, \dots$ ), as seen in Table 2.1 that shows the most common assumed solutions for each forced function, are to be determined in order to comply with the nonhomogeneous equation. A special case is treated slightly differently: when a term of  $f(t)$  corresponds to a term of  $y_H(t)$ , the corresponding term in  $y_P(t)$  must be multiplied by  $t$ . Also, when we find non-distinct roots of the characteristic equation (assume multiplicity  $m$  as an example), the corresponding term in  $y_P(t)$  shall be multiplied by  $t^m$ .

An *example* of a second order ordinary differential equation (ODE) with constant coefficients is considered as follows:

$$LC \frac{d^2 v_o(t)}{dt^2} + RC \frac{dv_o(t)}{dt} + v_o(t) = v_i(t), \quad (2.29)$$

where  $R = 2.0$  (in  $\Omega$ ),  $L = 2.0$  (in  $H$ ),  $C = 1/2$  (in  $F$ ), and  $v_i(t) = e^{-t}$  (in  $V$ ).

This equation describes the input  $\times$  output relationship of the electrical circuit shown in Figure 2.8 for  $t > 0$ .

Replacing the values of the components and the input voltage, the ODE becomes

$$\frac{d^2 v_o(t)}{dt^2} + \frac{dv_o(t)}{dt} + v_o(t) = \underbrace{e^{-t}}_{f(t)}. \quad (2.30)$$

The associated characteristic equation  $s^2 + s + 1 = 0$  has roots  $s = \frac{-1 \pm j\sqrt{3}}{2}$  leading to an homogeneous solution given by

$$\begin{aligned} v_{oH}(t) &= k_1 \cos\left(\frac{\sqrt{3}}{2}t\right) e^{-t/2} + k_2 \sin\left(\frac{\sqrt{3}}{2}t\right) e^{-t/2} \\ &= k_3 \cos\left(\frac{\sqrt{3}}{2}t + k_4\right) e^{-t/2}. \end{aligned} \quad (2.31)$$

Next, from the forcing function  $f(t) = e^{-t}$ , we assume  $v_{oP}(t) = k_5 e^{-t}$  and replace it in (2.30), resulting in  $k_5 = 1$  such that:

$$\begin{aligned} v_o(t) &= k_1 \cos\left(\frac{\sqrt{3}}{2}t\right) e^{-t/2} + k_2 \sin\left(\frac{\sqrt{3}}{2}t\right) e^{-t/2} + e^{-t} \\ &= k_3 \cos\left(\frac{\sqrt{3}}{2}t + k_4\right) e^{-t/2} + e^{-t}, \end{aligned} \quad (2.32)$$

where  $k_1$  and  $k_2$  (or  $k_3$  and  $k_4$ ) are constants to be obtained from previous knowledge of the physical system, the RLC circuit in this example. This knowledge comes as the initial conditions: an  $N$ -order differential equation having  $N$  constants and requiring  $N$  initial conditions.

*Initial conditions:* Usually, the differential equation describing the behavior of an electrical circuit is valid for any time  $t > 0$  (instant 0 assumed the initial reference in time); the initial conditions corresponds to the solution (and its  $N - 1$  derivatives) at  $t = 0^+$ . *In the absence of pulses, the voltage at the terminals of a capacitance and the current through an inductance cannot vary instantaneously* and must be the same value at  $t = 0^-$  and  $t = 0^+$ .

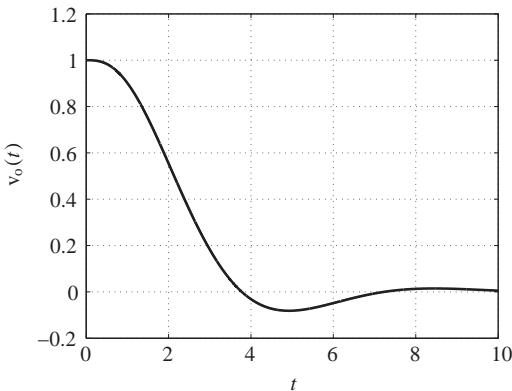

In the case of our example, based on the fact that there is a key switching  $v_i(t)$  to the RLC series at  $t = 0$ , we can say that the voltage across the inductor is  $v_o(0^-) = 1$  (the capacitor assumed charged with the DC voltage). Therefore, since the voltage across  $C$  and the current through  $L$  do not alter instantaneously, we know that  $v_o(0^+) = 1$  and  $i(0^+) = 0$ . Since we know that  $i(t) = C \frac{dv_o(t)}{dt}$ , we have  $\frac{dv_o(t)}{dt} \Big|_{t=0^+} = 0$ . With these initial conditions and from (2.32), we find  $k_1 = 0$  and  $k_2 = \frac{2\sqrt{3}}{3}$ .

Finally, the general solution is given as

$$v_o(t) = 1.1547 \sin(0.866t) e^{-t/2} + e^{-t}. \quad (2.33)$$

Figure 2.9 shows  $v_o(t)$  for  $0 \leq t \leq 10$ . An easy way to obtain this result with Matlab<sup>©</sup> is:

```
> y=dsolve ('D2y+Dy+y=exp(-t)', 'y(0)=1', 'Dy(0)=0');
> ezplot (y,[0 10])
```

**FIGURE 2.9**

Output voltage as a function of time,  $v_o(t)$ , for the circuit in Figure 2.8. See [Video 3](#) to watch animation.

To end this section, we represent this example using the state-space approach. We first rewrite (2.29) using the first and the second derivatives of  $v_o(t)$  as  $\dot{v}$  and  $\ddot{v}$ , respectively, and also  $u = v_i(t)$  as in

$$LC\ddot{v} + RC\dot{v} + v = u. \quad (2.34)$$

In this representation, we define a state vector  $\mathbf{x} = [v \ \dot{v}]^T$  and its derivative  $\dot{\mathbf{x}} = [\dot{v} \ \ddot{v}]^T$ , and from these definitions we write the *state equation* and the *output equation*:

$$\begin{cases} \dot{\mathbf{x}} = \mathbf{Ax} + \mathbf{Bu} = \begin{bmatrix} 0 & 1 \\ \frac{-1}{LC} & \frac{-R}{L} \end{bmatrix} \begin{bmatrix} v \\ \dot{v} \end{bmatrix} + \begin{bmatrix} 0 \\ \frac{1}{LC} \end{bmatrix} v_i(t), \\ y = \mathbf{Cx} + Du = [10] \begin{bmatrix} v \\ \dot{v} \end{bmatrix} + 0v_i(t), \end{cases} \quad (2.35)$$

where **A** is known as the *state matrix*, **B** as the *input matrix*, **C** as the *output matrix*, and **D** (equal to zero in this example) would be the *feedthrough* (or *feedforward*) matrix.

For further reading, we suggest [6–9].

## 1.02.4 Laplace transform: definition and properties

The Laplace transform [10] is named after the French mathematician Pierre-Simon Laplace. It is an important tool for solving differential equations, and it is very useful for designing and analyzing linear systems [11].

The Laplace transform is a mathematical operation that maps, or transforms, a variable (or function) from its original domain into the Laplace domain, or  $s$  domain. This transform produces a time-domain response to transitioning inputs, whenever time-domain behavior is more interesting than frequency-domain behavior. When solving engineering problems one has to model a physical phenomenon that

is dependent on the rates of change of a function (e.g., the velocity of a car as mentioned in Section 1.02.1). Hence, calculus associated with differential equations (Section 1.02.3), that model the phenomenon, are the natural candidates to be the mathematical tools. However, calculus solves (ordinary) differential equations provided the functions are continuous and with continuous derivatives. In addition, engineering problems have often to deal with impulsive, non-periodic or piecewise-defined input signals.

The Fourier transform, to be addressed in Section 1.02.7, is also an important tool for signal analysis, as well as for linear filter design. However, while the unit-step function (Figure 2.2a), discontinuous at time  $t = 0$ , has a Laplace transform, its forward Fourier integral does not converge. The Laplace transform is particularly useful for input terms that are impulsive, non-periodic or piecewise-defined [4].

The Laplace transform maps the time-domain into the  $s$ -domain, with  $s = \sigma + j\Omega$ , converting integral and differential equations into algebraic equations. The function is mapped (transformed) to the  $s$ -domain, eliminating all the derivatives. Hence, solving the equation becomes simple algebra in the  $s$ -domain and the result is transformed back to the time-domain. The Laplace transform converts a time-domain 1-D signal,  $x(t)$ , into a complex representation,  $X(s)$ , defined over a complex plane ( $s$ -plane). The complex plane is spanned by the variables  $\sigma$  (real axis) and  $\Omega$  (imaginary axis) [5].

The *two-sided* (or bilateral) *Laplace transform* of a signal  $x(t)$  is the function  $\mathcal{L}\{x(t)\}$  defined by:

$$X(s) = \mathcal{L}\{x(t)\} = \int_{-\infty}^{\infty} x(t)e^{-st} dt. \quad (2.36)$$

The notation  $X(s) = \mathcal{L}\{x(t)\}$  denotes that  $X(s)$  is the Laplace transform of  $x(t)$ . Conversely, the notation  $x(t) = \mathcal{L}^{-1}\{X(s)\}$  denotes that  $x(t)$  is the inverse Laplace transform of  $X(s)$ . This relationship is expressed with the notation  $x(t) \xrightarrow{\mathcal{L}} X(s)$ .

As  $e^{-st} = e^{-(\sigma+j\Omega)t} = e^{-\sigma t}(\cos \Omega t - j \sin \Omega t)$ , Eq. (2.36) can be rewritten as

$$\mathcal{L}\{x(t)\} = X(s)|_{s=\sigma+j\Omega} = \int_{-\infty}^{\infty} x(t)e^{-\sigma t} \cos \Omega t dt - j \int_{-\infty}^{\infty} x(t)e^{-\sigma t} \sin \Omega t dt. \quad (2.37)$$

This way, one can identify that the Laplace transform real part ( $\text{Re}(X(s))$ ) represents the contribution of the (combined) exponential and cosine terms to  $x(t)$ , while its imaginary part ( $\text{Im}(X(s))$ ) represents the contribution of the (combined) exponential and sine terms to  $x(t)$ . As the term  $e^{-st}$  is an eigenfunction, we can state that the Laplace transform represents time-domain signals in the  $s$ -domain as weighted combinations of eigensignals.

For those signals equal to zero for  $t < 0$ , the limits on the integral are changed for the *one-sided* (or unilateral) *Laplace transform*:

$$X(s) = \mathcal{L}\{x(t)\} = \int_{0^-}^{\infty} x(t)e^{-st} dt, \quad (2.38)$$

with  $x(t) = 0$  for  $t < 0^-$ , in order to deal with signals that present singularities at the origin, i.e., at  $t = 0$ .

As the interest will be in signals defined for  $t \geq 0$ , let us find the one-sided Laplace transform of  $x(t) = e^t u(t)$ :

$$\mathcal{L}\{x(t)\} = X(s) = \int_{0^-}^{\infty} e^t e^{-st} dt = \int_{0^-}^{\infty} e^{(1-s)t} dt = \frac{1}{1-s} e^{(1-s)t} \Big|_{0^-}^{\infty} = \frac{1}{s-1} \quad (2.39)$$

The integral, in (2.39), defining  $\mathcal{L}\{x(t)\}$  is true if  $e^{(1-s)t} \rightarrow 0$  as  $t \rightarrow \infty$ ,  $\forall s \in \mathcal{C}$  with  $\text{Re}(s) > 1$ , which is the region of convergence of  $X(s)$ .

As the analysis of convergence, as well as the conditions that guarantee the existence of the Laplace integral are beyond the scope of this chapter, please refer to [4,5].

For a given  $x(t)$ , the integral may converge for some values of  $\sigma$ ,  $\text{Re}(s = \sigma + j\Omega)$ , but not for others. So, we have to guarantee the existence of the integral, i.e.,  $x(t)e^{-\sigma t}$  has to be absolutely integrable. The region of convergence (ROC) of the integral in the complex  $s$ -plane should be specified for each transform  $\mathcal{L}\{x(t)\}$ , that exists if and only if the argument  $s$  is inside the ROC. The transformed signal,  $X(s)$  will be well defined for a range of values in the  $s$ -domain that is the ROC, which is always given in association with the transform itself.

When  $\sigma = 0$ , so that  $s = j\Omega$ , the Laplace transform reverts to the Fourier transform, i.e.,  $x(t)$  has a Fourier transform if the ROC of the Laplace transform in the  $s$ -plane includes the imaginary axis.

For finite duration signals that are absolutely integrable, the ROC contains the entire  $s$ -plane. As  $\mathcal{L}\{x(t)\} = X(s)$  cannot uniquely define  $x(t)$ , it is necessary  $X(s)$  and the ROC. If we wish to find the Laplace transform of a one-sided real exponential function  $x(t) = e^{at} u(t)$ ,  $a \in \mathcal{R}$ , given by:

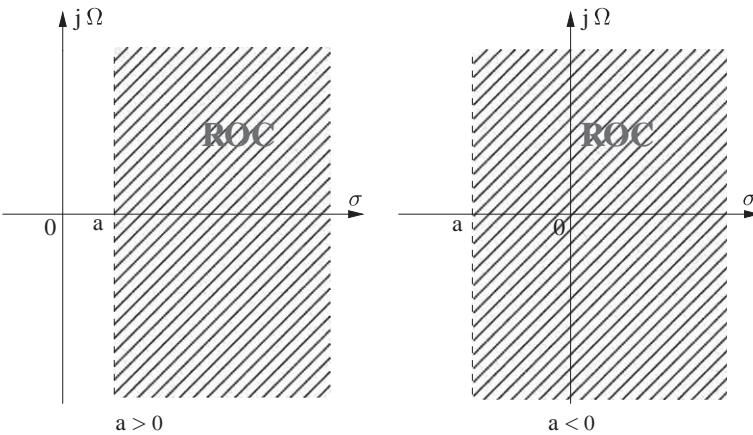

$$x(t) = \begin{cases} 0, & t \leq 0, \\ e^{at}, & t > 0, \end{cases} \quad (2.40)$$

we have

$$X(s) = \int_{0^-}^{\infty} e^{-(s-a)t} dt = -\frac{1}{s-a} e^{-(s-a)t} \Big|_{0^-}^{\infty} = \frac{1}{s-a}. \quad (2.41)$$

The integral of (2.41) converges if  $\sigma > a$ , and the ROC is the region of the  $s$ -plane to the right of  $\sigma = a$ , as pictured in Figure 2.10. If  $\sigma < a$  the integral does not converge as  $X(s) \rightarrow \infty$ , and if  $\sigma = a$  we cannot determine  $X(s)$ .

In other words, if a signal  $x(t)$  is nonzero only for  $t \geq 0$ , the ROC of its Laplace transform lies to the right hand side of its poles (please refer to Section 1.02.5). Additionally, the ROC does not contain

**FIGURE 2.10**

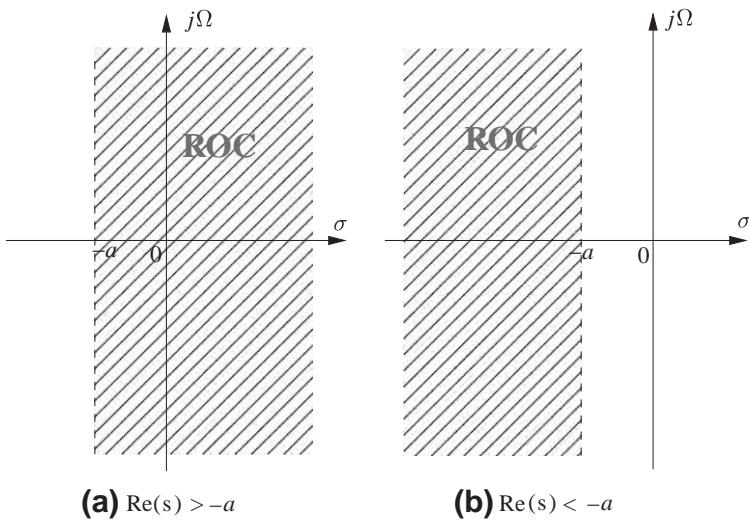

Region of Convergence (ROC) on the  $s$ -plane for the signal defined by Eq. (2.40). Note that, for a stable signal ( $a < 0$ ), the ROC contains the vertical axis  $s = j\Omega$ .

any pole. Poles are points where the Laplace transform reaches infinite value in the  $s$ -plane (e.g.,  $s = a$  in Figure 2.10).

An example of the two-sided Laplace transform of a right-sided exponential function  $x(t) = e^{-at} u(t)$ ,  $a \in \mathbb{R}$ , is given by

$$\begin{aligned}
 X(s) &= \int_{-\infty}^{\infty} e^{-at} u(t) e^{-st} dt \\
 &= \int_{0^-}^{\infty} e^{-(s+a)t} dt \\
 &= \int_{0^-}^{\infty} e^{-(\sigma+a)t} e^{-j\Omega t} dt \\
 &= -\frac{1}{s+a} e^{-(s+a)t} \Big|_{0^-}^{\infty} = \frac{1}{s+a}.
 \end{aligned} \tag{2.42}$$

As the term  $e^{-j\Omega t}$  is sinusoidal, only  $\sigma = \text{Re}(s)$  is important, i.e., the integral given by (2.42), when  $t$  tends to infinity, converges if  $e^{-(\sigma+a)t}$  is finite ( $\sigma > -a$ ) in order for the exponential function to decay. The integral of Eq. (2.42) converges if  $\text{Re}(s+1) > 0$ , i.e., if  $\text{Re}(s) > -a$ , and the ROC is the region of the  $s$ -plane to the right of  $\sigma = -a$ , as pictured in the left side of Figure 2.11. The ROC of the Laplace transform of a right-sided signal is to the right of its rightmost pole.

**FIGURE 2.11**

Regions of Convergence (ROCs) on the  $s$ -plane: (a) for right-sided signals,  $\text{Re}(s) > -a$ , and (b) for left-sided signals,  $\text{Re}(s) < -a$ .

If, we wish to find the two-sided Laplace transform of a left-sided signal,  $x(t) = -e^{-at}u(-t)$ ,  $a \in \mathcal{R}$ , we have

$$\begin{aligned} X(s) &= - \int_{-\infty}^{\infty} e^{-at} u(-t) e^{-st} dt \\ &= - \int_{-\infty}^{0^-} e^{-(s+a)t} dt \\ &= \frac{1}{s+a} e^{-(s+a)t} \Big|_{\infty}^{0^-} = \frac{1}{s+a}. \end{aligned} \quad (2.43)$$

The integral of Eq. (2.43) converges if  $\text{Re}(s) < -a$ , and the ROC is the region of the  $s$ -plane to the left of  $\sigma = -a$ , as pictured in the right side of Figure 2.11. The ROC of the Laplace transform of a left-sided signal is to the left of its leftmost pole.

For causal systems, where  $h(t) = 0$ ,  $t < 0$ , and right-sided signals, where  $x(t) = 0$ ,  $t < 0$ , the unilateral (one-sided) and bilateral (two-sided) transforms are equal. However, it is important to stress that some properties change, such as the differentiation property reduced to  $sX(s)$  for the bilateral case. Conversely, other properties, such as convolution, hold as is, provided the system is causal and the input starts at  $t = 0^-$ .

Common Laplace transform pairs [12] are summarized in Table 2.2.

Recalling Figure 2.3 from Section 1.02.1, where  $x(t)$  is the input to a linear system with impulse response  $h(t)$ , to obtain the output  $y(t)$  one could convolve  $x(t)$  with  $h(t)$  (2.11).

**Table 2.2** Laplace Transform Pairs

$x(t) = \mathcal{L}^{-1}\{X(s)\}$	$X(s) = \mathcal{L}\{x(t)\}$	ROC
$\delta(t)$	1	for all s
$\delta(t - \tau), \tau > 0$	$e^{-s\tau}$	for all s
$u(t)$	$\frac{1}{s}$	$\text{Re}(s) > 0$
$-u(-t)$	$\frac{1}{s}$	$\text{Re}(s) < 0$
$tu(t)$	$\frac{1}{s^2}$	$\text{Re}(s) > 0$
$t^n u(t)$	$\frac{n!}{s^{n+1}}, n = 1, 2, \dots$	$\text{Re}(s) > 0$
$e^{-at} u(t)$	$\frac{1}{s + a}$	$\text{Re}(s) > -\text{Re}(a)$
$-e^{-at} u(-t)$	$\frac{1}{s + a}$	$\text{Re}(s) < -\text{Re}(a)$
$t^n e^{-at} u(t)$	$\frac{n!}{(s + a)^{n+1}}, n = 1, 2, \dots$	$\text{Re}(s) > -\text{Re}(a)$
$\sin \Omega t u(t)$	$\frac{\Omega}{s^2 + \Omega^2}$	$\text{Re}(s) > 0$
$\cos \Omega t u(t)$	$\frac{s}{s^2 + \Omega^2}$	$\text{Re}(s) > 0$
$e^{-at} \sin \Omega t u(t)$	$\frac{\Omega}{(s + a)^2 + \Omega^2}$	$\text{Re}(s) > -\text{Re}(a)$
$e^{-at} \cos \Omega t u(t)$	$\frac{s + a}{(s + a)^2 + \Omega^2}$	$\text{Re}(s) > -\text{Re}(a)$
$\sin(\Omega t + \theta) u(t)$	$\frac{s \sin \theta + \Omega \cos \theta}{s^2 + \Omega^2}$	$\text{Re}(s) > 0$
$\cos(\Omega t + \theta) u(t)$	$\frac{s \cos \theta - \Omega \sin \theta}{s^2 + \Omega^2}$	$\text{Re}(s) > 0$
$e^{-at} (\Omega \cos \Omega t - a \sin \Omega t) u(t)$	$\frac{\Omega s}{(s + a)^2 + \Omega^2}$	$\text{Re}(s) > -\text{Re}(a)$

However, if  $X(s)$  and  $Y(s)$  are the associated Laplace transforms, the (computationally demanding) operation of convolution in the time-domain is mapped into a (simple) operation of multiplication in the  $s$ -domain:

$$y(t) = h(t) * x(t) \xleftarrow{\mathcal{L}} Y(s) = H(s)X(s). \quad (2.44)$$

Equation (2.44) shows that convolution in time-domain is equivalent to multiplication in Laplace domain. In the following, some properties of the Laplace transform disclose the symmetry between operations in the time- and  $s$ -domains.

*Linearity:* If  $x_1(t) \xrightarrow{\mathcal{L}} X_1(s)$ , ROC =  $R_1$ , and  $x_2(t) \xrightarrow{\mathcal{L}} X_2(s)$ , ROC =  $R_2$ , then

$$\mathcal{L}\{a_1x_1(t) + a_2x_2(t)\} = a_1\mathcal{L}\{x_1(t)\} + a_2\mathcal{L}\{x_2(t)\} = a_1X_1(s) + a_2X_2(s), \quad (2.45)$$

with  $a_1$  and  $a_2$  being constants and  $\text{ROC} \supseteq R_1 \cap R_2$ . The Laplace transform is a linear operation.

*Time shifting:* If  $x(t) \xrightarrow{\mathcal{L}} X(s)$ , ROC =  $R$ , then  $x(t - t_0) \xrightarrow{\mathcal{L}} e^{-st_0}X(s)$ ,  $\forall t_0 \in \mathbb{R}$ , ROC =  $R$ .

$$\begin{aligned} \int_{0^-}^{\infty} x(t - t_0)e^{-st} dt &= \int_{0^-}^{\infty} x(\tau)e^{-s(\tau+t_0)} d\tau \\ &= e^{-st_0} \int_{0^-}^{\infty} x(\tau)e^{-s(\tau)} d\tau \\ &= e^{-st_0} X(s), \end{aligned} \quad (2.46)$$

where  $t - t_0 = \tau$ . Time shifting (or time delay) in the time-domain is equivalent to modulation (alteration of the magnitude and phase) in the  $s$ -domain.

*Exponential scaling (frequency shifting):* If  $x(t) \xrightarrow{\mathcal{L}} X(s)$ , ROC =  $R$ , then  $e^{at}x(t) \xrightarrow{\mathcal{L}} X(s-a)$ , ROC =  $R + \text{Re}(a)$ ,  $\forall a \in \mathbb{R}$  or  $\mathcal{C}$ .

$$\mathcal{L}\{e^{at}x(t)\} = \int_{0^-}^{\infty} e^{at}x(t)e^{-st} dt = \int_{0^-}^{\infty} x(t)e^{-(s-a)t} dt = X(s-a). \quad (2.47)$$

Modulation in the time-domain is equivalent to shifting in the  $s$ -domain.

*Convolution:* If  $x_1(t) \xrightarrow{\mathcal{L}} X_1(s)$ , ROC =  $R_1$ , and  $x_2(t) \xrightarrow{\mathcal{L}} X_2(s)$ , ROC =  $R_2$ , then  $x_1(t) * x_2(t) \xrightarrow{\mathcal{L}} X_1(s)X_2(s)$ , ROC  $\supseteq R_1 \cap R_2$ :

$$\begin{aligned} \int_{0^-}^{\infty} [x_1(t) * x_2(t)]e^{-st} dt &= \int_{0^-}^{\infty} \left[ \int_{0^-}^{\infty} x_1(\tau)x_2(t-\tau) d\tau \right] e^{-st} dt \\ &= \int_{0^-}^{\infty} \int_{0^-}^{\infty} x_1(\tau)x_2(t-\tau)e^{-s(t-\tau+\tau)} d\tau dt \\ &= \int_{0^-}^{\infty} x_1(\tau)e^{-s\tau} d\tau \int_{0^-}^{\infty} x_2(v)e^{-sv} dv \\ &= X_1(s)X_2(s), \end{aligned} \quad (2.48)$$

where in the inner integral  $v = t - \tau$ . Convolution in time-domain is equivalent to multiplication in the  $s$ -domain.

*Differentiation in time:* If  $x(t) \xrightarrow{\mathcal{L}} X(s)$ , ROC =  $R$ , then  $\dot{x}(t) \xrightarrow{\mathcal{L}} sX(s) - x(0^-)$ , ROC  $\supseteq R$ . Integrating by parts, we have:

$$\begin{aligned} \int_{0^-}^{\infty} \frac{dx(t)}{dt} e^{-st} dt &= x(t)e^{-st} \Big|_{0^-}^{\infty} - \int_{0^-}^{\infty} x(t)(-s)e^{-st} dt \\ &= 0 - x(0^-) + s \int_{0^-}^{\infty} x(t)e^{-st} dt \\ &= sX(s) - x(0^-). \end{aligned} \quad (2.49)$$

where any jump from  $t = 0^-$  to  $t = 0^+$  is considered. In other words, the Laplace transform of a derivative of a function is a combination of the transform of the function, multiplicated by  $s$ , and its initial value. This property is quite useful as a differential equation in time can be turned into an algebraic equation in the Laplace domain, where it can be solved and mapped back into the time-domain (Inverse Laplace Transform).

The initial- and final-value theorems show that, the initial and the final values of a signal in the time-domain can be obtained from its Laplace transform without knowing its expression in the time-domain. *Initial-value theorem:* Considering stable the LTI system, that generated the signal  $x(t)$ , then

$$\lim_{s \rightarrow \infty} sX(s) = \lim_{t \rightarrow 0^+} x(t). \quad (2.50)$$

From the differentiation in time property, we have that  $\dot{x}(t) \xleftrightarrow{\mathcal{L}} sX(s) - x(0^-)$ . By taking the limit when  $s \rightarrow \infty$  of the first expression of (2.49), we find

$$\begin{aligned} \lim_{s \rightarrow \infty} \int_{0^-}^{\infty} \frac{dx(t)}{dt} e^{-st} dt &= \lim_{s \rightarrow \infty} \left( \int_{0^-}^{0^+} \frac{dx(t)}{dt} e^0 dt + \int_{0^+}^{\infty} \frac{dx(t)}{dt} e^{-st} dt \right) \\ &= \lim_{t \rightarrow 0^+} x(t) - \lim_{t \rightarrow 0^-} x(t) + 0 \\ &= \lim_{t \rightarrow 0^+} x(t) - \lim_{t \rightarrow 0^-} x(t). \end{aligned} \quad (2.51)$$

If we take the limit of  $s$  to  $\infty$  in the result of (2.49), we have

$$\lim_{s \rightarrow \infty} (sX(s) - x(0^-)) = \lim_{s \rightarrow \infty} sX(s) - \lim_{t \rightarrow 0^-} x(t), \quad (2.52)$$

then we can equal the results of (2.52) and (2.51) and get

$$\lim_{s \rightarrow \infty} sX(s) - \lim_{t \rightarrow 0^-} x(t) = \lim_{t \rightarrow 0^+} x(t) - \lim_{t \rightarrow 0^-} x(t). \quad (2.53)$$

As the right-hand side of (2.53) is obtained taking the limit when  $s \rightarrow \infty$  of the result of (2.49), we can see from (2.51) and (2.53) that

$$\lim_{s \rightarrow \infty} sX(s) = \lim_{t \rightarrow 0^+} x(t). \quad (2.54)$$

The initial-value theorem provides the behavior of a signal in the time-domain for small time intervals, i.e., for  $t \rightarrow 0^+$ . In other words, it determines the initial values of a function in time from its expression in the  $s$ -domain, which is particularly useful in circuits and systems.

*Final-value theorem:* Considering that the LTI system that generated the signal  $x(t)$  is stable, then

$$\lim_{s \rightarrow 0} sX(s) = \lim_{t \rightarrow \infty} x(t). \quad (2.55)$$

From the differentiation in time property, we have that  $\dot{x}(t) \xleftrightarrow{\mathcal{L}} sX(s) - x(0^-)$ . By taking the limit when  $s \rightarrow 0$  of the first expression of (2.49), we have

$$\begin{aligned} \lim_{s \rightarrow 0} \int_{0^-}^{\infty} \frac{dx(t)}{dt} e^{-st} dt &= \int_{0^-}^{\infty} \frac{dx(t)}{dt} dt \\ &= \lim_{t \rightarrow \infty} x(t) - \lim_{t \rightarrow 0^-} x(t). \end{aligned} \quad (2.56)$$

If we take the limit when  $s \rightarrow 0$  of the last expression of (2.49), we get

$$\lim_{s \rightarrow 0} (sX(s) - x(0^-)) = \lim_{s \rightarrow 0} sX(s) - \lim_{t \rightarrow 0^-} x(t); \quad (2.57)$$

then, we can write

$$\lim_{s \rightarrow 0} sX(s) - \lim_{t \rightarrow 0^-} x(t) = \lim_{t \rightarrow \infty} x(t) - \lim_{t \rightarrow 0^-} x(t). \quad (2.58)$$

As the right-hand side of (2.58) is obtained taking the limit when  $s \rightarrow 0$  of the result of (2.49), we can see from (2.56) and (2.58) that

$$\lim_{s \rightarrow 0} sX(s) = \lim_{t \rightarrow \infty} x(t). \quad (2.59)$$

The final-value theorem provides the behavior of a signal in the time-domain for large time intervals, i.e., for  $t \rightarrow \infty$ . In other words, it obtains the final value of a function in time, assuming it is stable and well defined when  $t \rightarrow \infty$ , from its expression in the  $s$ -domain. A LTI system, as will be seen in the next section, is considered stable if all of its poles lie within the left side of the  $s$ -plane. As  $t \rightarrow \infty$ ,  $x(t)$  must reach a steady value, thus it is not possible to apply the final-value theorem to signals such as sine, cosine or ramp.

A list of one-sided Laplace transform properties is summarized in Table 2.3.

The inverse Laplace transform is given by

$$\mathcal{L}^{-1}\{X(s)\} = x(t) = \int_{\sigma-j\infty}^{\sigma+j\infty} X(s)e^{st} ds. \quad (2.60)$$

The integration is performed along a line, parallel to the imaginary axis,  $(\sigma - j\infty, \sigma + j\infty)$  that lies in the ROC. However, the inverse transform can be calculated using partial fractions expansion with the method of residues. In this method, the  $s$ -domain signal  $X(s)$  is decomposed into partial fractions, thus expressing  $X(s)$  as a sum of simpler rational functions. Hence, as each term in the partial fraction is expected to have a known inverse transform, each transform may be obtained from a table like Table 2.2. Please recall that the ROC of a signal that is non-zero for  $t \geq 0$  is located to the right hand side of its poles. Conversely, for a signal that is non-zero for  $t \leq 0$ , the ROC of its Laplace transform lies to the left-hand side of its poles. In other words, if  $X(s) = 1/(s + a)$ ,  $a \in \mathcal{R}$ , its inverse Laplace transform is given as follows:

$$\mathcal{L}^{-1}\left\{\frac{1}{s+a}\right\} = \begin{cases} -e^{-at}, & \text{Re}(s) < -a, \\ e^{-at}, & \text{Re}(s) > -a, \end{cases} \quad (2.61)$$

In practice, the inverse Laplace transform is found recursing to tables of transform pairs (e.g., Table 2.2). Given a function  $X(s)$  in the  $s$ -domain and a region of convergence, its inverse Laplace transform is given by  $\mathcal{L}^{-1}\{X(s)\} = x(t)$  such that  $X(s) = \mathcal{L}\{x(t)\}$ ,  $s \in \text{ROC}$ .

An immediate application of the Laplace transform is on circuit analysis. Assuming that all initial conditions are equal to zero, i.e., there is no initial charge on the capacitor, the response  $y(t)$  of the circuit with input given by  $x(t) = u(t)$  displayed by Figure 2.4 could be obtained in the Laplace domain to be further transformed into the time-domain.

**Table 2.3** Properties of (One-Sided) Laplace Transform

Property	time-domain	s-domain	ROC
Linearity	$x(t)$	$X(s)$	$R$
	$x_1(t)$	$X_1(s)$	$R_1$
	$x_2(t)$	$X_2(s)$	$R_2$
	$a_1x_1(t) + a_2x_2(t)$	$a_1X_1(s) + a_2X_2(s)$	$\supseteq R_1 \cap R_2$
	$ax(t)$	$aX(s)$	$R$
	$x(at)$	$\frac{1}{a}X\left(\frac{s}{a}\right)$	$\frac{R}{ a }$
	$x(t - t_0)$	$e^{-st_0}X(s)$	$R$
	$e^{at}x(t)$	$X(s - a)$	$R + \text{Re}(a)$
	$\frac{dx(t)}{dt}$	$sX(s) - x(0^-)$	$\supseteq R$
Differentiation	$\frac{d^2x(t)}{dt^2}$	$s^2X(s) - sx(0^-) - \dot{x}(0^-)$	
	$\frac{d^n x(t)}{dt^n}$	$s^n X(s) - \sum_{k=1}^n s^{n-k} x^{(k-1)}(0^-)$	
	$-tx(t)$	$\frac{dX(s)}{ds}$	$R$
	$x_1(t) * x_2(t)$	$X_1(s)X_2(s)$	$\supseteq R_1 \cap R_2$
Convolution (in the s-domain)	$x_1(t)x_2(t)$	$\frac{1}{2\pi j}X_1(s) * X_2(s)$	$\supseteq R_1 \cap R_2$

First, the circuit elements are transformed from the time domain into the  $s$ -domain, thus creating an  $s$ -domain equivalent circuit. Hence, the RLC elements in the time domain and  $s$ -domain are:

*Resistor* (voltage-current relationship):

$$v(t) = Ri(t) \xleftrightarrow{\mathcal{L}} V(s) = RI(s). \quad (2.62)$$

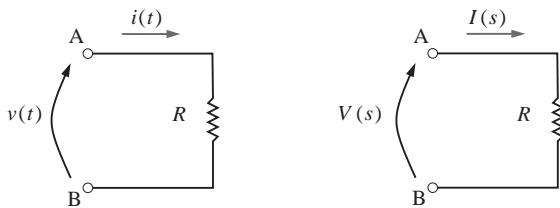

The equivalent circuit is depicted in Figure 2.12.

*Inductor* (initial current  $i(0^-)$ ):

$$v(t) = L \frac{di(t)}{dt} \xleftrightarrow{\mathcal{L}} V(s) = sLI(s) - Li(0^-); \quad (2.63)$$

applying the differentiation property (Table 2.3) leads to

$$I(s) = \frac{1}{sL}V(s) + \frac{i(0^-)}{s}. \quad (2.64)$$

**FIGURE 2.12**

Equivalent circuit of a resistor in the Laplace domain.

The equivalent circuit is depicted in Figure 2.13. The inductor,  $L$ , is an impedance  $sL$  in the  $s$ -domain in series with a voltage source,  $Li(0^-)$ , or in parallel with a current source,  $\frac{i(0^-)}{s}$ .  
*Capacitor* (initial voltage  $v(0^-)$ ):

$$i(t) = C \frac{dv(t)}{dt} \xleftrightarrow{\mathcal{L}} I(s) = sCV(s) - v(0^-); \quad (2.65)$$

applying the differentiation property (Table 2.3) leads to

$$V(s) = \frac{I(s)}{sC} + \frac{v(0^-)}{s}. \quad (2.66)$$

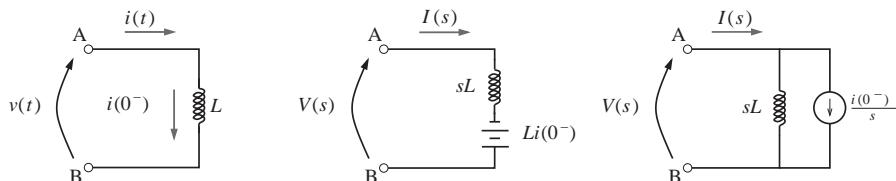

The capacitor,  $C$ , is an impedance  $\frac{1}{sC}$  in the  $s$ -domain in series with a voltage source,  $\frac{v(0^-)}{s}$ , or in parallel with a current source,  $Cv(0^-)$ . The voltage across the capacitor in the time-domain corresponds to the voltage across both the capacitor and the voltage source in the frequency domain.

As an example, the system's response given by the voltage across the capacitor,  $y(t)$ , depicted in Figure 2.4, is obtained in the Laplace domain as follows (see Figure 2.14):

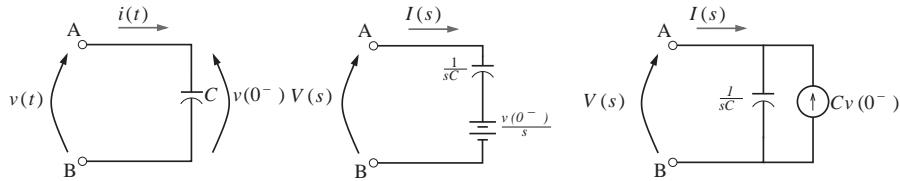

$$X(s) = \frac{1}{s} = I(s) \left( R + \frac{1}{sC} \right). \quad (2.67)$$

From (2.65), we have

$$Y(s) = \frac{I(s)}{sC} \quad (2.68)$$

**FIGURE 2.13**

Equivalent circuit of an inductor in the Laplace domain.

**FIGURE 2.14**

Equivalent circuit of a capacitor in the Laplace domain.

with

$$I(s) = \frac{X(s)}{R + \frac{1}{sC}}. \quad (2.69)$$

Substituting (2.69) in (2.68) and applying the inverse Laplace transform (Table 2.2) and the linearity property (Table 2.3), we get

$$\begin{aligned} \mathcal{L}^{-1}\{Y(s)\} &= \mathcal{L}^{-1}\left\{\frac{1}{s} - \frac{1}{s + \frac{1}{RC}}\right\}, \\ y(t) &= u(t) - e^{-t\frac{1}{RC}}u(t), \end{aligned} \quad (2.70)$$

which is the same result presented in (2.5).

Another example, where the Laplace transform is useful, is the RLC circuit displayed by Figure 2.8 where the desired response is the voltage across the capacitor  $C$ ,  $v_o(t) = v_C(t)$ . Note that the initial conditions are part of the transform, as well as the transient and steady-state responses. Given the input signal  $v_i(t) = e^{-t}u(t)$  with initial conditions  $v_o(0^-) = 1$ ,  $\dot{v}_o(0^-) = 0$ , and  $i_o(0^-) = 0$ , applying the Kirchhoff's voltage law to the circuit, we have:

$$v_i(t) = v_R(t) + v_L(t) + v_C(t). \quad (2.71)$$

Directly substituting (2.62), (2.63) and (2.65) in (2.71), and applying the Laplace transform to the input signal,  $v_i(t) = e^{-t}u(t)$ , we get

$$\begin{aligned} \frac{1}{s+1} &= \left( RI(s) + sLI(s) - Li_o(0^-) + \frac{1}{sC}I(s) + \frac{v_o(0^-)}{s} \right) \\ &= I(s) \left( R + sL + \frac{1}{sC} \right) - Li_o(0^-) + \frac{v_o(0^-)}{s} \\ &= \frac{I(s)}{sC} (s^2LC + sRC + 1) - Li_o(0^-) + \frac{v_o(0^-)}{s}, \end{aligned} \quad (2.72)$$

which, from (2.65),  $\frac{I(s)}{sC} = V_o(s) - \frac{v_o(0^-)}{s}$ , we have

$$\begin{aligned}\frac{1}{s+1} &= \left(V_o(s) - \frac{v_o(0^-)}{s}\right)(s^2LC + sRC + 1) - Li_o(0^-)\frac{v_o(0^-)}{s} \\ &= V_o(s)(s^2LC + sRC + 1) - \frac{v_o(0^-)}{s}(s^2LC + sRC + 1) \\ &\quad - Li_o(0^-) + \frac{v_o(0^-)}{s}.\end{aligned}\tag{2.73}$$

Substituting the values of  $R = 2.0$  (in  $\Omega$ ),  $L = 2.0$  (in H),  $C = 1/2$  (in F), the equation becomes

$$\begin{aligned}\frac{1}{s+1} &= V_o(s)(s^2 + s + 1) - \frac{v_o(0^-)}{s}(s^2 + s + 1) \\ &\quad - i_o(0^-) + \frac{v_o(0^-)}{s};\end{aligned}\tag{2.74}$$

considering that the initial conditions are  $v_0(0^-) = 1$ ,  $\dot{v}_o(0^-) = 0$ ,  $i_o(0^-) = 0$ , we get

$$\begin{aligned}\frac{1}{s+1} &= V_o(s)(s^2 + s + 1) - \frac{1}{s}(s^2 + s + 1) - 0 + \frac{1}{s} \\ &= V_o(s)(s^2 + s + 1) - s - 1 - \frac{1}{s} - 0 + \frac{1}{s} \\ &= V_o(s)(s^2 + s + 1) - s - 1 \\ V_o(s) &= \left(\frac{1}{s+1} + s + 1\right) \left(\frac{1}{s^2 + s + 1}\right) \\ &= \left(\frac{s^2 + 2s + 2}{s+1}\right) \left(\frac{1}{s^2 + s + 1}\right).\end{aligned}\tag{2.75}$$

After decomposing (2.75) into partial fractions and finding the poles and residues, the inverse Laplace transform is applied in order to find the expression of  $v_o(t)$ :

$$V_o(s) = \frac{1}{(s+1)} - j \frac{\frac{\sqrt{3}}{3}}{\left(s + \frac{1}{2} - j \frac{\sqrt{3}}{2}\right)} + j \frac{\frac{\sqrt{3}}{3}}{\left(s + \frac{1}{2} + j \frac{\sqrt{3}}{2}\right)}\tag{2.76}$$

$$\mathcal{L}^{-1}\{V_o(s)\} = \mathcal{L}^{-1} \left\{ \frac{1}{(s+1)} - j \frac{\frac{\sqrt{3}}{3}}{\left(s + \frac{1}{2} - j \frac{\sqrt{3}}{2}\right)} + j \frac{\frac{\sqrt{3}}{3}}{\left(s + \frac{1}{2} + j \frac{\sqrt{3}}{2}\right)} \right\}.\tag{2.77}$$

Applying the linearity property (Table 2.3) and recursing to the Laplace transform pair table (Table 2.2), we get

$$v_o(t) = e^{-t} - j \frac{\sqrt{3}}{3} e^{-\frac{t}{2} + jt \frac{\sqrt{3}}{2}} + j \frac{\sqrt{3}}{3} e^{-\frac{t}{2} - jt \frac{\sqrt{3}}{2}},\tag{2.78}$$

considering that the inverse Laplace transforms of  $\frac{1}{s+a}$ , for  $\text{Re}(s) > -\text{Re}(a)$ , given by Table 2.2, with  $a = \frac{1}{2} - j\frac{\sqrt{3}}{2}$  and  $a = \frac{1}{2} + j\frac{\sqrt{3}}{2}$  are

$$\begin{aligned}\mathcal{L}^{-1} \left\{ \frac{1}{(s + \frac{1}{2} - j\frac{\sqrt{3}}{2})} \right\} &= e^{-(\frac{1}{2} - j\frac{\sqrt{3}}{2})t} \text{ and,} \\ \mathcal{L}^{-1} \left\{ \frac{1}{(s + \frac{1}{2} + j\frac{\sqrt{3}}{2})} \right\} &= e^{-(\frac{1}{2} + j\frac{\sqrt{3}}{2})t},\end{aligned}$$

respectively.

Algebraically manipulating (2.78) and substituting the terms of complex exponentials by trigonometric identities, we have (for  $t \geq 0$ )

$$\begin{aligned}v_o(t) &= 2\frac{\sqrt{3}}{2}e^{-\frac{t}{2}} \sin\left(\frac{\sqrt{3}}{2}t\right) + e^{-t} \\ &= 1.1547 \sin(0.866t)e^{-\frac{t}{2}} + e^{-t}.\end{aligned}\tag{2.79}$$

The solution given by (2.79) is the same given by (2.33). However, in the solution obtained using the Laplace transform, the initial conditions were part of the transform. We could also have applied the Laplace transform directly to the ODE (2.30) assisted by Tables 2.3 and 2.2, as follows:

$$\mathcal{L}\{e^{-t}\} = \mathcal{L}\left\{ \frac{d^2v_o(t)}{dt^2} + \frac{dv_o(t)}{dt} + v_o(t) \right\},\tag{2.80}$$

where

$$\begin{aligned}\mathcal{L}\left\{ \frac{d^2v_o(t)}{dt^2} \right\} &= s^2V_o(s) - sv_o(0^-) - \dot{v}_o(0^-), \\ \mathcal{L}\left\{ \frac{dv_o(t)}{dt} \right\} &= sV_o(s) - v_o(0^-), \\ \mathcal{L}\{v_o(t)\} &= V_o(s), \text{ and} \\ \mathcal{L}\{e^{-t}\} &= \frac{1}{s+1}.\end{aligned}\tag{2.81}$$

Hence, substituting the expressions from (2.81) into (2.80) and considering the initial conditions, we obtain the same final expression presented in (2.75):

$$\begin{aligned}
 \frac{1}{s+1} &= V_o(s)(s^2 + s + 1) - sv_o(0^-) - v'_o(0^-) - v_o(0^-) \\
 &= V_o(s)(s^2 + s + 1) - s - 0 - 1 \\
 &= V_o(s)(s^2 + s + 1) - s - 1 \\
 V_o(s) &= \left( \frac{1}{s+1} + s + 1 \right) \left( \frac{1}{s^2 + s + 1} \right) \\
 &= \left( \frac{s^2 + 2s + 2}{s+1} \right) \left( \frac{1}{s^2 + s + 1} \right). \tag{2.82}
 \end{aligned}$$

In Section 1.02.2 the importance of working with a LTI system was introduced. The convolution integral in (2.9), that expresses the input signal,  $x(t)$ , as a sum of scaled and shifted impulse functions, uses delayed unit impulses as its basic signals. Therefore, a LTI system response is the same linear combination of the responses to the basic inputs.

Considering that complex exponentials, such as  $e^{-st}$ , are eigensignals of LTI systems, Eq. (2.36) is defined if one uses  $e^{-st}$  as a basis for the set of all input functions in a linear combination made of infinite terms (i.e., an integral). As the signal is being decomposed in basic inputs (complex exponentials), the LTI system's response could be characterized by weighting factors applied to each component in that representation.

In Section 1.02.7, the Fourier transform is introduced and it is shown that the Fourier integral does not converge for a large class of signals. The Fourier transform may be considered a subset of the Laplace transform, or the Laplace transform could be considered a generalization (or expansion) of the Fourier transform. The Laplace integral term  $e^{-st}$ , from (2.36), forces the product  $x(t)e^{-st}$  to zero as time  $t$  increases. Therefore, it could be regarded as the exponential weighting term that provides convergence to functions for which the Fourier integral does not converge.

Following the concept of representing signals as a linear combination of eigensignals, instead of choosing  $e^{-(\sigma+j\Omega)t}$  as the eigensignals, one could choose  $e^{-j\Omega t}$  as the eigensignals. The latter representation leads to the Fourier transform equation, and any LTI system's response could be characterized by the amplitude scaling applied to each of the basic inputs  $e^{-j\Omega t}$ .

Laplace transform and applications are discussed in greater detail in [2,4,5,8,10,11].

## 1.02.5 Transfer function and stability

The Laplace transform, seen in the previous section, is an important tool to solve differential equations and therefore to obtain, once given the input, the output of a linear and time invariant (LTI) system. For a LTI system, the Laplace transform of its mathematical representation, given as a differential equation—with constant coefficients and null initial conditions—as in (2.22) or, equivalently, given by a convolution integral as in (2.10), leads to the concept of *transfer function*, the ratio

$$H(s) = \frac{Y(s)}{X(s)} \tag{2.83}$$

between the Laplace transform of the output signal and the Laplace transform of the input signal. This representation of a LTI system also corresponds to the Laplace transform of its impulse response, i.e.,  $H(s) = \mathcal{L}\{h(t)\}$ .

Assuming that all initial conditions are equal to zero, solving a system using the concept of transfer function is usually easier for the convolution integral is replaced by a multiplication in the transformed domain:

$$Y(s) = \mathcal{L}\{h(t) * x(t)\} = H(s)X(s) \quad (2.84)$$

such that

$$y(t) = \mathcal{L}^{-1}\{H(s)X(s)\}, \quad (2.85)$$

the zero-state response of this system.

A simple example is given from the circuit in Figure 2.4 where

$$H(s) = \frac{1/RC}{s + 1/RC}.$$

If  $x(t) = u(t)$ ,  $X(s) = 1/s$ , and

$$\begin{aligned} Y(s) &= H(s)X(s) = \frac{1/RC}{(s + 1/RC)s} \\ &= \frac{1}{s} - \frac{1}{s + 1/RC}. \end{aligned}$$

Therefore,  $y(t) = \mathcal{L}^{-1}\{Y(s)\}$  corresponds to

$$y(t) = u(t) - e^{-\frac{1}{RC}t}u(t)$$

which is the same solution given in (2.5).

Given (2.10) and provided that all initial conditions are null, the transfer function  $H(s)$  corresponds to a ratio of two polynomials in  $s$ :

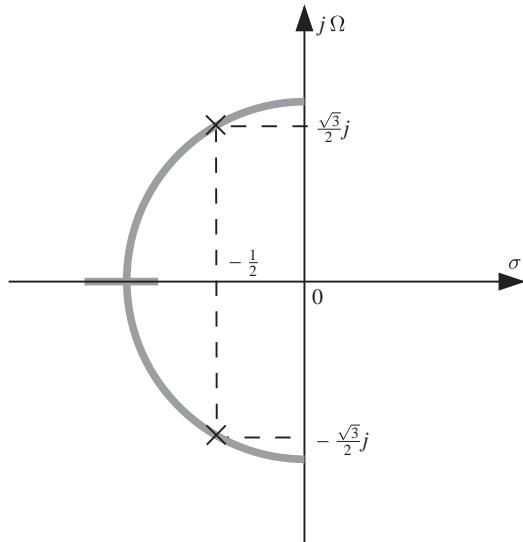

$$H(s) = \frac{P(s)}{Q(s)}. \quad (2.86)$$

The roots of the numerator  $P(s)$  are named *zeros* while the roots of the denominator  $Q(s)$  are known as *poles*. Both are usually represented in the complex plane  $s = \sigma + j\Omega$  and this plot is referred to as *pole-zero plot* or *pole-zero diagram*.

We use the ODE (2.29) to provide an example:

$$H(s) = \frac{V_o(s)}{V_i(s)} = \frac{1}{LCs^2 + RCs + 1}. \quad (2.87)$$

Using the same values,  $R = 2.0$  (in  $\Omega$ ),  $L = 2.0$  (in H),  $C = 1/2$  (in F), we obtain the poles (roots of the characteristic equation)  $s = \frac{-1 \pm j\sqrt{3}}{2}$  as seen in Figure 2.15.

**FIGURE 2.15**

An example of a pole-zero diagram of the transfer function in (2.87) for  $R = 2.0$  (in  $\Omega$ ),  $L = 2.0$  (in H),  $C = 1/2$  (in F). The gray curve corresponds to the root-locus of the poles when  $R$  varies from  $R = 0$  (poles at  $\pm j$ ) to  $R = 4.1$  (poles at  $-1.25$  and at  $-0.8$ ). See [Video 4](#) to watch animation.

For a LTI system, a complex exponential  $e^{st}$  can be considered an eigensignal:

$$\begin{aligned} x(t) = e^{st} \rightarrow y(t) &= e^{st} * h(t) = \int_{-\infty}^{\infty} h(\tau) e^{s(t-\tau)} d\tau \\ &= e^{st} \underbrace{\int_{-\infty}^{\infty} h(\tau) e^{-s\tau} d\tau}_{H(s)} \\ &= H(s)e^{st} = \frac{P(s)}{Q(s)}e^{st}, \end{aligned} \quad (2.88)$$

which is valid only for those values of  $s$  where  $H(s)$  exists.

If there is no common root between  $P(s)$  and  $Q(s)$ , the denominator of  $H(s)$  corresponds to the characteristic polynomial and, therefore, poles  $p_i$  of a LTI system correspond to their *natural frequencies*.

As mentioned in Section 1.02.2, the *stability* of a system, in a *bounded-input bounded-output* (BIBO) sense, implies that if  $|x(t)| < B_x$  then  $|y(t)| < B_y$ ,  $B_x$  and  $B_y < \infty$ , for all values of  $t$ . This corresponds to its input response being absolutely integrable, i.e.,

$$\int_{-\infty}^{\infty} |h(t)| dt = \|h(t)\|_1 < \infty. \quad (2.89)$$

As seen previously, the natural response of a linear system corresponds to a linear combination of complex exponentials  $e^{p_i t}$ . Let us assume, for convenience, that  $H(s)$  has  $N$  distinct poles and that the order of  $P(s)$  is lower than the order of  $Q(s)$ ; in that case, we can write

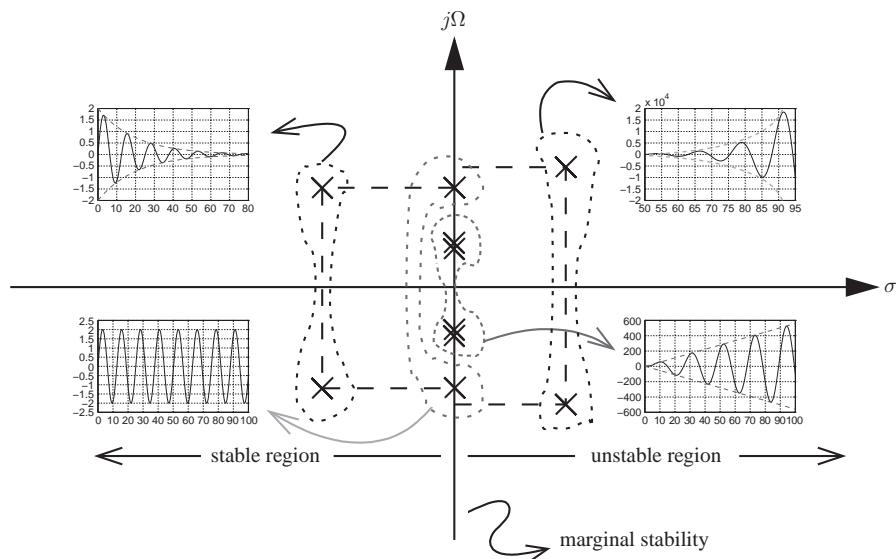

$$h(t) = \mathcal{L}^{-1} \left\{ \frac{P(s)}{\prod_{i=1}^N (s - p_i)} \right\} = \sum_{i=1}^N A_i e^{p_i t} u(t), \quad (2.90)$$

where constants  $A_i$  are obtained from simple partial fraction expansion.

In order for the system to be stable, each exponential should tend to zero as  $t$  tends to zero. Considering a complex pole  $p_i = \sigma_i + j\Omega_i$ ,  $\lim_{t \rightarrow \infty} |h(t)| \rightarrow 0$  should imply that  $\lim_{t \rightarrow \infty} |e^{(\sigma_i + j\Omega_i)t}| = \lim_{t \rightarrow \infty} |e^{\sigma_i t}| = 0$  or  $\sigma_i < 0$ ; that is, the real part of  $p_i$  should be negative.

While the location of the *zeros* of  $H(s)$  is irrelevant for the stability of a LTI system, their *poles* are of paramount importance. We summarize this relationship in the following:

1. A causal LTI system is BIBO stable if and only if all poles of its transfer function have negative real part (belong to the left-half of the  $s$ -plane).
2. A causal LTI system is unstable if and only if at least one of the following conditions occur: one pole of  $H(s)$  has a positive real part and repeated poles of  $H(s)$  have real part equal to zero (belong to the imaginary axis of the  $s$ -plane).
3. A causal LTI system is marginally stable if and only if there are no poles on the right-half of the  $s$ -plane and non-repeated poles occur on its imaginary axis.

**FIGURE 2.16**

Pole location on the  $s$ -plane and system stability: examples of impulse responses of causal LTI systems. Visit the “exploring the  $s$ -plane” <http://www.jhu.edu/signals/explore/index.html> website.

We can also state system stability from the region of convergence of  $H(s)$ : a LTI system is stable if and only if the ROC of  $H(s)$  includes the imaginary axis ( $s = j\Omega$ ). Figure 2.16 depicts examples of impulse response for BIBO stable, marginally stable, and unstable systems.

In this section, we have basically addressed BIBO stability which, although not sufficient for asymptotic stability (a system can be BIBO stable without being stable when initial conditions are not null), is usually employed for linear systems. A more thorough stability analysis could be carried out by using Lyapunov criteria [13].

The Laplace transform applied to the input response of the differential equation provides the transfer function which poles (roots of its denominator) determines the system stability: a causal LTI system is said to be stable when all poles lie in the left half of the complex  $s$ -plane. In this case, the system is also known as asymptotically stable for its output always tend to decrease, not presenting permanent oscillation.

Whenever distinct poles have their real part equal to zero (poles on the imaginary axis), permanent oscillation will occur and the system is marginally stable, the output signal does not decay nor grows indefinitely. Figure 2.16 shows the impulse response growing over time when two repeated poles are located on the imaginary axis. Although not shown in Figure 2.16, decaying exponential will take place of decaying oscillation when poles are real (and negative) while growing exponentials will appear for the case of real positive poles.

Although we have presented the key concepts of stability related to a linear system, much more could be said about stability theory. Hence, further reading is encouraged: [2, 13].

### 1.02.6 Frequency response

We have mentioned in the previous section that the complex exponential  $e^{st}$  is an eigensignal of a continuous-time linear system. A particular choice of  $s$  being  $j\Omega_0 = j2\pi f_0$ , i.e., the input signal

$$x(t) = e^{j\Omega_0 t} = \cos(\Omega_0 t) + j \sin(\Omega_0 t) \quad (2.91)$$

has a single frequency and the output, from (2.88), is

$$y(t) = e^{j\Omega_0 t} \underbrace{\int_{-\infty}^{\infty} h(\tau) e^{-j\Omega_0 \tau} d\tau}_{H(j\Omega_0)} \quad (2.92)$$

Being  $e^{j\Omega_0 t}$  an eigensignal,  $H(j\Omega_0)$  in (2.92) corresponds to its eigenvalue. Allowing a variable frequency  $\Omega = 2\pi f$  instead of a particular value  $\Omega_0 = 2\pi f_0$ , we define the *frequency response* of a linear system having impulse response  $h(t)$  as

$$H(j\Omega) = \int_{-\infty}^{\infty} h(\tau) e^{-j\Omega\tau} d\tau. \quad (2.93)$$

We note that the frequency response corresponds to the Laplace transform of  $h(t)$  on a specific region of the  $s$ -plane, the vertical (or imaginary) axis  $s = j\Omega$ :

$$H(j\Omega) = H(s)|_{s=j\Omega}. \quad (2.94)$$

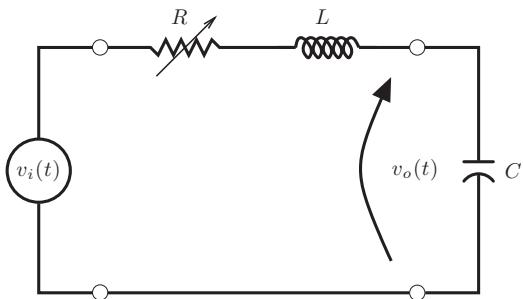

It is clear from (2.93) that the frequency response  $H(j\Omega)$  of a linear system is a complex function of  $\Omega$ . Therefore, it can be represented in its polar form as

$$H(j\Omega) = |H(j\Omega)|e^{\angle H(j\Omega)}. \quad (2.95)$$

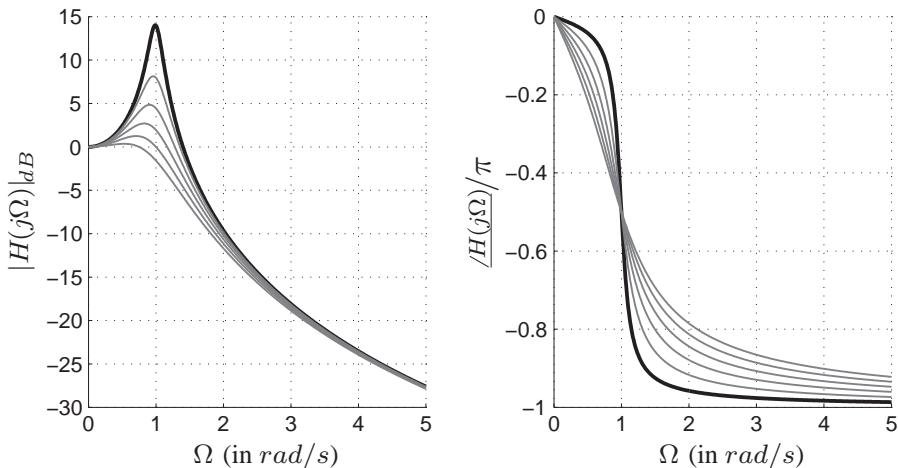

As an example, we use the RLC series circuit given in Figure 2.17 with  $L = 1.0$  (in H),  $C = 1.0$  (in F), and  $R$  varying from  $0.2\Omega$  to  $1.2\Omega$  (in  $\Omega$ ).

The frequency response, magnitude or absolute value (in dB) and argument or phase (in radians), are depicted in Figure 2.18. For this example, we consider the voltage applied to the circuit as input and the voltage measured at the capacitor as output. This is worth mentioning since the output could be, for instance, the current in the circuit or the voltage across the inductor.

In low frequencies, the capacitor tends to become an open circuit such that  $v_o(t) = v_i(t)$  and the gain tends to 1 or 0 dB. On the other hand, as the frequency  $\Omega$  goes towards infinity, the capacitor tends to become a short circuit such that  $v_o(t)$  goes to zero, gain in dB tending to minus infinity. The circuit behaves like a low-pass filter allowing low frequencies to the output while blocking high frequencies. Specially, when  $R$  has low values (when tending to zero), we observe a peak in  $|H(j\Omega)|$  at  $\Omega \approx \Omega_0 = 1$  rad/s. This *frequency*,  $\Omega_0 = 2\pi f_0$ , is termed the resonance frequency and corresponds to the absolute value of the pole responsible for this *oscillation*.

**FIGURE 2.17**

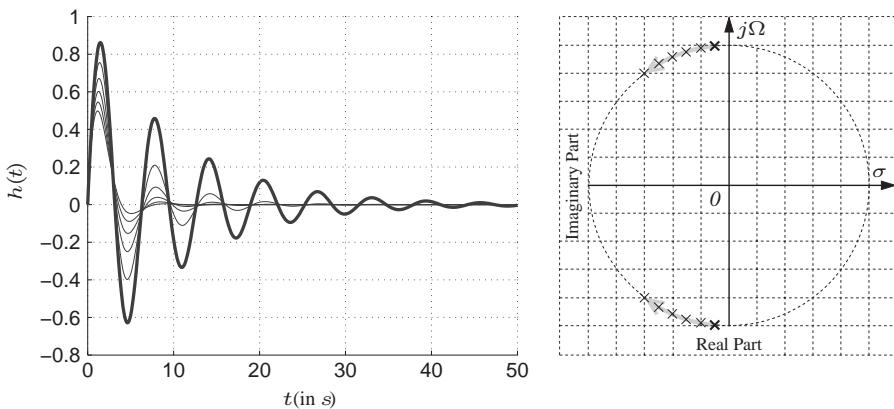

RLC series circuit: the transfer function is  $H(s) = \frac{V_o(s)}{V_i(s)}$ ,  $V_o(s) = \mathcal{L}\{v_0(t)\}$  and  $V_i(s) = \mathcal{L}\{v_i(t)\}$ , and the frequency response is given by  $H(j\Omega) = H(s)|_{s=j\Omega}$ .

**FIGURE 2.18**

Frequency response in magnitude ( $|H(j\Omega)|$  in dB) and normalized phase (argument of  $H(j\Omega)$  divided by  $\pi$ , i.e.,  $-1$  corresponds to  $-\pi$ ) for the circuit in Figure 2.17 with  $L = 1$  (in H),  $C = 1$  (in F), and  $R$  varying from 0.2 (in  $\Omega$ ) (highlighted highest peak in magnitude) to 1.2 (in  $\Omega$ ). Download the <http://www.ime.eb.br/~apolin/CTSS/Figs18and19.m> Matlab<sup>®</sup> code.

Let us write the frequency response from  $H(s)$ , as given in (2.87):

$$H(j\Omega) = H(s)|_{s=j\Omega} = \frac{1}{(1 - \Omega^2 LC) + j\Omega RC}. \quad (2.96)$$

**FIGURE 2.19**

Impulse responses and poles location in the  $s$ -plane (6 different values of  $R$ ) for the circuit in Figure 2.17. Note that, for lower values of  $R$ ,  $h(t)$  tends to oscillate and the poles are closer to the vertical axis (marginal stability region). Download the <http://www.ime.eb.br/~apolin/CTSS/Figs18and19.m> Matlab<sup>®</sup> code.

We note that, when  $R \rightarrow 0$ , the peak amplitude of  $|H(j\Omega)|$  occurs for  $1 - \Omega^2 LC \rightarrow 0$  (it tends to infinity as  $R$  goes to zero), i.e., the resonance frequency corresponds to  $\Omega_0 = \frac{1}{\sqrt{LC}}$ .

The impulse response as well as the pole diagram are shown in Figure 2.19; from this figure, we observe the oscillatory behavior of the circuit as  $R$  tends to zero in both time- and  $s$ -domain (poles approaching the vertical axis). The impulse response and the poles location for the minimum value of the resistance,  $R = 0.2$  (in  $\Omega$ ), are highlighted in this figure.

Before providing more details about the magnitude plot of the frequency response as a function of  $\Omega$ , let us show the (zero state) response of a linear system to a real single frequency excitation  $x(t) = A \cos(\Omega t + \theta)$ . We know that the complex exponential is an eigensignal to a linear system such that, making  $s = j\Omega$ ,

$$y(t)|_{x(t)=e^{j\Omega t}} = H(j\Omega)e^{j\Omega t}. \quad (2.97)$$

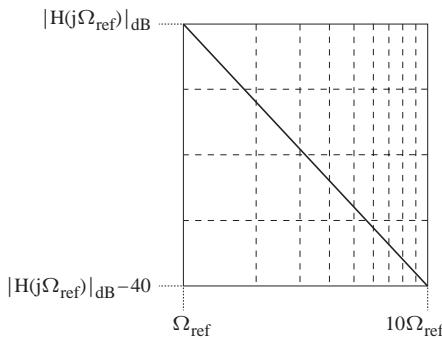

Since we can write  $A \cos(\Omega t + \theta)$  as  $A(e^{j(\Omega t + \theta)} + e^{-j(\Omega t + \theta)})/2$ , the output shall be given as

$$y(t) = \frac{A}{2}e^{j\theta}e^{j\Omega t}H(j\Omega) + \frac{A}{2}e^{-j\theta}e^{-j\Omega t}H(-j\Omega). \quad (2.98)$$

Assuming that  $h(t)$  is real, it is possible to assure that all poles of  $H(s)$  will occur in complex conjugate pairs, leading (as shall be also addressed in the next section) to  $H^*(j\Omega) = H(-j\Omega)$ . This conjugate symmetry property of the frequency response, i.e.,  $|H(j\Omega)| = |H(-j\Omega)|$  and  $\underline{H(j\Omega)} = (\underline{-H(j\Omega)})$ , when applied in (2.98), results in

$y(t)|_{x(t)=A \cos(\Omega t + \theta)} = |H(j\Omega)|A \cos(\Omega t + \theta + \angle H(j\Omega)).$

(2.99)

**FIGURE 2.20**

Asymptotical decay of 40 dB per decade.

The previous expression is also valid as regime solution when the input is a sinusoid, that is non-zero for  $t \geq 0$ , such as  $x(t) = A \cos(\Omega t + \theta)u(t)$ .

Now, back to our example of a frequency response given in (2.96), let us express its magnitude squared:

$$|H(j\Omega)|^2 = \frac{1}{1 + \Omega^2(R^2C^2 - 2LC) + \Omega^4L^2C^2}. \quad (2.100)$$

It is easy to see that, when  $\Omega$  tends to zero, the magnitude squared tends to one while, when  $\Omega$  tends to infinity, the dominant term becomes  $\Omega^4L^2C^2$ :

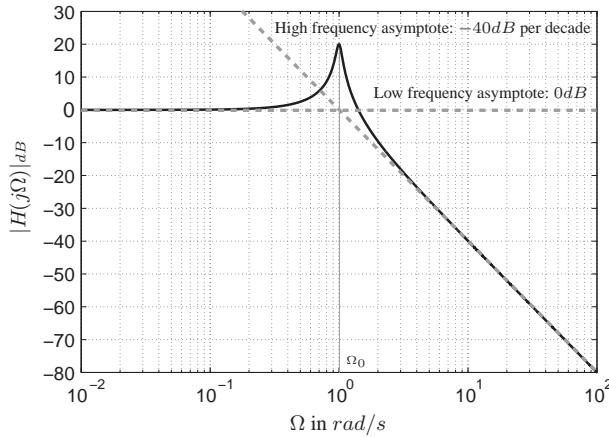

- (a)  $\Omega \rightarrow 0 \Rightarrow |H(j\Omega)| \rightarrow 1$  or 0 dB;
- (b)  $\Omega \rightarrow \infty \Rightarrow |H(j\Omega)| \rightarrow \frac{1}{\Omega^2LC}$  or, in dB,  $-40 \log(\Omega/\Omega_0)$ ,  $\Omega_0 = \frac{1}{\sqrt{LC}}$ .

These two regions of  $|H(j\Omega)|$ , close to zero and tending to infinity, could be visualized by lines in a semi-log plot, the frequency axis, due to its large range of values, is plotted using a logarithmic scale. Particularly, when  $\Omega \rightarrow \infty$ , the approximation in (b) tells us that, in an interval from  $\Omega_{ref}$  to  $10\Omega_{ref}$ ,  $\Omega_{ref} \gg \Omega_0$  (the resonance frequency), we have an attenuation of 40 dB as shown in Figure 2.20.

Magnitude in dB and phase of  $H(j\Omega)$  as a function of  $\Omega = 2\pi f$ , plotted in a logarithmic frequency scale, is known as *Bode Plots* or *Bode Diagrams*. A Bode Diagram may be sketched from lines (asymptotes) which are drawn from the structure of  $H(s)$ , its poles and zeros. For the case of a transfer function with two conjugate complex roots, we have

$$H(s) = \frac{\Omega_0^2}{s^2 + 2\xi\Omega_0s + \Omega_0^2}, \quad (2.101)$$

where, in our example in (2.87),  $\Omega_0 = \frac{1}{\sqrt{LC}}$  and  $\xi = \frac{R}{2}\sqrt{\frac{C}{L}}$ . Also note that (in order to have two conjugate complex roots)  $0 < \xi < 1$ .

**FIGURE 2.21**

Example of Bode Plot for  $H(s) = \frac{\Omega_0^2}{s^2 + 2\xi\Omega_0 s + \Omega_0^2}$  with  $\Omega_0 = 1$  and  $\xi = 0.05$ . Note that, for this case, the approximated height of the peak  $-20 \log(2\xi) = 20$  dB works well.

The magnitude of the frequency response in dB is given as

$$|H(j\Omega)|_{dB} = -10 \log \left( \left( 1 - \left( \frac{\Omega}{\Omega_0} \right)^2 \right)^2 + \left( 2\xi \frac{\Omega}{\Omega_0} \right)^2 \right). \quad (2.102)$$

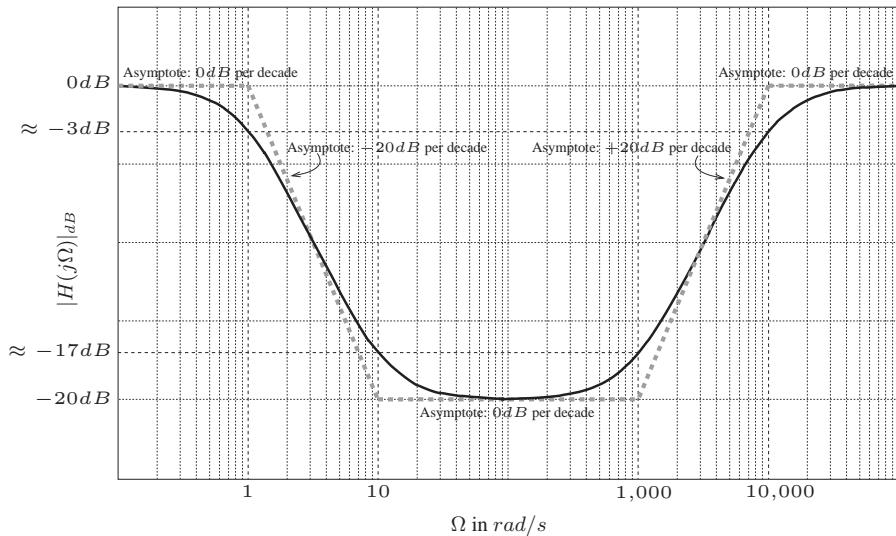

When  $\Omega = \Omega_0$ ,  $|H(j\Omega)| = -20 \log(2\xi)$ ; this value being a good approximation for the peak magnitude (see Figure 2.21) when  $\xi$  tends to zero (we have an error lower than 0.5% when  $\xi < 0.1$ ). The peak actually occurs in  $\Omega = \Omega_0\sqrt{1 - 2\xi^2}$ , having a peak height equal to  $\frac{1}{2\xi\sqrt{1-\xi^2}}$ ; we could also add that the peak is basically observable only when  $0 < \xi < 0.5$ . The Bode Plot of (2.87), with  $R = 0.1$  (in  $\Omega$ ),  $L = 1.0$  (in  $H$ ), and  $C = 1.0$  (in  $F$ ) showing the (low frequency and high frequency) asymptotes is depicted in Figure 2.21.

Another example with first order poles and zeros will end our discussion on Bode Plots. Let transfer function  $H(s)$ , with poles at  $-1$  and  $-10,000$ , and zeros at  $-10$  and  $-1000$ , be represented as follows:

$$\begin{aligned} H(s) &= \frac{s^2 + 1.01s + 10000}{s^2 + 10,001s + 10000} \\ &= \frac{(s + 1,000)(s + 10)}{(s + 10000)(s + 1)} \\ &= \frac{\left(1 + \frac{s}{1,000}\right)\left(1 + \frac{s}{10}\right)}{\left(1 + \frac{s}{10,000}\right)\left(1 + s\right)}. \end{aligned} \quad (2.103)$$

**Table 2.4** Asymptotes for the Bode Plot of Figure 2.22

$\Omega$ (rad/s)	event	asymptotic $ H(j\Omega) _{dB}$ (dB)
1	New asymptote starts ( $-20$ dB per decade)	0
10	New asymptote starts ( $+20$ dB per decade)	$-20$
1000	New asymptote starts ( $+20$ dB per decade)	$-20$
10,000	New asymptote starts ( $-20$ dB per decade)	0

**FIGURE 2.22**

Bode Magnitude (dB) Plot for  $H(s) = \frac{(1+\frac{s}{1,000})(1+\frac{s}{10})}{(1+\frac{s}{10,000})(1+\frac{s}{1})}$ . Download the <http://www.ime.eb.br/~apolin/CTSS/Fig22.m> Matlab<sup>®</sup> code.

The magnitude in  $dB$  of its frequency response could then be written as

$$\begin{aligned} |H(j\Omega)|_{dB} &= 20 \log \left| 1 + j \frac{\Omega}{1,000} \right| + 20 \log \left| 1 + j \frac{\Omega}{10} \right| \\ &\quad - 20 \log \left| 1 + j \frac{\Omega}{10,000} \right| - 20 \log |1 + j\Omega|. \end{aligned} \quad (2.104)$$

The first term, as in the previous example, can be checked for low and high frequencies:

- (a)  $\Omega \ll 1000 \Rightarrow 0_{dB}$ ;

(b)  $\Omega \gg 1000 \Rightarrow$  increases 20 dB per *decade* (from  $\Omega_{ref}$  to  $10\Omega_{ref}$ ) or, equivalently, 6 dB per *octave* (from  $\Omega_{ref}$  to  $2\Omega_{ref}$ ).

When  $\Omega = 1000$ , the value of this term is  $10 \log(2) = 3.0103$  dB which is the usual error at the these frequencies (*cutoff frequencies*).

We could, from the analysis of the first term, extend the results to all cutoff frequencies as shown in Table 2.4. The resulting asymptotic sketch and real curves are shown in Figure 2.22 where we observe the 3 dB errors at the cutoff frequencies.

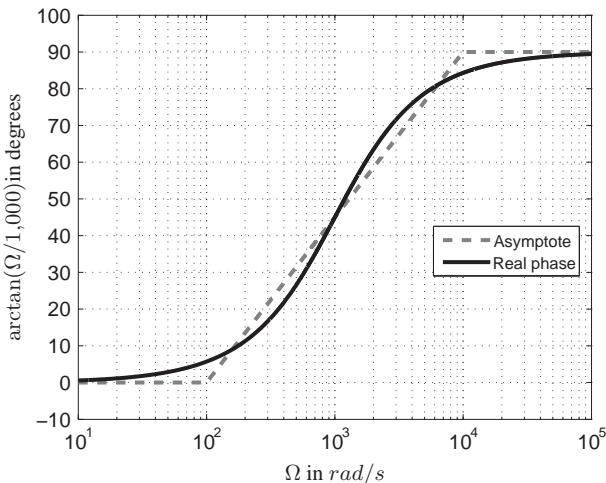

A final observation is regarded to the phase of the frequency response: similarly to the magnitude, a sketch of the phase can also be obtained from the poles and zeros of  $H(s)$ :

$$\angle H(j\Omega) = \angle 1+j\Omega/1000 + \angle 1+j\Omega/10 - \angle 1+j\Omega/10,000 - \angle 1+j\Omega. \quad (2.105)$$

The first term on the right hand side of (2.105),  $\angle 1+j\Omega/1000 = \arctan(\Omega/1000)$ , can be checked for low and high frequencies:

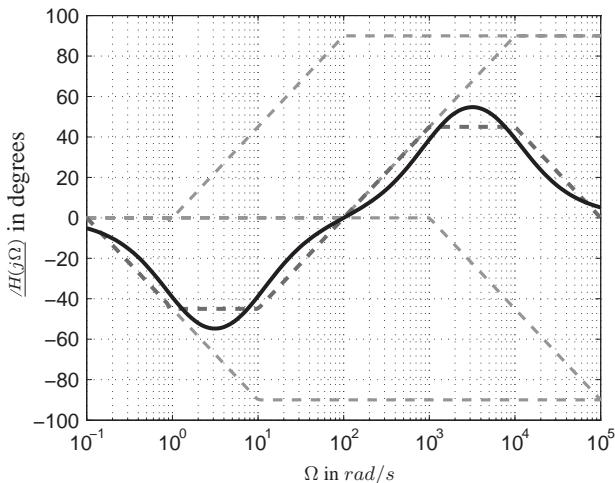

- (a)  $\Omega \ll 1000 \Rightarrow \arctan(\Omega/1000) \approx 0$ ;
- (b)  $\Omega \gg 1000 \Rightarrow \arctan(\Omega/1000) \approx 90^\circ$ .

Considering only this zero (corresponding cutoff frequency  $\Omega_0 = 1000$  rad/s), one may assume  $0.1\Omega_0$  (100 rad/s) and  $10\Omega_0$  (10,000 rad/s) sufficiently small and sufficiently large such that an asymptote could be drawn between points  $(10^2, 0^\circ)$  and  $(10^4, 90^\circ)$  as in Figure 2.23. For a pole, the asymptote is mirrored with respect to  $0^\circ$ .

**FIGURE 2.23**

Asymptotical behavior of the phase for a single zero.

**FIGURE 2.24**

Bode Phase Plot for  $H(s) = \frac{(1+\frac{s}{1.000})(1+\frac{s}{10})}{(1+\frac{s}{10.000})(1+\frac{s}{1})}$ . Lighter gray dashed lines represent the asymptotes and the darker dashed line corresponds to the asymptotic sketch (sum of the asymptotes); the real phase is the continuous curve in black. Download the <http://www.ime.eb.br/~apolin/CTSS/Fig24.m> Matlab<sup>®</sup> code.

The asymptotic sketch and real phase curves for (2.105) is shown in Figure 2.24; note that we have two negative slope asymptotes, starting in  $\Omega = 10^{-1}$  rad/s and  $\Omega = 10^3$  rad/s, and two positive slope asymptotes, starting at  $10^0$  rad/s and  $10^2$  rad/s.

The topics discussed in this section are found in the following books: [1, 3, 8, 14, 15].

## 1.02.7 The Fourier series and the Fourier transform

In electronic circuits we often deal with periodic and non-periodic signals. In addition, circuits could be driven by non-sinusoidal functions. Hence, methods that decompose continuous-time periodic (non-sinusoidal) and non-periodic signals into contributions from sinusoidal ( $\sin(\Omega t)$  and  $\cos(\Omega t)$ ) signals are extremely valuable for electronic system analysis; this is due to the fact that a LTI system only changes the amplitude and phase of a real sinusoid. Several properties make sinusoids an ideal choice to be the elementary basis functions for signal analysis and synthesis. For example, Eq. (2.99) shows that the LTI system changed the amplitude to  $|H(j\Omega)|A$  and the phase to  $\theta + \angle H(j\Omega)$  of the given sinusoidal input,  $x(t) = A \cos(\Omega t + \theta)$ . In addition, as sine and cosine are mutually orthogonal, sinusoidal basis functions are independent and can be processed independently. Usually, any sinusoidal function, such as the one mentioned above, can be expressed as a linear combination of sine and cosine functions:  $x(t) = C \cos(\Omega t) - D \sin(\Omega t)$ . If a signal is a sum of sinusoids, such as

$$x(t) = A_1 \cos(\Omega_1 t + \theta_1) + A_2 \cos(\Omega_2 t + \theta_2) \quad (2.106)$$

its impulse response, considering it is a linear system, would be given by

$$y(t) = A_1|H(j\Omega_1)| \cos(\Omega_1 t + \theta_1 + \angle H(j\Omega_1)) + A_2|H(j\Omega_2)| \cos(\Omega_2 t + \theta_2 + \angle H(j\Omega_2)) \quad (2.107)$$

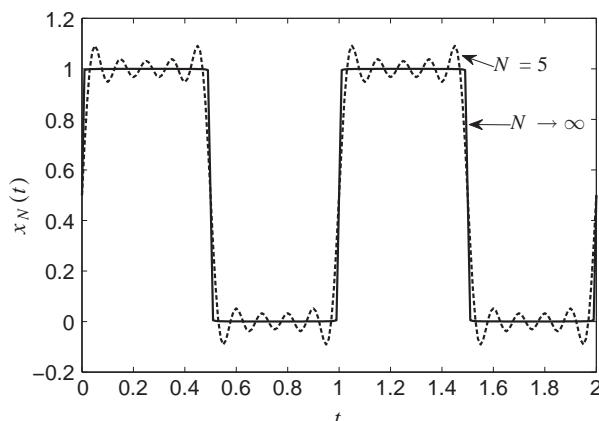

A periodic signal,  $x(t) = x(t+nT)$ ,  $\forall n = \pm 1, \pm 2, \pm 3, \dots$ , with period  $T$ , may contain components at frequencies  $\Omega = 2\pi n/T$ , where the fundamental frequency is given by  $\Omega_0 = 2\pi f_0$ ,  $f_0 = 1/T$ . The frequencies  $n\Omega_0$  are the harmonics, and any pair of signals are harmonically related if their periods are related by a integer ratio. In general, the resulting signal from a sum of harmonically related waveforms is also periodic, and its repetition period is equal to the fundamental period. The harmonic components exist only at discrete frequencies.

Consider that we add the harmonically related signals,  $x_n(t)$ , with  $\Omega_0 = 2\pi/T$ , over  $T = 1$  such that  $x(t) = \frac{1}{2} + \frac{2}{\pi} \sin(2\pi t) + \frac{2}{3\pi} \sin(6\pi t) + \frac{2}{5\pi} \sin(10\pi t) + \frac{2}{7\pi} \sin(14\pi t) + \dots$ , and get  $x_N(t)$  as the result when  $1 \leq N \leq 5$  and when  $N \rightarrow \infty$ , meaning that infinite terms are added:

$$x_N(t) = \frac{1}{2} + \sum_{n=1}^N x_n(t) = \frac{1}{2} + \frac{2}{\pi} \sum_{n=1}^N \frac{1}{2n-1} \sin(2\pi(2n-1)t). \quad (2.108)$$

The resulting waveforms,  $x_N(t)$  for  $1 \leq N \leq 5$  and  $x_N(t)$  when  $N$  is large, i.e.,  $N \rightarrow \infty$ , are displayed by Figure 2.25. It is clear that as the number of terms becomes infinite in (2.108) the result converges at every value of the period  $T$  (to the square wave) except at the discontinuities. Actually, the ringing effect at the discontinuities (not shown in Figure 2.25 for the curve with the large value of  $N$ ) never dies out as  $N$  becomes larger, yet reaching a finite limit (Gibbs phenomenon).

Hence, for a period  $T$ , for a fundamental frequency  $\Omega_0$  with frequencies that are integer multiples of the fundamental frequency such that  $n\Omega_0$ ,  $\forall n \in \mathbb{Z}$  (the set of all integers), the representation of the

**FIGURE 2.25**

Synthesized square wave from Eq. (2.108).

harmonic components,  $x_n(t)$ , of a signal  $x(t)$  can be written as

$$\begin{aligned}x_n(t) &= A_n \sin(n\Omega_0 t + \theta_n) \\&= a_n \cos(n\Omega_0 t) + b_n \sin(n\Omega_0 t) \\&= \frac{1}{2}(a_n - jb_n)e^{jn\Omega_0 t} + \frac{1}{2}(a_n + jb_n)e^{-jn\Omega_0 t}.\end{aligned}\quad (2.109)$$

Equation (2.109) presents three equivalent forms to express the harmonic components  $x_n(t)$ : the first one is written as a sine function with amplitude  $A_n$  and phase  $\theta_n$ ; the second one as sum of sine and cosine functions with real coefficients  $a_n$  and  $b_n$ , respectively; and the last form writes  $x_n(t)$  in terms of complex exponentials.

The derivation, providing proofs, of the expressions for computing the coefficients in a Fourier series is beyond the scope of this chapter. Hence, we simply state, without proof, that if  $x(t)$  is periodic with period  $T$  and fundamental frequency  $\Omega_0$ , any arbitrary real periodic signal  $x(t)$  could be represented by the infinite summation of harmonically related sinusoidal components, known as the Fourier series:

$$\begin{aligned}x(t) &= \frac{1}{2}a_0 + \sum_{n=1}^{\infty} A_n \sin(n\Omega_0 t + \theta_n) \\&= \frac{1}{2}a_0 + \sum_{n=1}^{\infty} (a_n \cos(n\Omega_0 t) + b_n \sin(n\Omega_0 t)),\end{aligned}\quad (2.110)$$

where for  $n = 0$ , we have the term  $\frac{a_0}{2}$  corresponding to the mean value of the signal, with frequency of 0 Hz, known as the DC value (or level), and the other terms are as follows:

$$\begin{aligned}a_n &= A_n \sin(\theta_n), \\b_n &= A_n \cos(\theta_n), \\A_n &= \sqrt{a_n^2 + b_n^2}, \\\theta_n &= \arctan\left(\frac{a_n}{b_n}\right).\end{aligned}\quad (2.111)$$

If in the last form presented in (2.109), we substitute

$$\begin{aligned}c_n &= \frac{1}{2}(a_n - jb_n), \\c_{-n} &= \frac{1}{2}(a_n + jb_n),\end{aligned}\quad (2.112)$$

to have a third representation of the Fourier series, given by

$$\begin{aligned}x(t) &= c_0 + \sum_{n=1}^{\infty} c_n e^{jn\Omega_0 t} + \sum_{n=-1}^{-\infty} c_n e^{jn\Omega_0 t} \\&= \sum_{n=-\infty}^{\infty} c_n e^{jn\Omega_0 t},\end{aligned}\quad (2.113)$$

where  $c_0$  is real and  $c_n$  are complex, for  $n \neq 0$ , coefficients. The coefficients of terms for positive ( $c_n$ ) and negative ( $c_{-n}$ ) values of  $n$  are complex conjugates ( $c_{-n} = c_n^*$ ). This Fourier series form demands the summation to be performed over all  $n \in \mathbb{Z}$ , as the continuous-time complex sinusoids,  $e^{jn\Omega_0 t}$ , present an infinite number of terms (specific frequencies  $n\Omega_0$ ). Moreover, for every integer value of  $n$ ,  $e^{jn\Omega_0 t} = \cos(n\Omega_0 t) + j \sin(n\Omega_0 t)$  is periodic with  $T = 2\pi$ . Hence, the periodic signal  $x(t)$  must have  $T = 2\pi$  in order to compute the Fourier series expansion. However, the analysis of the Fourier cosine series of a function  $x$  in the interval  $[0, \pi]$  is equivalent to the analysis of its extension first to  $[-\pi, \pi]$  as an even function, then to all of components with period  $T = 2\pi$ .

The complex exponential representation of the Fourier series, given by (2.113) generates a *two-sided spectrum*, as the summation requires all  $n \in \mathbb{Z}$ . The first and second representations of the Fourier series, presented in (2.110) produce a *one-sided spectra*, as the sum is computed only for values of  $n > 0$ .

Equations (2.110) and (2.113) are called Fourier synthesis equations as it is possible to synthesize any periodic (time) signal,  $x(t)$ , from an infinite set of harmonically related signals.

If  $x(t)$  is periodic with fundamental frequency  $\Omega_0$  and period  $T$ , the coefficients of the three Fourier series equivalent representations are given by

$$c_n = \frac{1}{T} \int_{t_1}^{t_1+T} x(t) e^{-jn\Omega_0 t} dt, \quad (2.114)$$

and by manipulating (2.112) we obtain

$$\begin{aligned} a_n &= \frac{2}{T} \int_{t_1}^{t_1+T} x(t) \cos(n\Omega_0 t) dt, \text{ and} \\ b_n &= \frac{2}{T} \int_{t_1}^{t_1+T} x(t) \sin(n\Omega_0 t) dt, \end{aligned} \quad (2.115)$$

where the integrals in (2.114) and (2.115) are obtained over any interval that corresponds to the period  $T$ , with the initial time  $t_1$  for the integration arbitrarily defined.

Equations (2.114) and (2.115) are known as Fourier analysis or Fourier decomposition as the signal is being decomposed into its spectral components (basic inputs).

The continuous-time Fourier series expands any continuous-time periodic signal into a series of sine waves. The Fourier analysis methods are named after the French mathematician Jean-Baptiste Joseph Fourier. In general, almost any periodic signal can be written as an infinite sum of complex exponential functions (or real sinusoidal functions) and thus be represented as a Fourier series. Therefore, finding the response to a Fourier series, means finding the response to any periodic function, and its effect on its spectrum. When computing trigonometric coefficients, one could multiply a random signal by sinusoids of different frequencies to disclose all the (hidden) frequency components of the signal. In this way, it becomes easier to isolate the signal of the television station we want to watch from the others that are being simultaneously received by our television set.

In addition, the multiplication of a signal by  $e^{j\Omega_0 t}$  means that the signal if being frequency shifted to  $\Omega_0$ . Which is equivalent to the Frequency Shift Laplace Property (Table 2.3).

Consider  $x(t) = 3/4 + \cos(\Omega_0 t) + \cos(2\Omega_0 t + \pi/3) + 1/3 \cos(5\Omega_0 t + \pi/4)$ , where  $\Omega_0 = 2\pi$ ,  $3/4$  is the DC level, and three non-null harmonics ( $n = 1, 2$ , and  $5$ ) with the time-domain representation displayed by Figure 2.1. The signal has several (hidden) frequencies, and no clue is provided when visually inspecting Figure 2.1. The Fourier series representations are very helpful in this case, showing the amplitudes and phases of each harmonic in the frequency-domain.

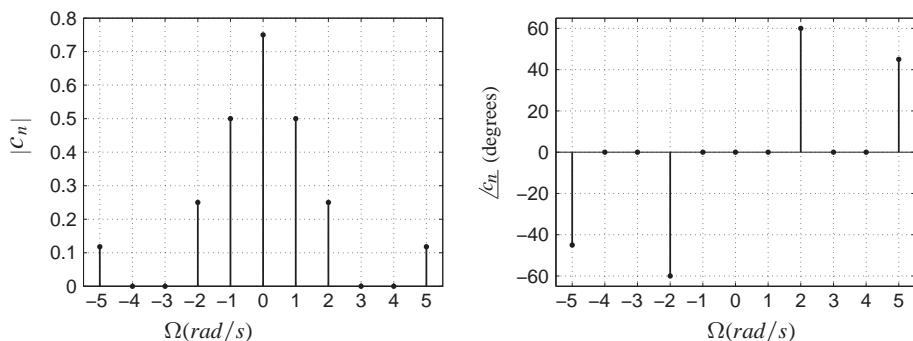

The exponential form, recursing to trigonometric identities, is given by:

$$x(t) = \underbrace{\frac{3}{4}}_{c_0} + \left( \underbrace{\frac{1}{2} e^{j\Omega_0 t}}_{c_1} + \underbrace{\frac{1}{2} e^{-j\Omega_0 t}}_{c_{-1}} \right) + \left( \underbrace{\frac{1}{2} e^{j\frac{\pi}{3}} e^{j2\Omega_0 t}}_{c_2} + \underbrace{\frac{1}{2} e^{-j\frac{\pi}{3}} e^{-j2\Omega_0 t}}_{c_{-2}} \right) + \left( \underbrace{\frac{1}{6} e^{j\frac{\pi}{4}} e^{j5\Omega_0 t}}_{c_5} + \underbrace{\frac{1}{6} e^{-j\frac{\pi}{4}} e^{-j5\Omega_0 t}}_{c_{-5}} \right), \quad (2.116)$$

and the Fourier series exponential form coefficients are (all other terms are zero).

The complex-valued coefficient  $c_n$  conveys both the amplitude ( $|c_n|$ ) and phase ( $\angle c_n$ ) of the frequency content of the signal  $x(t)$  at each value  $n\Omega_0$  rad/s as pictured in Figure 2.26.

The sinusoidal basis functions of the Fourier series are smooth and infinitely differentiable but they only represent periodic signals. The Fourier representation for a non-periodic (time-domain) signal has to treat the frequency spectrum of non-periodic signals as a continuous function of frequency. This representation could be obtained by considering a non-periodic signal as a special case of a periodic signal with an infinite period. The idea is that if the period of a signal is infinite ( $T \rightarrow \infty$ ), then it is never repeated. Hence, it is non-periodic. As  $T \rightarrow \infty$ ,  $\Omega_0 \rightarrow 0$ , thus decreasing the spacing between each adjacent line spectra (representing each harmonic contribution in the spectrum) towards a continuous representation of frequency.

**FIGURE 2.26**

Two-sided spectrum of periodic signal  $x(t)$  depicted in Figure 2.1.

The generalization to non-periodic signals is known as the *Fourier transform* and is given by (2.117). It is analogous to the Fourier series analysis Eq. (2.114). It expresses the time-domain function  $x(t)$  as a continuous function of frequency  $X(j\Omega)$  defined as follows:

$$X(j\Omega) = \mathcal{F}\{x(t)\} = \int_{-\infty}^{\infty} x(t)e^{-j\Omega t} dt. \quad (2.117)$$

The inverse Fourier transform is analogous to the Fourier series synthesis equation (2.113). It obtains the time-domain signal,  $x(t)$ , from its frequency-domain representation  $X(j\Omega)$ :

$$x(t) = \mathcal{F}^{-1}\{X(j\Omega)\} = \frac{1}{2\pi} \int_{-\infty}^{\infty} X(j\Omega)e^{j\Omega t} d\Omega. \quad (2.118)$$

The notation  $X(j\Omega) = \mathcal{F}\{x(t)\}$  denotes that  $X(j\Omega)$  is the Fourier transform of  $x(t)$ . Conversely,  $x(t) = \mathcal{F}^{-1}\{X(j\Omega)\}$  denotes that  $x(t)$  is the inverse Fourier transform of  $X(j\Omega)$ . This relationship is expressed with  $x(t) \xrightarrow{\mathcal{F}} X(j\Omega)$ .

The Fourier series coefficients have distinct units of amplitude, whereas  $X(j\Omega)$  has units of amplitude density. The magnitude of  $X(j\Omega)$  is termed as the *magnitude spectrum* ( $|X(j\Omega)|$ ) and its phase as the *phase spectrum* ( $\angle X(j\Omega)$ ).

Following the concept of representing signals as a linear combination of eigensignals, instead of choosing  $e^{-(\sigma+j\Omega)t}$  as the eigensignals, one could choose  $e^{-j\Omega t}$  as the eigensignals. The latter representation leads to the Fourier transform equation, and any LTI system's response could be characterized by the amplitude scaling applied to each of the basic inputs  $e^{-j\Omega t}$ .

This transform is very useful as it produces the frequency complex content of a signal,  $X(j\Omega)$ , from its temporal representation,  $x(t)$ . Moreover, the mapping provides a representation of the signal as combination of complex sinusoids (or exponentials) for frequency-domain behavior analysis, where the (computationally consuming) computation of the convolution in the time-domain is replaced by the (simple) operation of multiplication in the frequency-domain.

Nevertheless, functions such as the unit-step (Figure 2.2a), discontinuous at time  $t = 0$ , does not have forward Fourier transform as its integral does not converge.

An analysis of convergence is beyond the scope of this chapter, hence we assume that the existence of the Fourier transform is assured by three (modified) Dirichlet conditions (for non-periodic signals), requiring the temporal signal,  $x(t)$ : to have a finite number of discontinuities, with the size of each discontinuity being finite; to have a finite number of local maxima and minima; and to be absolutely integrable, i.e.,

$$\int_{-\infty}^{\infty} |x(t)| dt < \infty. \quad (2.119)$$

These are sufficient conditions, although not strictly necessary as several common signals, such as the unit-step, are not absolutely integrable. Nevertheless, we can define a transform pair that satisfies the Fourier transform properties by the usage of impulses when dealing with this class of signals.

The Fourier transform converts a 1-D time-domain signal,  $x(t)$ , into its 1-D complex spectrum  $X(j\Omega)$  representation in frequency-domain. In Section 1.02.4, the Laplace transform maps a time-domain 1-D

**Table 2.5** Fourier Transform Pairs

$x(t) = \mathcal{F}^{-1}\{X(j\Omega)\}$	$X(j\Omega) = \mathcal{F}\{x(t)\}$
$\delta(t)$	1
1	$2\pi\delta(\Omega)$
$u(t)$	$\pi\delta(\Omega) + \frac{1}{j\Omega}$
$ t $	$-\frac{2}{\Omega^2}$
$e^{-at}$	$\frac{1}{a+j\Omega}$
$e^{-a t }, a > 0$	$\frac{2a}{a^2+\Omega^2}$
$e^{j\Omega_0 t}$	$2\pi\delta(\Omega - \Omega_0)$
$sgn(t)$	$\frac{2}{j\Omega}$
$\sin \Omega_0 t$	$-j\pi[\delta(\Omega - \Omega_0) + \delta(\Omega + \Omega_0)]$
$\cos \Omega_0 t$	$\pi[\delta(\Omega - \Omega_0) + \delta(\Omega + \Omega_0)]$

signal,  $x(t)$ , to a complex representation,  $X(s)$ , defined over a complex plane ( $s$ -plane), spanned by its two variables  $\sigma$  and  $\Omega$ , as  $s = \sigma + j\Omega$ . The Laplace and the Fourier transforms are closely related, when  $s = j\Omega$ , i.e.,  $\sigma = 0$ , the Laplace integral becomes the Fourier transform. Referring to Figure 2.10 (Section 1.02.4), as the imaginary axis ( $j\Omega$ ) lies within the ROC, the Fourier transform exists only if  $a < 0$ . For a certain class of signals, there is a simple relationship between the Fourier and the Laplace transforms given by

$$\mathcal{F}\{x(t)\} = \mathcal{L}\{x(t)\}|_{s=j\Omega}. \quad (2.120)$$

The Laplace transform for  $x(t) = e^{-at}u(t), a > 0$  is  $X(s) = 1/(s+a)$  for  $\sigma > -a$  (Table 2.2).  $X(s)$  has a pole at  $s = -a$ , which lies at the left-half  $s$ -plane. The ROC is located at the right side of  $-a$  (right side of Figure 2.11), thus containing the imaginary axis ( $j\Omega$ ) of the  $s$ -plane. Hence, the signal  $x(t)$  has a Fourier transform given by  $X(j\Omega) = 1/(j\Omega + a)$ . However, the Fourier transform does not converge for  $\text{Re}(s) < -a$  because  $x(t)$  is not absolutely integrable, whereas  $x(t)$  has a Laplace transform with the ROC pictured in the left side of Figure 2.11.

Common Fourier transform pairs are summarized in Table 2.5.

As the Laplace transform, the Fourier transform presents a set of properties. A comprehensive description of the properties of the Fourier transform is beyond the intent of this chapter, and the properties we examine are due to their importance in the study of electronic system analysis. Much of the usefulness of the Fourier transform arises from its properties, that have important interpretations in the context of continuous-time signal processing. Understanding the relationship between time- and frequency-domains (symmetry between operations) is a key point in the study (and usage) of the Fourier transform.

(Time and frequency) scaling: If  $x(t) \xrightarrow{\mathcal{F}} X(j\Omega)$ , then  $x(at) \xleftrightarrow{\mathcal{F}} \frac{1}{|a|}X\left(j\frac{\Omega}{a}\right)$ , with  $a \neq 0 \in \mathbb{R}$ :

$$\mathcal{F}\{x(at)\} = \int_{-\infty}^{\infty} x(at)e^{-j\Omega t} dt, \quad (2.121)$$

substituting  $u = at$  we get

$$\mathcal{F}\{x(at)\} = \begin{cases} \int_{-\infty}^{\infty} x(u)e^{-j\frac{u}{a}\Omega} \frac{du}{a}, & a > 0; \\ \int_{\infty}^{\infty} x(u)e^{-j\frac{u}{a}\Omega} \frac{du}{a}, & a < 0. \end{cases} \quad (2.122)$$

The two previous expressions can be combined in one single expression given by

$$\begin{aligned} \mathcal{F}\{x(at)\} &= \frac{1}{|a|} \int_{-\infty}^{\infty} x(u)e^{-j\frac{\Omega}{a}u} du \\ &= \frac{1}{|a|} X\left(j\frac{\Omega}{a}\right), \end{aligned} \quad (2.123)$$

implying that a linear expansion of the time axis in the time-domain leads to linear compression of the frequency axis in the frequency-domain, and vice versa. This property indicates an important trade-off between the two domains, as narrow time-domain signals have wide Fourier representations (narrow pulses have wide bandwidth).

*Symmetry:* The symmetry properties are quite useful as for a real-valued, a real-valued and even, a real-valued and odd, and an imaginary temporal signal,  $x(t)$ , we have the following relations:

$x(t)$ real	$\xleftrightarrow{\mathcal{F}}$	$X^*(j\Omega) = X(-j\Omega)$
$x(t)$ real and even	$\xleftrightarrow{\mathcal{F}}$	$\text{Im}(X(j\Omega)) = 0$
$x(t)$ real and odd	$\xleftrightarrow{\mathcal{F}}$	$\text{Re}(X(j\Omega)) = 0$
$x(t)$ imaginary	$\xleftrightarrow{\mathcal{F}}$	$X^*(j\Omega) = -X(-j\Omega)$

These properties are important as for a real-valued function in time its Fourier transform is conjugate symmetric,  $X^*(j\Omega) = X(-j\Omega)$ . This means that its real part (the magnitude) is an even function of frequency, and that its imaginary part (phase) is an odd function of frequency. Therefore, when we obtain the Fourier transform of a real-valued time function, it is only necessary to display the transform for positive values of  $\Omega$ . If the signal is even, i.e.,  $x(t) = x(-t)$ , it has a Fourier transform that is a purely real function,  $X(j\Omega) = |X(j\Omega)|$ . Conversely, the transform of an odd function is an purely imaginary function.

Furthermore, other properties deserve to be highlighted. We start with the Frequency Shifting property presented in Table 2.6. As its representation in the frequency-domain indicates,  $X(j(\Omega - \Omega_0))$ , a multiplication by  $e^{j\Omega_0 t}$  in the time-domain, modulates the signal  $x(t)$  onto a different frequency. As most modulation and demodulation techniques involve multiplication, it is important to stress the importance of the convolution property (Table 2.6). A simple operation of multiplication in time becomes a computationally intensive operation of convolution in frequency. Conversely, a convolution operation in the time-domain is much easier to analyze in the frequency-domain (multiplication in the frequency-domain). Hence, as the convolution in the time-domain defines the output of a time-invariant filter to a given input, the analysis and design of filters are typically performed in the frequency-domain.

Another important relation is the Parseval's Relationship. It indicates that the information (energy) contained in the time-domain is preserved when representing the signal in the frequency-domain. If the

**Table 2.6** Properties of Fourier Transform

Property	Time-domain	Frequency-domain
Linearity	$a_1 x_1(t) + a_2 x_2(t)$	$a_1 X_1(j\Omega) + a_2 X_2(j\Omega)$
Scaling	$x(at)$	$\frac{1}{ a } X(j\frac{\Omega}{a})$
Time shifting	$x(t - t_0)$	$e^{-j\Omega t_0} X(j\Omega)$
Frequency shifting	$e^{j\Omega_0 t} x(t)$	$X(j(\Omega - \Omega_0))$
Differentiation in time	$\frac{dx(t)}{dt}$	$j\Omega X(j\Omega)$
	$\frac{d^n x(t)}{dt^n}$	$(j\Omega)^n X(j\Omega)$
Integration in time	$\int_{-\infty}^t x(\tau) d\tau$	$\frac{1}{j\Omega} X(j\Omega) + \pi X(0)\delta(\Omega)$
Differentiation in frequency	$-jtx(t)$	$\frac{dX(j\Omega)}{d\Omega}$
Convolution (in time)	$x_1(t) * x_2(t)$	$X_1(j\Omega) X_2(j\Omega)$
Convolution (in frequency)	$x_1(t)x_2(t)$	$\frac{1}{2\pi} X_1(j\Omega) * X_2(j\Omega)$

power associated with a (complex) signal  $x(t)$  is  $|x(t)|^2$ , Parseval's Relationship states that the signal is represented equivalently in either the time- or frequency-domain without lost or gain of energy:

$$\int_{-\infty}^{\infty} |x(t)|^2 dt = \frac{1}{2\pi} \int_{-\infty}^{\infty} |X(j\Omega)|^2 d\Omega. \quad (2.124)$$

Hence, we can compute average power in either the time- or frequency-domain. The term  $|X(j\Omega)|^2$  is known as the *energy spectrum* or *energy density spectrum* of the signal and shows how the energy of  $x(t)$  is distributed across the spectrum.

A list of Fourier transform properties are summarized in Table 2.6.

One more time, we take, as an example, the RLC circuit displayed by Figure 2.8, where the desired response is the voltage,  $v_o(t)$ , across the capacitor  $C$ ,  $v_C(t)$ . If we use the Fourier transform, assisted by its differentiation property (Table 2.6), to solve the ODE in (2.30) we have

$$\mathcal{F}\{e^{-t}\} = V_i(j\Omega) = \mathcal{F}\left\{LC \frac{d^2 v_o(t)}{dt^2} + RC \frac{dv_o(t)}{dt} + v_o(t)\right\} \quad (2.125)$$

and we get the following result

$$V_i(j\Omega) = -LC\Omega^2 V_o(j\Omega) + jRC\Omega V_o(j\Omega) + V_o(j\Omega), \quad (2.126)$$

where the output in the frequency-domain,  $V_o(j\Omega)$ , is given by

$$V_o(j\Omega) = \frac{V_i(j\Omega)}{(1 - LC\Omega^2) + jRC\Omega}, \quad (2.127)$$

which exhibits a resonant behavior exactly as in (2.96). Also note that the frequency response, defined in (2.93), corresponds to the Fourier transform of the impulse response.

Fourier methods and applications are presented in [1, 4, 5, 16, 17].

### 1.02.8 Conclusion and future trends

This chapter provided an introductory overview on the general concepts of signals, systems, and analysis tools used in the continuous-time domain.

We believe that the knowledge of continuous-time signals and systems, even for a book directed for methods used in the discrete-time domain, is extremely important for, while exploring their differences, the reader can enhance the understanding of the natural phenomena.

A few papers discuss the relevance of teaching (analog) circuits and systems, as well its importance to an engineering career [18].

Analog circuit engineers have to deal with the entire circuit, and many parameters must be considered in their design. In order to simplify circuit models, designers have to make approximations about the analog components, which requires expertise and years of education.

This chapter dealt with traditional electrical components and their fundamental variables: resistors having a direct relationship between voltage and current ( $v = Ri$ ,  $R$  the resistance), inductors relating voltage and current with its flux ( $d\phi = v dt$  and  $d\phi = L di$ ,  $L$  the inductance), and capacitors relating voltage and current with charge ( $dq = C dv$  and  $dq = i dt$ ,  $C$  the capacitance). After first theorized in the early seventies, the *memristor* regained the media in 2008 when a first real implementation was announced: the fourth fundamental circuit element relating charge and flux as in its axiomatic definition,  $d\phi = M dq$  ( $M$  the *memristance*) [19]. The use of this component in usual electronic gadgets as well as teaching its theory even in undergraduate courses seems to be an upcoming technology trend.

In addition, most electronic devices have to interface with the external, analog, world, where data conversion is needed at the input and output sides. Analog technologies are used along with digital technologies, spanning from human interface components to analog circuits in wireless components. Furthermore, analog design is also present in the mixed-signal integrated circuits, and it is becoming increasingly critical due to high-speed circuitry [20]. Analog circuits are also used to process signals in very high frequency ranges, such as microwave and RF. In addition, electronic digital circuits are supplied with power, and the trend is to reduce power consumption of digital circuitry. Hence, knowledge of analog circuits is required if an engineer is designing a high performance digital circuit.

We have tried to condense in few pages, all pertinent information regarding analog signals and systems in order to help a complete understanding of the forthcoming chapters. Nevertheless, we have not exhausted the description of all details. For more interested readers, we outline in the following suggested references for further reading. We hope you enjoy the rest of the book.

## Glossary

BIBO	refers to a certain class of stability known as <i>bounded-input bounded-output</i>
Convolution	operation between two functions: the output (zero-state solution) of a linear and time-invariant system corresponds to the convolution integral between the input signal and the impulse response, i.e., $y(t) = \int_{-\infty}^{\infty} x(\tau)h(t - \tau)d\tau$

Frequency response	of a linear system corresponds to the Fourier transform of its impulse response: $H(j\Omega) = \int_{-\infty}^{\infty} h(\tau)e^{-j\Omega\tau} d\tau$
Impulse signal	$\delta(t)$ is a pulse of infinite amplitude and infinitesimal time characterized by being equal to zero when $t \neq 0$ and $\int_{-\infty}^{\infty} \delta(t)dt = 1$
Impulse response	$h(t)$ is the output of a linear and time-invariant system when the input corresponds to the impulse $\delta(t)$
LTI	linear and time-invariant system: when the output of a continuous-time system corresponds to a linear operation on the input signal while not depending on a particular instant but remaining the same as time goes by
ODE	ordinary differential equation: a differential equation having only one independent variable
RLC	is usually related to a circuit with resistor (R), inductor (L) and capacitor (C)
ROC	region of convergence of the Laplace transform of a given signal $x(t)$ : in the Laplace transform domain, it corresponds to the set of values of the complex variable $s$ that ensures the existence of $\mathcal{L}\{x(t)\}$
Transfer function	is the representation in the $s$ -domain of the input-output relation for a linear system; it corresponds to the Laplace transform of the impulse response, i.e., $H(s) = \frac{Y(s)}{X(s)} = \mathcal{L}\{h(t)\}$
Unit-step signal	$u(t)$ is equal to 0 when $t < 0$ , equal to 1 when $t > 0$ and relates to the impulse signal as follows: $u(t) = \int_{-\infty}^t \delta(t)dt$

## 1.03.1 Introduction

Discrete-time systems are signal processing entities that process discrete-time signals, i.e., sequences of signal values that are generally obtained as equidistant samples of continuous-time waveforms along the time axis. Usually a clock signal will determine the period  $T$  (sampling interval) in which the input signal values enter the system and, respectively, the output samples leave the system. The interval  $T$  also determines the cycle in which the internal signal values within the system are processed. Typical representatives of this class of systems are the analog discrete-time signal processing systems (switched capacitor circuits, charge-coupled devices (CCD), bucket-brigade devices (BBD)) as well as digital systems. In the case of the last, the sequence value for each sampling interval will also be discretized, i.e., it will be represented with a finite set of amplitudes, usually in a binary representation. [Chapter 5](#) covers the topic of sampling and quantization of continuous-time signals.

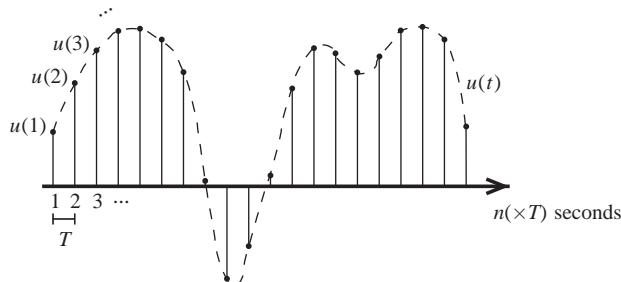

It is worth mentioning, that in the case of multi-rate discrete-time systems, the interval in which the internal signals and possibly the output signal are processed will usually be different from  $T$ . The topic of multi-rate discrete-time systems is covered in [Chapter 9](#).

It is important to emphasize that the discussion in this chapter considers the special case of discrete-time signals with unquantized values. This means that the amplitude of all the signals and the value of the parameters (coefficients) that describe the discrete-time systems are represented with infinite word length. This is an abstraction from real digital signals and systems, where the finite word length representation of both signals and parameters have to be taken into account to fully cover all important phenomena, such as limit cycles. Design of digital filters and their implementation will be discussed in [Chapter 7](#).

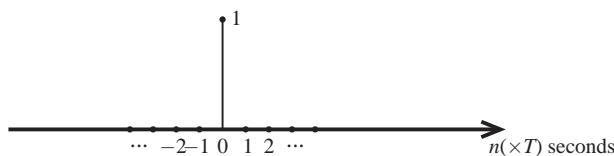

---

## 1.03.2 Discrete-time signals: sequences

Discrete-time signals can arise naturally in situations where the data to be processed is inherently discrete in time, like in financial or social sciences, economy, etc. Generally, the physical quantities that the discrete-time signal represents evolve continuously over time (for example, voice, temperature, voltages, currents or scattering variables), but inside a sampling interval of  $T$  seconds, can be completely characterized by means of a single value only, see [Figure 3.1](#). In the last case, the continuous-time signals are first sampled or discretized over time and possibly also quantized in amplitude.

**FIGURE 3.1**

Discrete-time signal as a sampled version of a continuous-time waveform.

**FIGURE 3.2**

Discrete-time unit impulse.

Still images are usually described as two dimensional discrete signals, where the two dimensions are spatial dimensions. For moving images, a third dimension is added.

Important examples of discrete-time signals that are used in practice are addressed in the following.

Analogously to the continuous-time unit impulse, known as the Dirac delta function, we can also define a discrete-time unit impulse, known as the Kronecker delta function, as

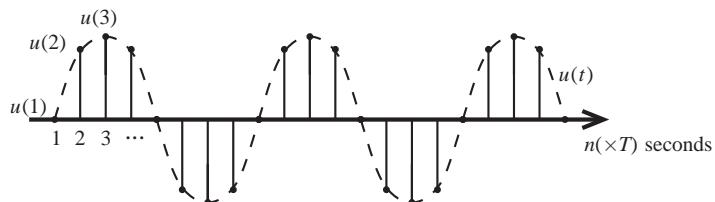

$$\delta(n) = \begin{cases} 1, & n = 0, \\ 0, & \text{else,} \end{cases} \quad (3.1)$$

where  $n$  is an integer number. The discrete time unit impulse is graphically shown in Figure 3.2. Any arbitrary discrete time sequence can be represented as a sum of weighted and delayed unit impulses. Also analogous to the continuous-time systems, the input–output behavior of a discrete-time system can also be described by the impulse response, as we will see in details in a later section.

Another commonly used test signal is a sequence, where the samples are equidistantly taken from a sinusoid

$$u(n) = U \sin(nT\omega + \varphi), \quad (3.2)$$

with  $U$  and  $\varphi$  being real constants.  $\omega$  is the frequency of the sinusoid in rad/s. In some cases it is important to analyze a system for certain frequencies and in this case a sinusoid input with the frequencies of interest can be applied at the input. An example of a discrete-time sinusoid and the corresponding continuous-time waveform are depicted in Figure 3.3

**FIGURE 3.3**

Discrete-time sinusoid and corresponding continuous-time.

We can also define a random sequence, an example being the case where the samples are distributed according to a normal distribution with zero mean and given variance  $\sigma^2$  and the individual samples are statistically independent, i.e.,

$$E [u(n)u(n - k)] = \begin{cases} \sigma^2, & k = 0, \\ 0, & \text{else.} \end{cases} \quad (3.3)$$

This is the discrete equivalent of the white Gaussian noise and it is useful if the behavior of the discrete time system is to be analyzed for all frequencies at once. Also in the case where some noise sources are to be included during the analysis or modeling of a discrete-time system implementation, this random sequence is the most used one. See [Chapter 4](#) for more details on random sequences.

### 1.03.3 Discrete-time systems

A discrete-time system with discrete-time input sequence  $u(n)$  and output sequence  $y(n)$  is an operator  $\mathcal{T}$  that performs the mapping

$$y(n) = \mathcal{T}\{u(n)\}. \quad (3.4)$$

It is important to note that this mapping is applied to the entire input sequence  $u(n)$ , beginning with some starting instant in the far distant past, including the present instant  $n$  and up to a far future instant, to obtain the present output  $y(n)$ .

#### 1.03.3.1 Classification

There are many different classes of discrete-time systems. They can be categorized according to various important properties that will allow us to analyze and design systems using specific mathematical tools. All the properties explained here find an equivalent for continuous-time systems.

##### 1.03.3.1.1 Memoryless systems

One sample of the output sequence  $y(n)$  of a memoryless system for a specific index  $n_0$  depends exclusively on the input value  $u(n_0)$ . The output depends neither on any past or future value of the input  $\dots, u(n_0 + 1), u(n_0 - 1), u(n_0 - 2), \dots$  nor on any past or future value of the output  $\dots, y(n_0 + 1),$

$y(n_0 - 1), y(n_0 - 2), \dots$ , i.e.,

$$y(n_0) = \mathcal{T}\{u(n_0)\}. \quad (3.5)$$

### 1.03.3.1.2 Dynamic systems

In contrast, a memory or dynamic system has its output dependent on at least one past value, either the output or the input

$$y(n) = \mathcal{T}\{u(n), u(n-1), \dots, u(n-N), y(n-1), \dots, y(n-N)\}. \quad (3.6)$$

The positive integer constant  $N$  is usually called the degree of the system. We have assumed here, without loss of generality, that the same number of past inputs and outputs influence a certain output sample.

### 1.03.3.1.3 Linear systems

If the system is a linear system, the superposition principle should hold. Let us consider an input  $u_1$  for the system. Then the output is

$$y_1(n) = \mathcal{T}\{u_1(n)\}. \quad (3.7)$$

Similarly, with another input  $u_2$ , the output is

$$y_2(n) = \mathcal{T}\{u_2(n)\}. \quad (3.8)$$

The superposition principle tells us that if each input is scaled by any constant  $\alpha$ , and moreover, the sum of the inputs is employed as a new input, then for the new output, it holds that

$$\begin{aligned} \mathcal{T}\{\alpha_1 u_1(n) + \alpha_2 u_2(n)\} &= \mathcal{T}\{\alpha_1 u_1(n)\} + \mathcal{T}\{\alpha_2 u_2(n)\} \\ &= \alpha_1 \mathcal{T}\{u_1(n)\} + \alpha_2 \mathcal{T}\{u_2(n)\} = \alpha_1 y_1(n) + \alpha_2 y_2(n). \end{aligned} \quad (3.9)$$

This can be extended for any number of different inputs and any value of the scaling factors. One of the simplest and probably most popular linear dynamic system is the recurrence used to generate Fibonacci sequences [1]:

$$y(n) = u(n) + y(n-1) + y(n-2), \quad (3.10)$$

where  $u(n) = \delta(n)$ .

### 1.03.3.1.4 Non-linear systems

In the case of non-linear systems, the superposition principle does not apply. An example of this is the famous logistic map [2] or discrete logistic equation, that arise in many contexts in the biological, economical and social sciences.

$$y(n) = u(n) + \alpha y(n-1)(1 - y(n-1)), \quad (3.11)$$

where  $\alpha$  is a positive real number,  $u(n) = \gamma \delta(n)$  and  $\gamma$  represents a initial ratio of population to a maximum population. The logistic map is a discrete-time demographic model analogous to the continuous-time logistic equation [3] and is a simple example of how chaotic behavior can arise. In this chapter we are mainly interested in linear systems, since there exist many well established analysis tools.

### 1.03.3.1.5 Time-invariant systems

If the samples of the input sequence are delayed by  $n_1$  and the output samples are delayed by the same interval, a discrete-time system is called time-invariant.

$$y(n - n_1) = T\{u(n - n_1)\}. \quad (3.12)$$

Both the Fibonacci recurrence and the logistic map are Time-invariant systems.

### 1.03.3.1.6 Time-variant systems

In the case of time-variant systems, internal parameters of the system, like multiplier coefficients, can also vary with time. This is the case for the so-called adaptive systems or adaptive filters (see [Chapter 11](#) for more details). A simple example of a time-variant system is the amplitude modulation

$$y(n) = \sin(nT\omega + \varphi)u(n). \quad (3.13)$$

There exists a special case of time-variant systems where the internal multiplier coefficients do not necessarily vary with time, but the sampling rate is changed within the system. Those systems are called multi-rate systems and they frequently present a cyclical output. This means that for a certain multiple delay of the input signal, the output sequence will have the same samples as for the non-delayed input.

### 1.03.3.1.7 Causal systems

In a causal system, the output samples only depend on the actual or past samples of the input sequence, and on past samples of the output itself. If the system is non-causal, it means that the output sample depends on an input value that has not yet entered the system. The definition of dynamic systems in [\(1.03.3.1\)](#) is already considered a causal case. Non-causal systems are not relevant for almost all practical applications.

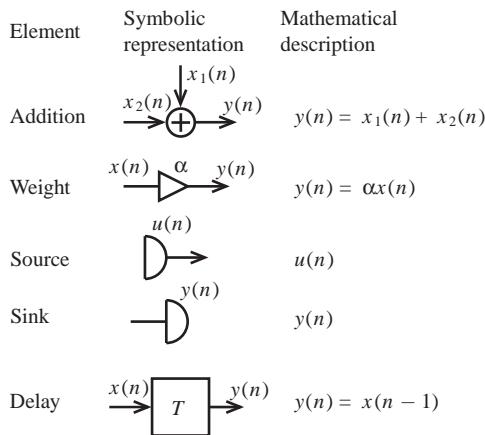

## 1.03.4 Linear Time-Invariant (LTI) Systems

This is a technically important class of discrete-time systems, for which a rich mathematical framework exists.

Linear time-invariant continuous-time systems in the electrical/electronic domain can be built with memoryless (resistive) elements such as resistors, independent and controlled sources and memory possessing (reactive) elements, for example, capacitors or inductors. In linear time-invariant discrete-time systems, we also have memoryless and memory-possessing elements such as

- adders and multipliers, signal source and sink,
- delay elements.

The symbolic representations of these aforementioned elements are depicted in [Figure 3.4](#). It is important to note that in this context, nothing is said about how these elements are realized—neither with which electronic components nor with which technology.

**FIGURE 3.4**

Basic building blocks of a discrete time system.

#### 1.03.4.1 State-space description

Any linear time-invariant system can be structured into a memoryless linear  $(2N + 2)$  terminal network with  $N$  delay elements and a single input and a single output. Although the system can easily extend to multiple inputs and/or multiple outputs, we will consider only single input/single output (SISO) systems, with which we can study all important phenomena.

Because everything within the linear time-invariant memoryless box in Figure 3.5 can only perform weighted sums, the  $(N + 1)$  dimensional input vector (state vector  $\mathbf{x}(n)$  stacked with scalar input  $u(n)$ ) is mapped onto the  $(N + 1)$  dimensional output vector (state vector  $\mathbf{x}(n + 1)$  stacked with scalar output  $y(n)$ ) through multiplication with the  $(N + 1) \times (N + 1)$  matrix  $\mathcal{S}$

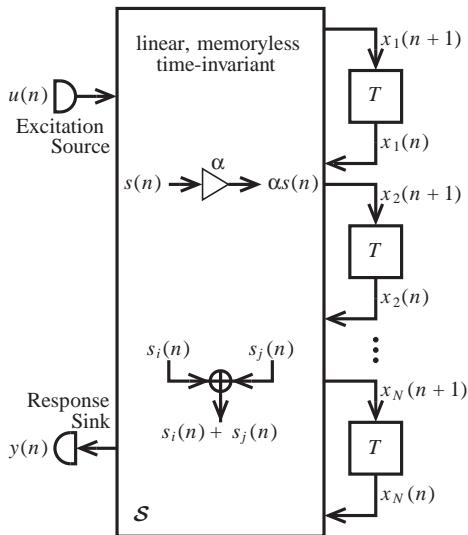

$$\begin{bmatrix} x_1(n+1) \\ x_2(n+1) \\ \vdots \\ x_N(n+1) \\ y(n) \end{bmatrix} = \begin{bmatrix} \mathbf{A} & \mathbf{b} \\ \mathbf{c}^T & d \end{bmatrix} \begin{bmatrix} x_1(n) \\ x_2(n) \\ \vdots \\ x_N(n) \\ u(n) \end{bmatrix} = \mathcal{S} \cdot \begin{bmatrix} \mathbf{x}(n) \\ u(n) \end{bmatrix}. \quad (3.14)$$

The matrix  $\mathcal{S}$  can obviously be partitioned into the well-known state space description

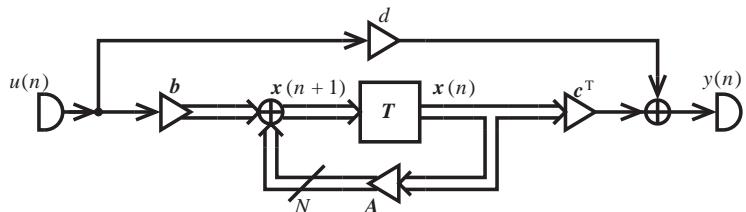

$$\begin{aligned} \mathbf{x}(n+1) &= \mathbf{A}\mathbf{x}(n) + \mathbf{b}u(n), \\ y(n) &= \mathbf{c}^T\mathbf{x}(n) + du(n), \end{aligned} \quad (3.15)$$

where  $\mathbf{A} \in \mathbb{R}^{N \times N}$ ,  $\mathbf{b} \in \mathbb{R}^N$ ,  $\mathbf{c}^T \in \mathbb{R}^{1 \times N}$ ,  $d \in \mathbb{R}$ ,  $\mathbf{x}(n), \mathbf{x}(n+1) \in \mathbb{R}^N$  and  $u(n), y(n) \in \mathbb{R}$ .

Now we can take (3.15) and refine the block diagram depicted in Figure 3.5 to show Figure 3.6, which is the general state-space realization. The structure in Figure 3.6 is still rather general, because for each element of  $\mathbf{A}$ ,  $\mathbf{b}$ ,  $\mathbf{c}$  and  $d$ , a multiplication has to be performed, especially if we assume all of their elements with non-trivial values. The total number of multiplications is in this case,  $N(N + 2) + 1$ .

**FIGURE 3.5**

Discrete-time system.

**FIGURE 3.6**

General state space realization a discrete system.

But, as we will see later, that  $\mathbf{A}$ ,  $\mathbf{b}$  and  $\mathbf{c}$  are not uniquely determined by a given input–output mapping. Consequently there is room for optimization, e.g., to reduce the number of actual multiplications to be performed per sample.

Let us compute the output signal  $y(n)$ , using an initial state vector  $\mathbf{x}(0)$ , and the input signal sequence from the time instant  $n = 0$  onwards

$$\begin{aligned}
 \mathbf{x}(n) &= \mathbf{A}\mathbf{x}(n-1) + \mathbf{b}u(n-1) \\
 &= \mathbf{A}(\mathbf{A}\mathbf{x}(n-2) + \mathbf{b}u(n-2)) + \mathbf{b}u(n-1) \\
 &= \dots \\
 &= \mathbf{A}^n\mathbf{x}(0) + \sum_{k=1}^n \mathbf{A}^{k-1}\mathbf{b}u(n-k),
 \end{aligned} \tag{3.16}$$

$$y(n) = \underbrace{\mathbf{c}^T \mathbf{A}^n \mathbf{x}(0)}_{\text{zero-input response}} + \underbrace{\sum_{k=1}^n (\mathbf{c}^T \mathbf{A}^{k-1} \mathbf{b} u(n-k))}_{\text{zero-state response}} + d u(n). \quad (3.17)$$

From this general response we can also derive the so-called impulse response, for which we set  $\mathbf{x}(0) = \mathbf{0}$  and  $u(n) = \delta(n)$ , the unit impulse which was defined in (3.1). This leads to

$$y(n) = h(n) = \begin{cases} d & n = 0, \\ \mathbf{c}^T \mathbf{A}^{n-1} \mathbf{b} & n \geq 1. \end{cases} \quad (3.18)$$

By making use of the impulse response  $h(n)$ , we can reformulate the zero-state response with a general input sequence  $u(n)$

$$\begin{aligned} y(n) &= \sum_{k=1}^n (\mathbf{c}^T \mathbf{A}^{k-1} \mathbf{b} u(n-k)) + d u(n) \\ &= \sum_{k=0}^n h(n) u(n-k) = h(n) * u(n), \end{aligned} \quad (3.19)$$

which is the so-called convolution sum. This summation formulation is corresponding to the so-called convolution integral for continuous-time signals and systems.

Now it is time to show that we can generate a whole class of equivalent systems (equivalent in the sense that they have the same zero-state response and the same input-output mapping respectively) with the aid of a so-called similarity transform.

With a non-singular  $N \times N$  matrix  $\mathbf{T}$  we can define a new state vector as the linear transformation of the original one as  $\mathbf{x}'(n) = \mathbf{T}^{-1} \mathbf{x}(n)$ , then we can rewrite the state-space equations with the new state vector  $\mathbf{x}'(n)$  as

$$\begin{aligned} \mathbf{T} \mathbf{x}'(n+1) &= \mathbf{A} \mathbf{T} \mathbf{x}'(n) + \mathbf{b} u(n), \\ y(n) &= \mathbf{c}^T \mathbf{T} \mathbf{x}'(n) + d u(n), \end{aligned} \quad (3.20)$$

and by multiplying the first equation with  $\mathbf{T}^{-1}$  from the left side we get

$$\begin{aligned} \mathbf{x}'(n+1) &= \mathbf{T}^{-1} \mathbf{A} \mathbf{T} \mathbf{x}'(n) + \mathbf{T}^{-1} \mathbf{b} u(n), \\ y(n) &= \mathbf{c}^T \mathbf{T} \mathbf{x}'(n) + d u(n). \end{aligned} \quad (3.21)$$

The new state-space representation can now be formulated as

$$\begin{aligned} \mathbf{x}'(n+1) &= \mathbf{A}' \mathbf{x}'(n) + \mathbf{b}' u(n), \\ y(n) &= \mathbf{c}'^T \mathbf{x}'(n) + d' u(n), \end{aligned} \quad (3.22)$$

where the equations

$$\mathbf{A}' = \mathbf{T}^{-1} \mathbf{A} \mathbf{T}, \quad \mathbf{b}' = \mathbf{T}^{-1} \mathbf{b}, \quad \mathbf{c}'^T = \mathbf{c}^T \mathbf{T} \text{ and } d' = d \quad (3.23)$$

hold.

By inserting  $\mathbf{A}'$ ,  $\mathbf{b}'$ ,  $\mathbf{c}'$  and  $d'$  into the zero-state response, we see that this response is invariant to the above transformation.

Depending on the choice of the transformation matrix, the matrix  $\mathbf{A}'$  can have different forms. A particularly interesting form is the so-called normal form, where the state matrix is diagonalized, allowing a much lower complexity than a dense matrix. First we apply an eigenvalue decomposition [4] to  $\mathbf{A}$ :

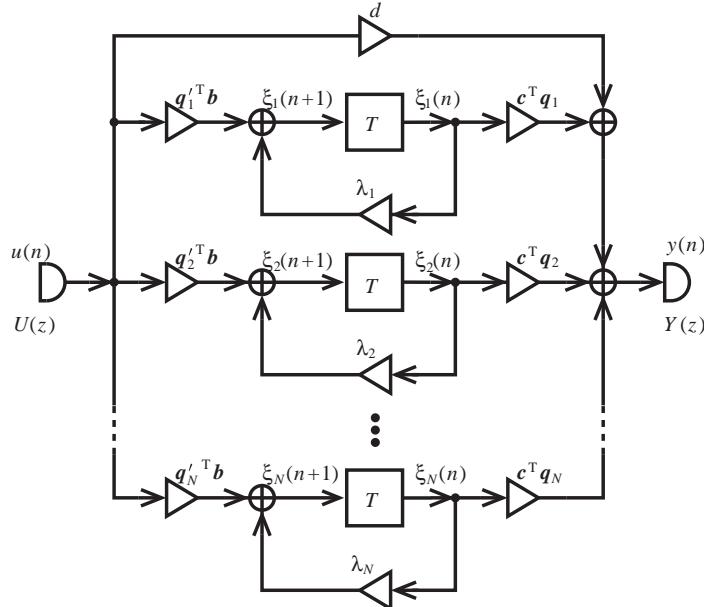

$$\begin{aligned}\mathbf{A} &= \mathbf{Q} \Lambda \mathbf{Q}^{-1} && \text{Eigenvalue decomposition of } \mathbf{A}, \\ \mathbf{Q} &= [\mathbf{q}_1, \mathbf{q}_2, \dots, \mathbf{q}_n] && \text{Modal matrix with the eigenvectors } \mathbf{q}_k, \\ \Lambda &= \text{diag}(\lambda_k)_{k=1}^n && \text{Eigenvalue } \lambda_k \text{ with } \mathbf{A}\mathbf{q}_k = \lambda_k\mathbf{q}_k,\end{aligned}$$

where we have assumed that  $\mathbf{A}$  is diagonalizable and we do not need to resort to the Jordan form. The transformation matrix and the new state vector are  $\mathbf{T} = \mathbf{Q}$  and  $\xi(n) = \mathbf{Q}^{-1}\mathbf{x}(n)$ . The system can then be described by

$$\begin{aligned}\dot{\xi}(n+1) &= \Lambda \xi(n) + \mathbf{Q}^{-1} \mathbf{b} u(n), \\ y(n) &= \mathbf{c}^T \mathbf{Q} \xi(n) + d u(n),\end{aligned}\tag{3.24}$$

which leads to the new specific implementation of Figure 3.7. With this new implementation, the number of coefficients, and consequently the number of multiplications, is reduced to  $3N + 1$ .

If some of the eigenvalues are complex valued (if this is the case they will always come in complex conjugate pairs provided  $\mathbf{A}$  is real valued), we always will merge the two corresponding first order

**FIGURE 3.7**

Normal form for real valued eigenvalues.

systems to one second order system with real valued multiplier coefficients only. This is equivalent to have a block diagonal state matrix (with 2-by-2 blocks) instead of a diagonal one.

Now we can compute the transfer function by transforming (3.15) to the frequency domain with the  $\mathcal{Z}$ -transform.

#### 1.03.4.2 Transfer function of a discrete-time LTI system

Similar to continuous-time systems we can also analyze a discrete-time system with the help of a functional transform to make a transition to the frequency domain. However, we have only sequences of signal values in the time domain and not continuous waveforms. Therefore, we have to apply the  $\mathcal{Z}$ -transform [5]:

$$\begin{aligned}\mathcal{Z}\{u(n)\} &= \sum_{n=-\infty}^{\infty} u(n)z^{-n} = U(z), \\ \mathcal{Z}\{y(n)\} &= \sum_{n=-\infty}^{\infty} y(n)z^{-n} = Y(z), \\ \mathcal{Z}\{\mathbf{x}(n)\} &= \sum_{n=-\infty}^{\infty} \mathbf{x}(n)z^{-n} = \mathbf{X}(z).\end{aligned}\quad (3.25)$$

The delay in the time-domain is represented in the frequency domain by a multiplication by  $z^{-1}$ .

$$\begin{aligned}\mathcal{Z}\{\mathbf{x}(n+1)\} &= \sum_{n=-\infty}^{\infty} \mathbf{x}(n+1)z^{-n} = z \sum_{n=-\infty}^{\infty} \mathbf{x}(n+1)z^{-(n+1)} \\ &\stackrel{n'=n+1}{=} z \sum_{n'=-\infty}^{\infty} \mathbf{x}[n']z^{-n'} = z\mathcal{Z}\{\mathbf{x}(n)\} = z\mathbf{X}(z).\end{aligned}\quad (3.26)$$

Now we can transform the state-space equations to the frequency domain

$$\begin{aligned}z\mathbf{X}(z) &= \mathbf{A}\mathbf{X}(z) + \mathbf{b}U(z), \\ Y(z) &= \mathbf{c}^T\mathbf{X}(z) + dU(z),\end{aligned}\quad (3.27)$$

and after we eliminate the state vector  $\mathbf{X}(z)$ , we obtain the transfer function

$$H(z) = \frac{Y(z)}{U(z)} = \mathbf{c}^T(z\mathbf{1} - \mathbf{A})^{-1}\mathbf{b} + d.\quad (3.28)$$

Since

$$z = e^{j\omega T} \quad \text{and hence for technical frequencies } z|_{p=j\omega} = e^{j\omega T} \quad (3.29)$$

holds,  $H(e^{j\omega T})$  is obviously a periodical function of  $\omega$  resp.  $f$  with frequency-period  $2\pi/T$  resp.  $1/T$ .

The question that arises here is: What type of function is (3.28)? To answer that we have to consider the expression  $(z\mathbf{1} - \mathbf{A})^{-1}$  more closely. We assume of course that  $(z\mathbf{1} - \mathbf{A})^{-1}$  is nonsingular and

therefore the inverse exists (this means that the inversion will only be performed for the values of  $z$  at which it is possible). The inverse reads

$$(z\mathbf{1} - \mathbf{A})^{-1} = \frac{\text{adj}(z\mathbf{1} - \mathbf{A})}{\det(z\mathbf{1} - \mathbf{A})}, \quad (3.30)$$

where the determinant is a polynomial in  $z$  of degree  $N$ , also called the characteristic polynomial

$$\det(z\mathbf{1} - \mathbf{A}) = z^N + \alpha_1 z^{N-1} + \cdots + \alpha_{N-1} z + \alpha_N, \quad \alpha_k \in \mathcal{R} \quad (3.31)$$

and the elements of the adjugate matrix are the transposed cofactors of the matrix. The cofactors on the other hand are sub-determinants of  $(z\mathbf{1} - \mathbf{A})$  and therefore polynomials of at most degree  $(N - 1)$ .

The numerator of  $\mathbf{c}^T(z\mathbf{1} - \mathbf{A})^{-1}\mathbf{b}$  is hence a linear combination of cofactors, i.e., a linear combination of polynomials of degree  $(N - 1)$  and therefore a polynomial of at most degree  $(N - 1)$ . If we apply this result in Eq. (3.28), we will obtain a rational fractional function of  $z$

$$H(z) = \frac{\beta_0 z^N + \beta_1 z^{N-1} + \cdots + \beta_{N-1} z + \beta_N}{z^N + \alpha_1 z^{N-1} + \cdots + \alpha_{N-1} z + \alpha_N}, \quad (3.32)$$

where  $\beta_0 \neq 0$  only for  $d \neq 0$ , since  $\beta_0 = d$ .

We usually divide the nominator and the denominator by  $z^n$  and obtain in the numerator and in the denominator polynomials in  $z^{-1}$ :

$$H(z) = \frac{\beta_N z^{-N} + \beta_{N-1} z^{-(N-1)} + \cdots + \beta_1 z^{-1} + \beta_0}{\alpha_N z^{-N} + \alpha_{N-1} z^{-(N-1)} + \cdots + \alpha_1 z^{-1} + 1} = \frac{\sum_{k=0}^N \beta_k z^{-k}}{1 + \sum_{k=1}^N \alpha_k z^{-k}} = \frac{Y(z)}{U(z)}. \quad (3.33)$$

By multiplying both sides of (3.33) with the denominator we get

$$Y(z) \left( 1 + \sum_{k=1}^N \alpha_k z^{-k} \right) = U(z) \sum_{k=0}^N \beta_k z^{-k}. \quad (3.34)$$

Now we go back to the time domain with help of the inverse  $\mathcal{Z}$ -transform and obtain a global difference equation

$$\begin{aligned} y(n) + \sum_{k=1}^N \alpha_k y(n-k) &= \sum_{k=0}^N \beta_k u(n-k), \\ y(n) &= \sum_{k=0}^N \beta_k u(n-k) - \sum_{k=1}^N \alpha_k y(n-k). \end{aligned} \quad (3.35)$$

The difference equation is equivalent to the description of a discrete-time system like a differential equation is for the description of a continuous-time system.

The representation of Eq. (3.35) leads us to an important special case, for which we have no equivalent in continuous-time systems built with lumped elements: the so-called finite impulse (FIR) response systems.

### 1.03.4.3 Finite duration impulse response systems

Those are systems with, as the name says, a finite duration impulse response (FIR), i.e., the  $\alpha_i$ 's in (3.35) are equal to zero such that

$$y(n) = \sum_{k=0}^N \beta_k u(n-k) \quad (3.36)$$

and with a unit impulse as excitation  $u(n) = \delta(n)$  we get

$$y(n) = h(k) = \sum_{k=0}^N \beta_k \delta(n-k) = \begin{cases} 0, & n < 0, \\ \beta_n, & 0 \leq n \leq N, \\ 0, & n > N. \end{cases} \quad (3.37)$$

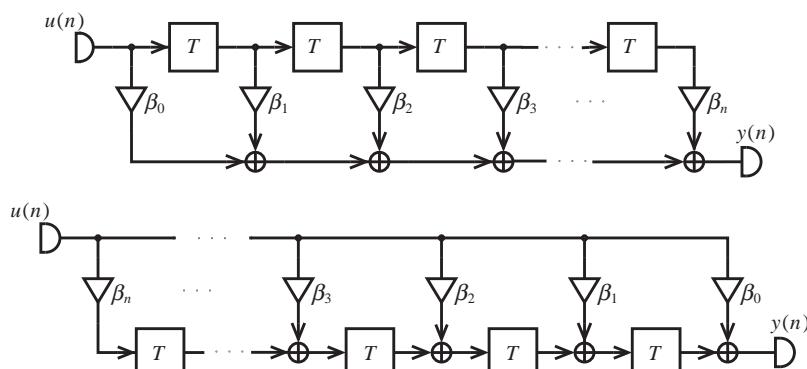

We can see that the coefficients of the polynomial transfer function directly give then values of the impulse response and so that it takes us directly to an implementation, see Figure 3.8. Note that the two structures are inter-convertible if the principle of flow reversal is applied to the block diagram.

Let us now write down the state space description for the uppermost structure in Figure 3.8. By calling the input of the delay elements  $x_k(n+1)$  and their outputs  $x_k(n)$  indexing them from the left most to the rightmost we can see that

$$\begin{aligned} x_1(k+1) &= u(n), \\ x_2(k+1) &= x_1(n), \\ &\vdots = \vdots \\ x_N(k+1) &= x_{N-1}(n), \end{aligned} \quad (3.38)$$

and for the output

$$y(n) = \beta_1 x_1(n) + \beta_2 x_2(n) + \cdots + \beta_N x_N(n) + \beta_0 u(n) \quad (3.39)$$

**FIGURE 3.8**

Two FIR realizations inter-convertible through the principle of flow reversal.

holds. In matrix vector notation we get

$$\begin{bmatrix} x_1(n+1) \\ x_2(n+1) \\ \vdots \\ x_N(n+1) \end{bmatrix} = \begin{bmatrix} 0 & 0 & \cdots & 0 \\ 1 & 0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & 1 & 0 \end{bmatrix} \begin{bmatrix} x_1(n) \\ x_2(n) \\ \vdots \\ x_N(n) \end{bmatrix} + \begin{bmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{bmatrix} u(n), \quad (3.40)$$

$$y(n) = [\beta_1 \beta_2 \cdots \beta_N] \mathbf{x}(n) + \beta_0 u(n). \quad (3.41)$$

It can be easily demonstrated that the second structure in Figure 3.8 is obtained by a transposition of the state-space description of the first structure, the matrix and vectors for it are then given by

$$\mathbf{A}' = \mathbf{A}^T, \quad \mathbf{b}' = \mathbf{c}, \quad \mathbf{c}'^T = \mathbf{b}^T, \quad d' = d. \quad (3.42)$$

Other usual names for FIR systems are:

- Non-recursive systems,
- Moving Average (MA),
- Transversal filter.

#### 1.03.4.4 Infinite duration impulse response systems

On the other hand if the  $\alpha_i$ 's are different from zero, then the impulse response will have infinite duration, as the name says. We can again clearly derive a realization structure from the corresponding time-domain description, in this case from Eq. (3.35), see Figure 3.9. This per se inefficient realization (two times the number of necessary delay elements) can be transformed into the well known direct form through simple rearranging the two blocks like in Figure 3.10. This is called a canonical realization because it possesses a minimum number of delay elements.

Now we can setup the state-space equations for the IIR system structure of Figure 3.10. As already mentioned we label the output of the delays the states  $x_k(n)$  and their inputs  $x_k(n+1)$ . By numbering from the topmost to the lowest delay we can see that

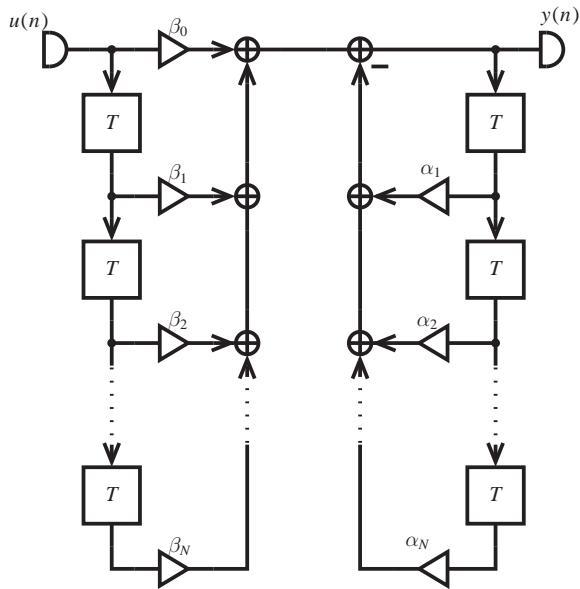

$$x_1(n+1) = -\alpha_1 x_1(n) - \alpha_2 x_2(n) - \dots - \alpha_N x_N(n) + u(n) \quad (3.43)$$

holds and from the second until the  $N$ th-state we get

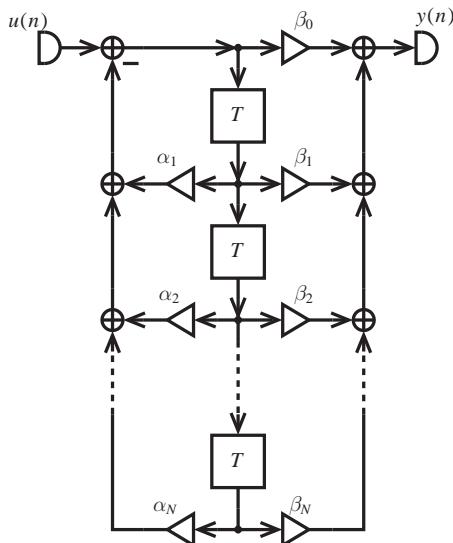

$$\begin{aligned} x_2(n+1) &= x_1(n), \\ x_3(n+1) &= x_2(n), \\ &\vdots = \vdots \\ x_N(n+1) &= x_{N-1}(n). \end{aligned} \quad (3.44)$$

For the output we can see that

$$\begin{aligned} y(n) &= \beta_0 x_1(n+1) + \beta_1 x_1(n) + \beta_2 x_2(n) + \dots + \beta_N x_N(n) \\ &= (\beta_1 - \beta_0 \alpha_1) x_1(n) + (\beta_2 - \beta_0 \alpha_2) x_2(n) + \dots + (\beta_N - \beta_0 \alpha_N) x_N(n) + \beta_0 u(n), \end{aligned} \quad (3.45)$$

**FIGURE 3.9**

IIR realization according to Eq. (3.35).

**FIGURE 3.10**

Canonical direct realization of an IIR system.

where we have used the definition of  $x_1(n+1)$  of (3.43). In matrix vector notation we get

$$\begin{bmatrix} x_1(n+1) \\ x_2(n+1) \\ \vdots \\ x_N(n+1) \end{bmatrix} = \begin{bmatrix} -\alpha_1 & -\alpha_2 & \cdots & -\alpha_N \\ 1 & 0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & 1 & 0 \end{bmatrix} \begin{bmatrix} x_1(n) \\ x_2(n) \\ \vdots \\ x_N(n) \end{bmatrix} + \begin{bmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{bmatrix} u(n), \quad (3.46)$$

$$y(n) = [\beta_1 - \beta_0\alpha_1, \beta_2 - \beta_0\alpha_2, \dots, \beta_N - \beta_0\alpha_N] \mathbf{x}(n) + \beta_0 u(n), \quad (3.47)$$

where because of its particular structure,  $\mathbf{A}$  is called a companion matrix.

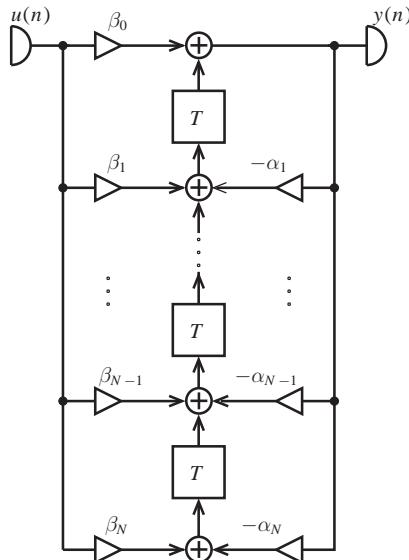

If we apply the principle of flow reversal to the diagram of Figure 3.10 we will end up with the realization shown in Figure 3.11. This is again equivalent to transform the state-space description into the transposed system, i.e., the transformed system is represented by

$$\mathbf{A}' = \mathbf{A}^T, \quad \mathbf{b}' = \mathbf{c}, \quad \mathbf{c}'^T = \mathbf{b}^T, \quad d' = d. \quad (3.48)$$

If we apply these definitions to (3.28) we can see that

$$\begin{aligned} H'(z) &= \mathbf{c}'^T (z\mathbf{1} - \mathbf{A}')^{-1} \mathbf{b}' + d' = \mathbf{b}^T (z\mathbf{1} - \mathbf{A}^T)^{-1} \mathbf{c} + d = (H'(z))^T \\ &= \mathbf{c}^T ((z\mathbf{1} - \mathbf{A}^T)^{-1})^T (\mathbf{b}^T)^T + d = \mathbf{c}^T (z\mathbf{1} - \mathbf{A})^{-1} \mathbf{b} + d = H(z). \end{aligned} \quad (3.49)$$

This means that the transposed realization has the same transfer function as the original system.

**FIGURE 3.11**

Transposed realization of the system from Figure 3.10.

Other usual names for IIR systems are:

- Recursive systems,
- Autoregressive Moving Average (ARMA),
- Systems with feedback.

#### 1.03.4.5 Observability and controllability

As we have seen in the previous section every LTI system can be completely characterized by a state-space description

$$\mathbf{x}(n+1) = \mathbf{A}\mathbf{x}(n) + \mathbf{b}u(n), \quad (3.50)$$

$$y(n) = \mathbf{c}^T\mathbf{x}(n) + du(n), \quad (3.51)$$

from which we can uniquely derive the corresponding transfer function

$$H(z) = \mathbf{c}^T (z\mathbf{1} - \mathbf{A})^{-1} \mathbf{b} + d. \quad (3.52)$$

It is important to note that although the way from a given state-space description to the input–output transfer function is unique, the same is not true for the other direction. For one given transfer function there are infinitely many different state-space realizations, which all may have a number of different properties, with the very same input–output relation. One of those properties is the stability of the so-called LTI system.

An often applied stability criterion is to check whether the zeroes of the denominator polynomial of the transfer function  $H(z)$  lie within the unit circle of the  $z$ -plane or equivalently the impulse response

$$h(n) = \mathcal{Z}^{-1}\{H(z)\} \quad (3.53)$$

decays over time. In the following we will see that this is not telling us the complete truth about the stability of LTI systems. Because stability depends on the actual implementation, which in detail is reflected in the state-space description and not only in transfer function or impulse response. To get a clear view, we have to introduce the concept of observability and controllability, and based on these concepts define different types of stability.

Let us start with the definition of observability.

Starting with the state-space description (3.50) we assume that the excitation  $u(n) = 0$  for  $n \geq 0$  and an initial state  $\mathbf{x}(0) \neq \mathbf{0}$ . Let us now compute the system output in time domain:

$$\begin{aligned} y(0) &= \mathbf{c}^T \mathbf{x}(0), \\ y(1) &= \mathbf{c}^T \mathbf{x}(1) = \mathbf{c}^T (\mathbf{A}\mathbf{x}(0)), \\ &\vdots \\ y(N-1) &= \mathbf{c}^T \mathbf{A}^{N-1} \mathbf{x}(0). \end{aligned} \quad (3.54)$$

Let us stack these subsequent  $N$  output values in one vector

$$\mathbf{y}(0) = \begin{bmatrix} y(0) \\ y(1) \\ y(2) \\ \vdots \\ y(N-1) \end{bmatrix} = \begin{bmatrix} \mathbf{c}^T \\ \mathbf{c}^T \mathbf{A} \\ \mathbf{c}^T \mathbf{A}^2 \\ \vdots \\ \mathbf{c}^T \mathbf{A}^{N-1} \end{bmatrix} \mathbf{x}(0) = \mathcal{O}(\mathbf{c}^T, \mathbf{A}) \mathbf{x}(0). \quad (3.55)$$

From (3.55) we see that this output vector  $\mathbf{y}(0)$  is given by the product of the so called observability matrix  $\mathcal{O}(\mathbf{c}^T, \mathbf{A})$ , which is completely determined by  $\mathbf{A}$  and  $\mathbf{c}^T$  and the system state at the time instant  $n = 0 : \mathbf{x}(0)$ . Now if the observability matrix is invertible, we can compute the state vector

$$\mathbf{x}(0) = \mathcal{O}(\mathbf{c}^T, \mathbf{A})^{-1} \mathbf{y}(0). \quad (3.56)$$

If this is possible, the system (3.50) is completely observable.

Next we define controllability in a corresponding way by assuming an initial zero state  $\mathbf{x}(0) = \mathbf{0}$  and let us look for a sequence  $u(n)$ ,  $n \geq 0$  to drive the system into some desired state  $\mathbf{x}(k)$ . We look at the evolution of the state as controlled by the excitation

$$\begin{aligned} \mathbf{x}(1) &= \mathbf{b}u(0), \\ \mathbf{x}(2) &= \mathbf{Ax}(1) + \mathbf{bu}(1) = \mathbf{Ab}u(0) + \mathbf{bu}(1), \\ \mathbf{x}(3) &= \mathbf{Ax}(2) + \mathbf{bu}(2) = \mathbf{A}^2\mathbf{b}u(0) + \mathbf{Ab}u(1) + \mathbf{bu}(2), \\ &\vdots \\ \mathbf{x}(N) &= \mathbf{A}^{N-1}\mathbf{b}u(0) + \mathbf{A}^{N-2}\mathbf{b}u(1) + \dots + \mathbf{A}^2\mathbf{b}u(N-3) + \mathbf{Ab}u(N-2) + \mathbf{bu}(N-1). \end{aligned} \quad (3.57)$$

This can be put together as

$$\mathbf{x}(N) = [\mathbf{b}, \mathbf{Ab}, \mathbf{A}^2\mathbf{b}, \dots, \mathbf{A}^{N-1}\mathbf{b}] \begin{bmatrix} u(N-1) \\ u(N-2) \\ u(N-3) \\ \vdots \\ u(0) \end{bmatrix} = \mathcal{C}(\mathbf{b}, \mathbf{A})\mathbf{u}(N), \quad (3.58)$$

where  $\mathcal{C}(\mathbf{b}, \mathbf{A})$  is the so called controllability matrix and  $\mathbf{u}(N)$  is the vector, in which the subsequent excitation samples have been stacked. If the controllability matrix is invertible, we can solve for the excitation

$$\mathbf{u}(N) = \mathcal{C}(\mathbf{b}, \mathbf{A})^{-1} \mathbf{x}(N), \quad (3.59)$$

which will steer the system from the zero initial state into a specified desired state  $\mathbf{x}(N)$ . If this is possible, the system (3.50) is completely controllable.

### 1.03.4.6 Stability

Based on the concepts of observability and controllability we can now define different concepts of stability:

- Internal stability,
- Output-stability,
- Input-stability,
- Input–output stability.

We will start with **internal stability** by requiring that the Euclidean norm of the state vector hat to decay over time from any initial value with zero excitation:

$$\forall \mathbf{x}(0) \in \mathcal{R}^N \text{ and } u(n) = 0, \text{ for } n \geq 0 : \lim_{n \rightarrow \infty} \|\mathbf{x}(n)\|_2 = 0. \quad (3.60)$$

This is equivalent to require the state vector converge to the zero vector.

By looking at the evolution of the state vector over time

$$\begin{aligned} \mathbf{x}(1) &= \mathbf{A}\mathbf{x}(0), \\ \mathbf{x}(2) &= \mathbf{A}\mathbf{x}(1) = \mathbf{A}^2\mathbf{x}(0), \\ &\vdots \\ \mathbf{x}(n) &= \mathbf{A}^n\mathbf{x}(0), \end{aligned} \quad (3.61)$$

and making use of the eigenvalue decomposition (EVD) of  $\mathbf{A} = \mathbf{Q}\Lambda\mathbf{Q}^{-1}$ ,  $\Lambda = \text{diag}\{\lambda_i\}_{i=1}^N$  we get

$$\mathbf{Q}^{-1}\mathbf{x}(n) = \Lambda^n \mathbf{Q}^{-1}\mathbf{x}(0). \quad (3.62)$$

From (3.62) we can conclude that the vector  $\mathbf{Q}^{-1}\mathbf{x}(n)$  will converge to the zero vector, i.e.,  $\lim_{n \rightarrow \infty} \|\mathbf{Q}^{-1}\mathbf{x}(n)\|_2 = 0$  if and only if all eigenvalues  $\lambda_i$  of  $\mathbf{A}$  are smaller than one in magnitude

$$|\lambda_i| < 1 \iff \lim_{n \rightarrow \infty} \|\mathbf{Q}^{-1}\mathbf{x}(n)\|_2 = 0 \iff \lim_{n \rightarrow \infty} \|\mathbf{x}(n)\|_2 = 0. \quad (3.63)$$

This equivalent to say that the poles of the transfer function are localized inside the unity circle, since the eigenvalues of  $\mathbf{A}$  equal to the poles of the transfer function. In the above derivation we have assumed that  $\mathbf{A}$  is a diagonalizable matrix. If this is not the case because of multiple eigenvalues, we have to refrain to the so called Jordan form. Although this is slightly more complicated, it leads to the same result.

A somewhat weaker stability criterion is to check only if the system output decays to zero from any initial state and zero excitation:

$$\forall \mathbf{x}(0) \in \mathcal{R}^N \text{ and } u(n) = 0 \text{ for } n \geq 0 : \lim_{n \rightarrow \infty} |y(n)|^2 = 0. \quad (3.64)$$

Computing the output we get

$$\begin{aligned} y(n) &= \mathbf{c}^T \mathbf{x}(n) = \mathbf{c}^T \mathbf{A}^n \mathbf{x}(0) = \mathbf{c}^T \mathbf{Q} \Lambda^n \mathbf{Q}^{-1} \mathbf{x}(0) = \eta^T \Lambda^n (\mathbf{Q}^{-1} \mathbf{x}(0)) \\ &= [\eta_1 \ \eta_2 \cdots \eta_N] \begin{bmatrix} \lambda_1^n & 0 & \cdots & 0 \\ 0 & \lambda_2^n & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \lambda_N^n \end{bmatrix} (\mathbf{Q}^{-1} \mathbf{x}(0)) = \sum_{i=1}^N \eta_i \lambda_i^n (\mathbf{Q}^{-1} \mathbf{x}(0))_i. \end{aligned} \quad (3.65)$$

$\eta^T = \mathbf{c}^T \mathbf{Q}$  is the transformed output vector. If an entry  $\eta_i$  is equal to zero, then the eigenmode (normal mode)  $\lambda_i$  will not contribute to the system output and, therefore, a non-decaying eigenmode  $|\lambda_i| \geq 1$  will not violate the **output-stability** criterion. This can only happen if the observability matrix is not full rank. From (3.55) we have

$$\begin{aligned} \mathbf{y}(0) &= \mathcal{O}(\mathbf{c}^T, \mathbf{A})\mathbf{x}(0) = \mathcal{O}(\mathbf{c}^T, \mathbf{A})\mathbf{Q}(\mathbf{Q}^{-1}\mathbf{x}(0)) = \mathcal{O}(\eta^T, \Lambda)(\mathbf{Q}^{-1}\mathbf{x}(0)) \\ &= \begin{bmatrix} \eta_1 & \eta_2 & \dots & \eta_N \\ \eta_1\lambda_1 & \eta_2\lambda_2 & \dots & \eta_N\lambda_N \\ \eta_1\lambda_1^2 & \eta_2\lambda_2^2 & \dots & \eta_N\lambda_N^2 \\ \vdots & \vdots & \ddots & \vdots \\ \eta_1\lambda_1^{N-1} & \eta_2\lambda_2^{N-1} & \dots & \eta_N\lambda_N^{N-1} \end{bmatrix} (\mathbf{Q}^{-1}\mathbf{x}(0)) \end{aligned} \quad (3.66)$$

and that  $\mathcal{O}(\eta^T, \Lambda)$  is rank deficient if at least one  $\eta_i$  is zero, and since  $\mathbf{Q}$  is full rank  $\mathcal{O}(\mathbf{c}^T, \mathbf{A})$  must also be rank deficient. Therefore, a system can be output stable without being internally stable, if it is not completely observable.

A complementary criterion is that of **input-stability**, requiring the state vector converging to the zero vector, but not from any arbitrary initial state, but only from states which can be controlled from the system input. Now we start with an initial state  $\mathbf{x}(N)$ , which can be generated from an input sequence (see (3.58))

$$\mathbf{x}(N) = \mathcal{C}(\mathbf{b}, \mathbf{A})\mathbf{u}(N). \quad (3.67)$$

The transformed state  $\mathbf{Q}^{-1}\mathbf{x}(N)$  then reads

$$\mathbf{Q}^{-1}\mathbf{x}(N) = \mathbf{Q}^{-1}\mathcal{C}(\mathbf{b}, \mathbf{A})\mathbf{u}(N) = \mathcal{C}(\mu, \Lambda)\mathbf{u}(N) \quad (3.68)$$

with the transformed input vector  $\mu = \mathbf{Q}^{-1}\mathbf{b}$ . After the input  $\mathbf{u}(N)$  has produced the state  $\mathbf{x}(N)$  it is switched off, i. e.  $u(n) = 0$  for  $n \geq N$ .

We ask whether the state vector can converge to the zero vector although the system may not be internally stable. The answer is given by the structure of

$$\mathcal{C}(\mu, \Lambda) = \begin{bmatrix} \mu_1 & \mu_2 & \dots & \mu_N \\ \mu_1\lambda_1 & \mu_2\lambda_2 & \dots & \mu_N\lambda_N \\ \vdots & \vdots & \ddots & \vdots \\ \mu_1\lambda_1^{N-1} & \mu_2\lambda_2^{N-1} & \dots & \mu_N\lambda_N^{N-1} \end{bmatrix} = \mathbf{Q}^{-1}\mathcal{C}(\mathbf{b}, \mathbf{A}). \quad (3.69)$$

If some  $\mu_i = 0$ , then  $\mathbf{Q}^{-1}\mathbf{x}(0)$  will converge to the zero vector, even if the corresponding  $|\lambda_i| \geq 1$ , because this non-decaying eigenmode cannot be excited from the regular input. But this is only possible, if  $\mathcal{C}(\mathbf{b}, \mathbf{A})$  is not full rank and the system is, therefore, not completely controllable.

Finally we look at the concept of the commonly used **input-output-stability**, i.e., we excite the system with zero initial state with a unit pulse and require the output to converge to zero over time. In this setting the state and the output evolves as

$$\mathbf{x}(n) = \mathbf{A}^n \mathbf{b}, \quad (3.70)$$

$$y(n) = \mathbf{c}^T \mathbf{A}^n \mathbf{b} = \mathbf{c}^T \mathbf{Q} \Lambda^n \mathbf{Q}^{-1} \mathbf{b} = \eta^T \Lambda^n \mu = \sum_{i=1}^N \eta_i \mu_i \lambda_i^n. \quad (3.71)$$

The output will converge to zero, even if there are non-decaying eigenmodes  $\lambda_i$ , as long as for every such  $\lambda_i$  there is a  $\eta_i = 0$  or a  $\mu_i = 0$ , or both are zero. We see that a system could be input–output stable, although it is neither internally stable nor input- or output-stable.

Only for systems, which are completely observable and controllable, the four different stability criteria coincide.

**Example 3.1.** The four stability concepts will now be illustrated with an example: the Cascade Integrator Comb (CIC) filter [6]. These filters are attractive in situations where either a narrow-band signal should be extracted from a wideband source or a wideband signal should be constructed from a narrowband source. The first situation is associated with the concept of sampling rate decrease or decimation and the second one leads to the concept of sampling rate increase or interpolation. CIC filters are very efficient from a hardware point of view, because they need no multipliers. In the first case, i.e., decimation, the integrators come first, then the sampling rate will be decreased by a factor of  $R$  followed by a subsequent cascade of comb filters (Figure 3.12a), while in the second case, i.e., interpolation, the comb filters come first, then the sampling rate increase is followed by a subsequent cascade of integrators (Figure 3.12b).

The stability problem in these CIC filters stems from the integrators, which obviously exhibit a non-decaying eigenmode (pole with unit magnitude). To analyze the stability of such CIC filters we set the sampling rate decrease/increase factor  $R = 1$  and the number of integrators and comb filters stages to  $L = 1$  without loss of generality. In addition we assume a differential delay of  $M = 3$  samples per stage. This leads us to the following two implementations to be analyzed which are shown in Figures 3.13a and b.

Let us start with an analysis of the filter in Figure 3.13a, the state space description of which reads

$$\mathbf{A}_1 = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}, \mathbf{b}_1 = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}, \mathbf{c}_1 = \begin{bmatrix} 1 \\ 0 \\ -1 \end{bmatrix}, d_1 = 1 \quad (3.72)$$

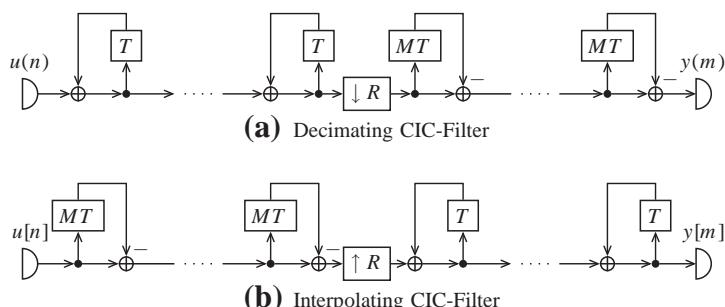

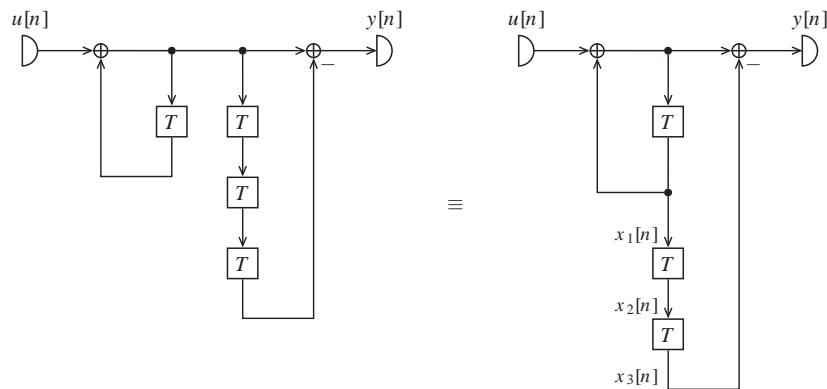

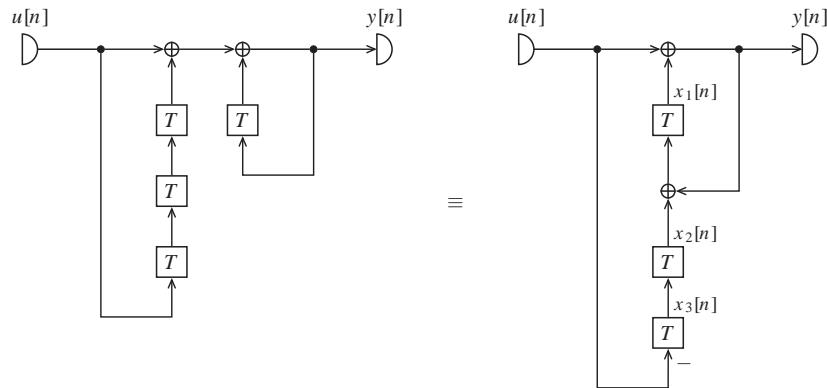

FIGURE 3.12

Multiplierless decimator and integrator.

(a) Cascade of Integrator and Comb Filter

(b) Cascade of Comb and Integrator Filter

**FIGURE 3.13**

CIC Filters without sampling rate alteration with  $R = 1$ ,  $L = 1$  and  $M = 3$ .

and leads to the transfer function

$$H_1(z^{-1}) = \frac{1 - z^{-3}}{1 - z^{-1}} = 1 + z^{-1} + z^{-2}. \quad (3.73)$$

The observability matrix

$$\mathcal{O}(\mathbf{c}_1^T, \mathbf{A}_1) = \begin{bmatrix} 1 & 0 & -1 \\ 1 & -1 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad \det(\mathcal{O}(\mathbf{c}_1^T, \mathbf{A}_1)) = 0 \quad (3.74)$$

is obviously rank deficient and the system is therefore not completely observable.

Since the state matrix  $\mathbf{A}$  is not diagonalizable, we have to refrain to a Jordan form

$$\mathbf{A}_1 = \mathbf{Q}_1 \mathbf{J} \mathbf{Q}_1^{-1} = \begin{bmatrix} 0 & 0 & \frac{1}{\sqrt{3}} \\ 0 & 1 & \frac{1}{\sqrt{3}} \\ 1 & 0 & \frac{1}{\sqrt{3}} \end{bmatrix} \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} -1 & 0 & 1 \\ -1 & 1 & 0 \\ \sqrt{3} & 0 & 0 \end{bmatrix}, \quad (3.75)$$

which shows the three eigenvalues are  $\lambda_1 = 0$ ,  $\lambda_2 = 0$  and  $\lambda_3 = 1$ . Not all eigenvalues are less than one in magnitude. Therefore, the system of Figure 3.13a is not internally stable. But transforming the observability matrix according to (3.66), we get

$$\mathcal{O}(\boldsymbol{\eta}^T, \mathbf{J}) = \mathcal{O}(\mathbf{c}_1^T, \mathbf{A}_1) \mathbf{Q}_1 = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} 0 & 0 & \frac{1}{\sqrt{3}} \\ 0 & 1 & \frac{1}{\sqrt{3}} \\ 1 & 0 & \frac{1}{\sqrt{3}} \end{bmatrix} = \begin{bmatrix} -1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad (3.76)$$

with the third component  $\eta_3$  of the transformed output vector  $\boldsymbol{\eta}^T = \mathbf{c}_1^T \mathbf{Q}_1$  equal to zero. This clearly means that the non-vanishing third eigenmode is not observable at the system output. Therefore the system is output stable, i.e., the output converges in the limit  $\lim_{n \rightarrow \infty} \mathbf{y}(n) = 0$ , although the state vector does not converge to the zero vector. But the controllability matrix

$$\mathcal{C}(\mathbf{b}_1, \mathbf{A}_1) = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 0 & 0 & 1 \end{bmatrix}, \quad \det(\mathcal{C}(\mathbf{b}_1, \mathbf{A}_1)) = 1 \quad (3.77)$$

is full rank, i.e., the system is completely controllable, and an arbitrary input sequence may excite the non-decaying eigenmode. Therefore, the system is not input-stable.

Now let us analyze the filter in Figure 3.13b, which has the following state-space description

$$\mathbf{A}_2 = \begin{bmatrix} 1 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}, \quad \mathbf{b}_2 = \begin{bmatrix} 1 \\ 0 \\ -1 \end{bmatrix}, \quad \mathbf{c}_2 = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}, \quad d_2 = 1 \quad (3.78)$$

and the same transfer function as the previous filter from Figure 3.13a. It is interesting to note that the second filter can be obtained from the first one by applying transposition

$$\mathbf{A}_2 = \mathbf{A}_1^T, \quad \mathbf{b}_2 = \mathbf{c}_1, \quad \mathbf{c}_2 = \mathbf{b}_1, \quad d_2 = d_1. \quad (3.79)$$

The controllability matrix of the second system

$$\mathcal{C}(\mathbf{b}_2, \mathbf{A}_2) = \begin{bmatrix} 1 & 1 & 0 \\ 0 & -1 & 0 \\ -1 & 0 & 0 \end{bmatrix}, \quad \det(\mathcal{C}(\mathbf{b}_2, \mathbf{A}_2)) = 0 \quad (3.80)$$

is obviously rank deficient and the system is therefore not completely controllable.

Since the state matrix  $\mathbf{A}_2 = \mathbf{A}^T$  is not diagonalizable we have again to refrain to a Jordan form

$$\mathbf{A}_2 = \mathbf{Q}_2 \mathbf{J} \mathbf{Q}_2^{-1} = \begin{bmatrix} \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} & 1 \\ -\frac{1}{\sqrt{2}} & 0 & 0 \\ 0 & -\frac{1}{\sqrt{2}} & 0 \end{bmatrix} \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 0 & -\sqrt{2} & 0 \\ 0 & 0 & -\sqrt{2} \\ 1 & 1 & 1 \end{bmatrix}, \quad (3.81)$$

which again shows obviously the same eigenvalues  $\lambda_1 = 0$ ,  $\lambda_2 = 0$  and  $\lambda_3 = 1$ . The second system is again not internally stable. Transforming the above controllability matrix according to (3.68) we get

$$\mathcal{C}(\boldsymbol{\mu}, \mathbf{J}) = \mathbf{Q}_2^{-1} \mathcal{C}(\mathbf{b}_2, \mathbf{A}_2) = \begin{bmatrix} 0 & -\sqrt{2} & 0 \\ 0 & 0 & -\sqrt{2} \\ 1 & 1 & 1 \end{bmatrix} \begin{bmatrix} 1 & 1 & 0 \\ 0 & -1 & 0 \\ -1 & 0 & 0 \end{bmatrix} = \begin{bmatrix} 0 & \sqrt{2} & 0 \\ \sqrt{2} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad (3.82)$$

with the third component  $\mu_3$  of the transformed input vector  $\boldsymbol{\mu} = \mathbf{Q}_2^{-1} \mathbf{b}_2$  being equal to zero. This shows that the non-decaying third eigenmode will not be excited by any possible input signal. Therefore, the system is input-stable, although it is not internally stable.

The observability matrix of the second system

$$\mathcal{O}(\mathbf{c}_2^T, \mathbf{A}_2) = \begin{bmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \\ 1 & 1 & 1 \end{bmatrix}, \quad \det(\mathcal{O}(\mathbf{b}_2, \mathbf{A}_2)) = 1 \quad (3.83)$$

is full rank and the second system is completely observable. Therefore the non-decaying eigenmode, although not excited by any input sequence, is observable at the output. This can always happen because of an unfavorable initial state accidentally occurring in the switch-on transient of the power supply or because of some disturbance entering the system not through the regular input path. Therefore, the system is not output-stable.

But both systems are input–output-stable, because both have the same impulse response with finite duration.

This example shows, that the standard input–output stability criterion, i.e., requiring a decaying impulse response, is not always telling the whole story. Judging whether a system is stable or not needs a detailed knowledge about the system structure, or in other words the realization, and not only about input–output-mapping.

## 1.03.5 Discrete-time signals and systems with MATLAB

In this section we will provide some examples how to generate discrete-time signals in MATLAB and how to represent and implement basic discrete-time systems. We assume here a basic MATLAB installation. The commands and programs shown here are not unique in the way they perform the analysis and implement discrete-time signals and systems. Our objective here is to give an introduction with very simple commands and functions. With this introduction the reader will get more familiar with this powerful tool that is widely employed to analyze, simulate and implement digital signal processing systems. If one has access to the full palette of MATLAB toolboxes, like e.g., Signal Processing Toolbox, Control System Toolbox, Communications System Toolbox and DSP System Toolbox, many of the scripts included here can be substituted by functions encountered in those libraries.

### 1.03.5.1 Discrete-time signals

Discrete-time signals are defined in MATLAB as one dimensional arrays, i.e., as vectors. They can be row or column vectors and their entries can be either real or complex valued. The signals we will generate and analyze in this section are always row vectors and their entries are always real valued. The length of the vectors will be defined according to the time span in which the system is supposed to be analyzed.

#### 1.03.5.1.1 Unit impulse

The unit impulse  $\delta(n)$  can be generated with the commands

```
L = 100;
delta = [1 zeros(1,L-1)];
```

where  $L$  is the length of the desired input and the function `zeros(1,L-1)` generates a row vector with  $L-1$  zeros.

The unit impulse can be further weighted and delayed. For example,  $2*\delta(n - 5)$  can be generated by

```
L = 100;
N = 5;
delta = [zeros(1,N) 2 zeros (1,L-1-N)];
```

where we have assumed a delay of 5 samples or sampling periods.

The length of the vector containing only a unit impulse depends on the objective of the analysis. For example, if the impulse response of a discrete-time system is to be studied, there should be enough elements in the input array so that a significant part of the impulse response is contained in the output vector.

#### 1.03.5.1.2 Sinusoid

A sinusoid can be generated with the help of the function `sin`. Below is an example of a sinusoid where all its parameters are first defined

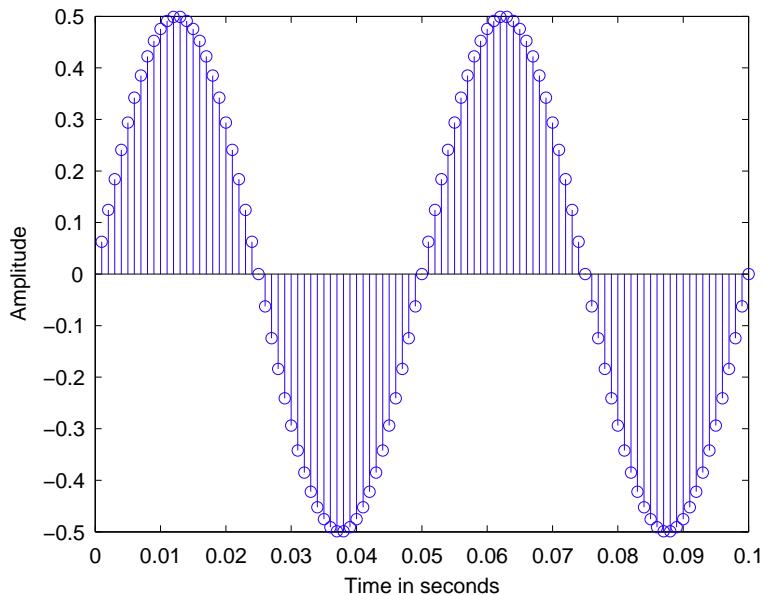

```
fs = 1000; % Sampling frequency in Hz
T = 1/fs; % Sampling period
n = 1:100; % Time indexes
U = 0.5; % Amplitude of the sinusoid
fc = 20; % Sinusoid frequency in Herz
omega = 2*pi*fc; % Sinusoid angular frequency in rad/s
phi = 0; % phase in radians
x = U* sin(omega*n*T+phi);
```

We can see that the comments after each command explain what the parameter means.

If we would like to graphically represent the sinusoid, we could use

```
stem(n*T,x);
xlabel('Time in seconds');
ylabel('Amplitude');
```

and we get the plot in Figure 3.14, where we can see two periods of the sinusoid. An alternative to `stem` is the command `plot`. If we employ it using the same parameters and the same syntax we obtain

**FIGURE 3.14**

Discrete sinusoid with  $f_c = 20$  Hz and  $f_s = 1$  kHz plotted in MATLAB.

Figure 3.15, where it should be noted that MATLAB graphically connects the amplitude samples with a straight line and as a consequence the discrete-time sinusoid looks like a continuous-time one. It is important to keep in mind that the true discrete-time sinusoid is only defined for certain time instants and the amplitude between two true samples in the Figure 3.15 is only an approximation of the amplitude of the equivalent continuous-time sinusoid.

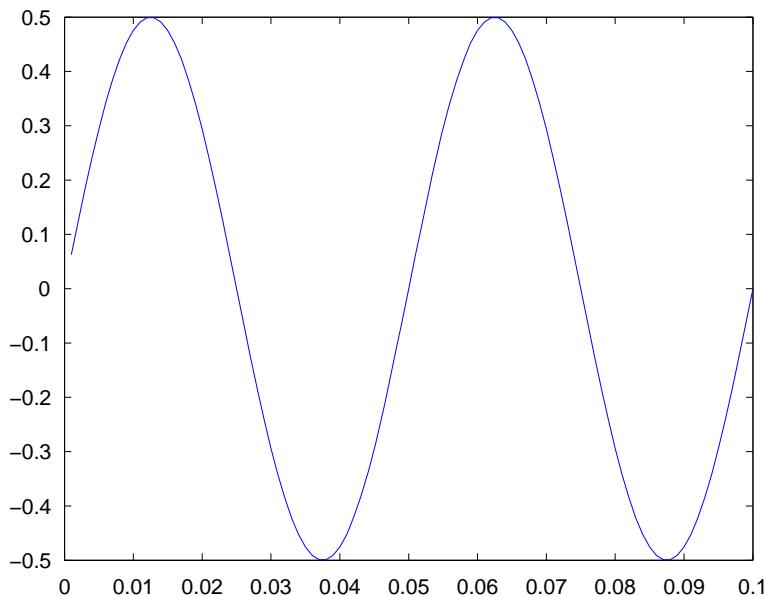

As an exercise the reader could play around with the parameters of the sinusoid. For example, he or she could change the phase  $\phi$  to  $\pi/2$  and plot the sinusoid again, then try to use the function `cos` instead of `sin` and set  $\phi$  to 0 again and compare with the previous plots. Change the sinusoid frequency until you reach the Nyquist frequency, which is 500 Hz for the example above. Compare the use of the command `plot` for different sampling rates and different sinusoid frequencies to see how the approximation of the continuous-time sinusoid gets worse.

### 1.03.5.1.3 White gaussian noise

To generate a WGN signal we have to employ the function `randn` that generates pseudo-random numbers following the normal or Gaussian distribution with zero mean and unit variance. By using

```
L = 100;
sigma2 = 0.5; % Variance of the WGN
u = sqrt(sigma2)*randn(1,L);
```

we generate a white Gaussian noise vector with zero mean and variance  $\sigma^2 = 0.5$ .

**FIGURE 3.15**

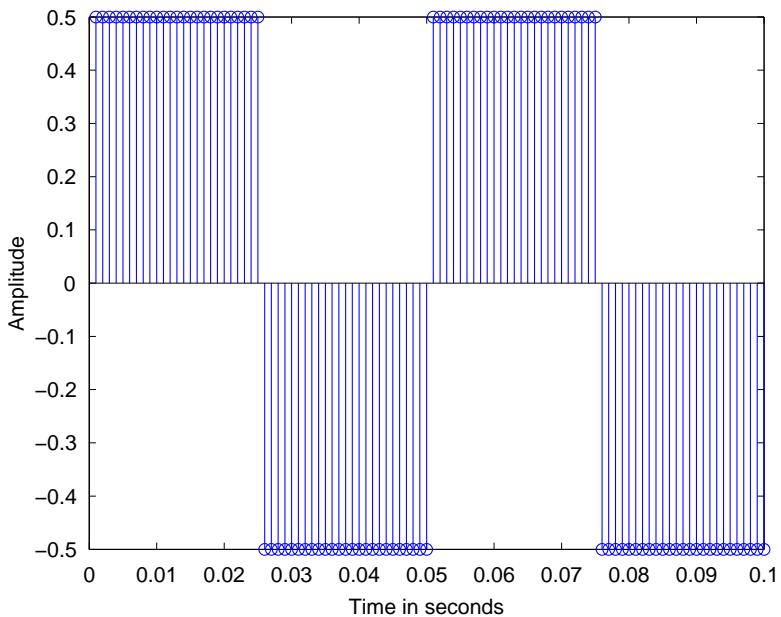

Discrete-time sinusoid represented in MATLAB with the command `plot`.

#### 1.03.5.1.4 Elaborated signal model

Many operations can be further performed with the generated signals, they can be, for example, added to each other or be multiplied by a constant or by another signal. As a last example let us generate a typical signal model used in communications systems. Let us consider an input signal composed by a sum of weighted and delayed unit impulses. This could be a data carrying signal generated at the transmitter. Then we multiply it by a sinusoid, that could represent a modulation to a higher frequency, for example the radio frequency (RF), to allow the propagation of the signal as an electromagnetic wave in a physical medium between transmitter and receiver. Finally, we add white Gaussian noise that represents the thermal noise generated by the analog components used in the transmitter and receiver.

The program to generate this signal is the following

```
L = 100;
u_in = [0.5*ones(1,L/4) -0.5*ones(1,L/4) 0.5*ones(1,L/4)
         -0.5*ones(1,L/4)]; % Sum of weighted and delayed unit impulses
fs = 1000; % Sampling frequency in Hz
T = 1/fs; % Sampling period
n = 1:L; % Time indexes
U = 1; % Amplitude of the sinusoid
fc = 50; % Sinusoid frequency in Herz
```

**FIGURE 3.16**

Weighted and delayed sum of unit impulses  $u_{in}$ .

```

omega = 2*pi*fc; % Sinusoid frequency in rad/s
phi = 0; % Phase in radians
u_sin = U*sin(omega*n*T+phi); % Sinusoid
sigma2 = 0.02; % Variance of the White Gaussian Noise
u_awgn = sqrt(sigma2)*randn(1,L); % White Gaussian Noise Vector
u_mod = u_in.*u_sin+u_awgn; % Modulation and noise addition

```

In Figure 3.16 we can see the signal that is composed by a sum of weighted and delayed unit impulses.

In Figure 3.17 the modulated sinusoid is depicted.

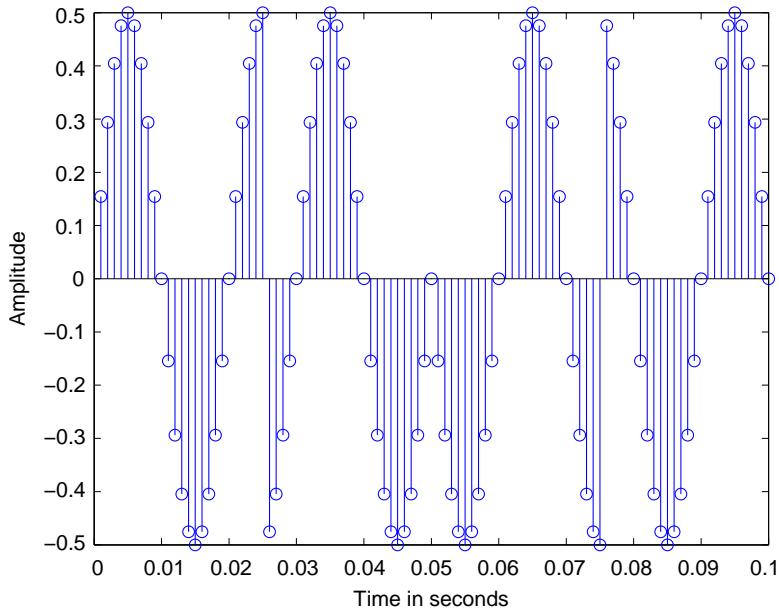

We can see in Figure 3.18 the modulated sinusoid with the additive white Gaussian noise.

### 1.03.5.2 Discrete-time systems representation and implementation

There are different ways to represent a discrete-time system in MATLAB, like, for example, the space-state or the transfer function. To start we revisit the elaborated signal model introduced in the last section. If we would like to, at least approximately, recover the input signal represented by the sum of delayed and weighted unit impulses, we should first demodulate it by multiplying it by a sinusoid with the same frequency of the one used to modulate

```
u_demod=u_mod.*u_sin
```

We will then obtain the sequence shown in Figure 3.19.

**FIGURE 3.17**

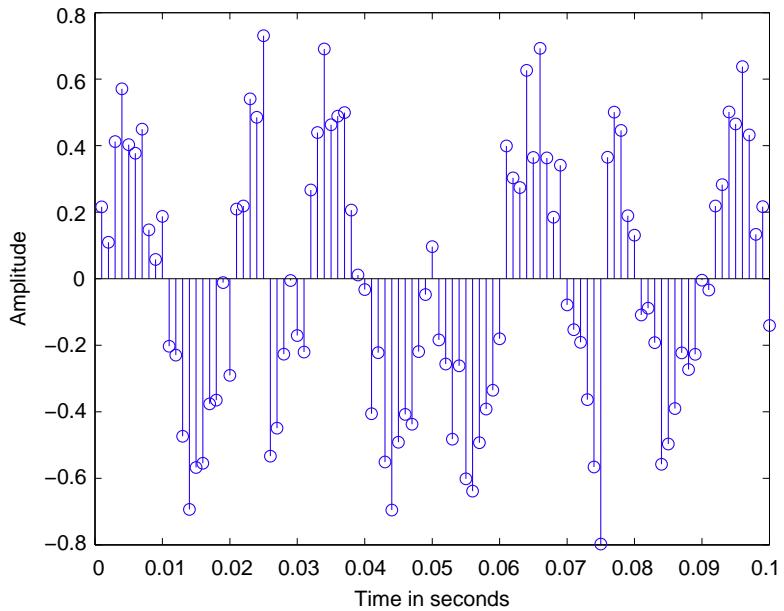

Modulated sinusoid  $u_{\text{in}} * u_{\text{sin}}$ .

The only problem with the new sequence is that not only an approximation of the desired signal is obtained, but also another modulated version of it, but this time with a sinusoid with the double of the original modulation frequency, and we still have the additive noise. If the noise variance is low enough we are still able to approximately recover the original signal without any further processing. But we have first to eliminate the modulated signal component and for this we will apply a discrete-time filter specific designed for this task. We assume here that the filter is given and we only care on how to represent and implement it. In [7] and the references therein many methods for the design of discrete-time filters can be encountered.

Let us say that a state-space description of the filter is already known and is defined as

```
A = [ 0.6969    0.8263   -0.6089   0.0111;
      1           0           0           0 ;
      0           1           0           0 ;
      0           0           1           0 ];
b = [1;
      0;
      0;
      0];
c = [-0.4272    1.0189   -0.1298   0.0160];
d = [0.9738];
```

where we can identify the companion matrix structure of  $\mathbf{A}$ .

**FIGURE 3.18**

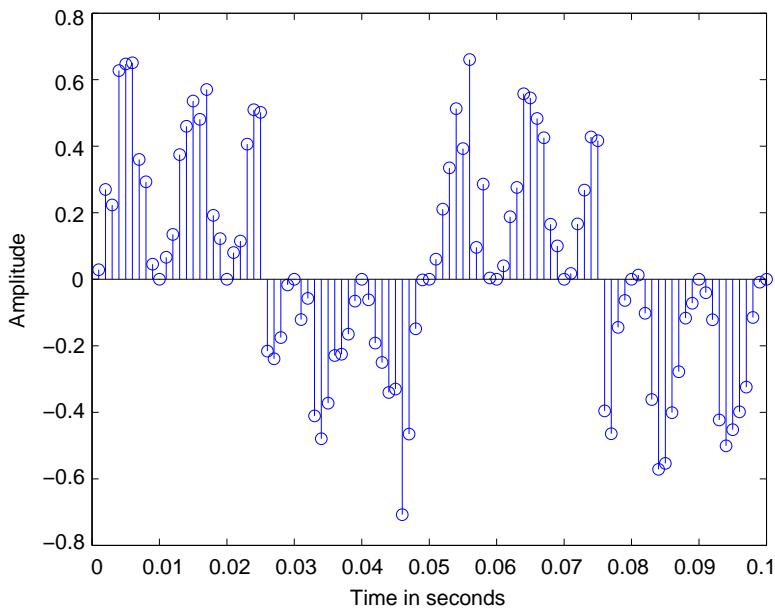

Modulated sinusoid with additive white Gaussian noise  $u_{\text{mod}}$ .

To compute the output of the filter given an initial state and the input signal, the state equations can be directly employed and iteratively calculated as

```
L = 100;
u= [1 zeros (1,L-1)]; % Input signal, here a unit impulse
x= [0; 0; 0; 0]; % Initial state vector
y = zeros(1,L); % Initialization of the output vector
for n = 1:L
    y(n)=c*x+d*u(n);
    x = A*x+b*u(n);
end
```

where we can see that the values of the state-vector are not stored for all time instants. If one is interested in looking at the internal states evolution, a matrix could be defined with so many rows as the number of states and so many columns as the length of the input/output signal, and the state vector for each time instant can be saved in its columns.

If we substitute the unit impulse by the demodulated signal as the input  $u = u_{\text{demod}}$  we obtain the signal depicted in Figure 3.20. One can see that we do not obtain exactly the input signal  $u_{\text{in}}$  but an approximation, particularly in communications systems that is usually the case, where it is important to recover the information contained in  $u_{\text{in}}$ , even if the waveform has been distorted, and not the waveform itself.

**FIGURE 3.19**

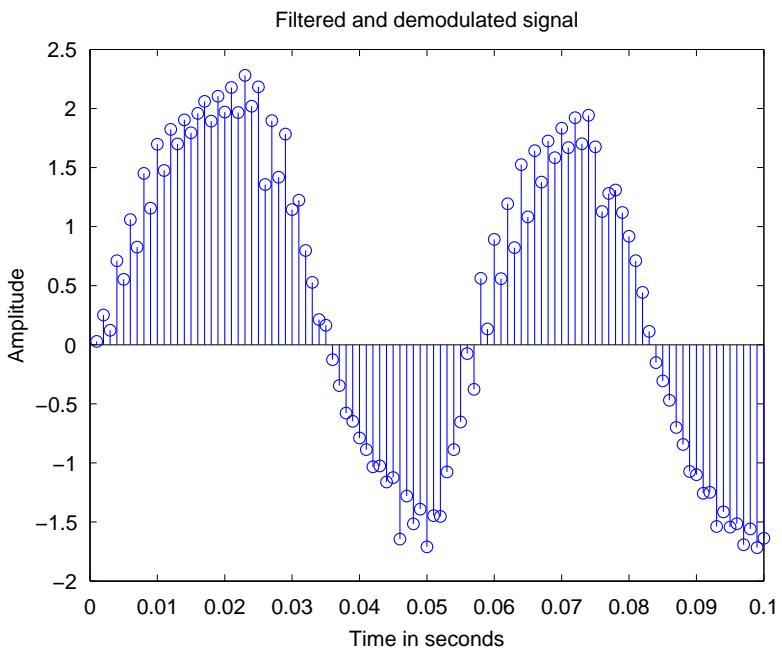

Demodulated signal  $u_{\text{demod}}$ .

But if one would like to implement Eq. (3.17) the program becomes more complicated as shown below

```

L=100;
u=[1 zeros(1,L-1)]; % Input signal, here a unit impulse
x_0z=[0; 0; 0; 0]; % Initial state vector
y=zeros(1,L); % Allocation of the output vector
cAb_array=zeros(1,L); % Allocation of the array c*A^(k-1)*b
A_power=eye(4); % Allocation of the powers of A matrix
cAb_array(1)=c*b; % First element of the array cAb_array
y(1)=d*u(1); % Output at sample n=0
for n=2:L
    cAb_array(n)=c*A_power*b; % Inclusion of a new element in cAb_array
    y(n)=c*(A*A_power)*x_0+sum(cAb_array(1:n).*u(n:-1:1))+d*u(n);
    % Output
    A_power=A*A_power; % New power of A
end

```

**FIGURE 3.20**

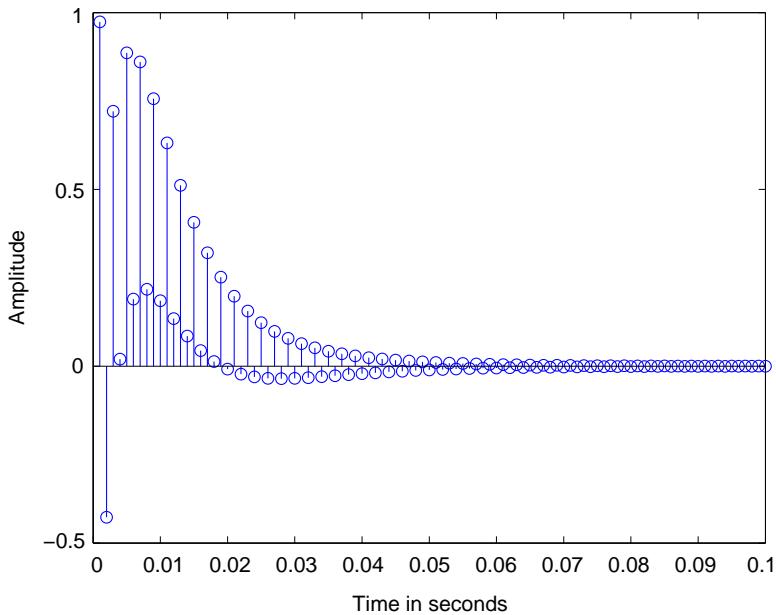

Demodulated and filtered signal  $u_{\text{demod}}$ .

In both programs presented above the impulse response can be obtained and its first 100 samples are plotted in Figure 3.21.

The similarity transformation can also be easily implemented. Let us consider the transformation into the normal form. The code to perform it is

```
[Q,Lambda]=eig(A); % Eigenvalue decomposition:  
% Lambda -> Eigenvalues in main diagonal  
% Q -> Eigenvectors in the columns  
T=Q;  
A_norm=inv(T)*A*T;  
b_norm=inv(T)*b;  
c_norm=c*T;  
d_norm=d;
```

The resulting state-space description for our example is

**FIGURE 3.21**

First 100 samples of the impulse response.

```

A_norm = [-0.9242      0      0      0
           0      0.8057      0      0
           0      0      0.7968      0
           0      0      0     0.0186];
b_norm = [ 0.6380;
           126.6454;
           127.3681;
           1.7322];
c_norm = [ -0.7502   0.2283   -0.2268   0.0140];
d_norm = 0.9738;

```

From the state-space representation it is possible to calculate the coefficients of the numerator and of the denominator polynomials of the transfer function with help of the Faddeev-Leverrier algorithm [8]

```

beta = [d zeros(1,3)];
alpha = [1 zeros(1,3)];
F = eye(4);
for i=1:4
    alpha(i+1) = -(1/i)*trace(A*F);

```

```

beta(i+1) = c*F*b+d*alpha(i+1);
F = A*F+alpha(i+1)*eye(4);
end

```

where the arrays beta and alpha contain the coefficients of the nominator and denominator polynomials.

With the coefficients of the transfer function it is also possible to calculate the output given the input of the system and some past values of the output by using the difference equation that can be implemented as

```

L=100;
u=[1 zeros(1,L-1)];
y=zeros(1,L);           % We assume a relaxed initial condition
y(1)=beta(1).*u(1);    % Transition phase or first initial output
y(2)=sum(beta(1:2).*u(2:-1:1))-alpha(2).*y(1);
y(3)=sum(beta(1:3).*u(3:-1:1))-sum(alpha(2:3).*y(2:-1:1));
y(4)=sum(beta(1:4).*u(4:-1:1))-sum(alpha(2:4).*y(3:-1:1));
for n=5:L
    y(n)=sum(beta.*u(n:-1:n-4))-sum(alpha(2:end).*y(n-1:-1:n-4));
end

```

As we saw before this equivalent to a state-space realization in direct form.

## 1.03.6 Conclusion

In this chapter we have introduced an important and fundamental topic in electrical engineering that provides the basics for digital signal processing. We have started with the presentation of some frequently used discrete-time signals. Then we have showed how to classify discrete-time systems and started the study of the widely employed class of linear time-invariant systems. We have showed the most basic way of representing LTI systems in a way that not only the input–output behavior is described, but also important internal signals, the so-called state-space representation. We have seen that the state-space representation is not unique and, consequently, there is room for optimization in the way discrete-time systems are realized. After that, the transfer function was derived from the state-space description and the two main classes of discrete-time systems, namely FIR and IIR were introduced. We formulated the concepts of controllability and observability, and showed how they can be used to evaluate the stability of the system. We finally gave some examples how to implement and analyze simple discrete-time signals and systems with MATLAB.

## 1.04.1 Introduction

Probability is an abstract concept useful to model chance experiments. The definition of a numerical representation for the outcomes of such experiments (the random variable) is essential to build a complete and general framework for probabilistic models. Such models can be extended to non-static outcomes in the form of time signals,<sup>1</sup> leading to the so-called stochastic process, which can evolve along continuous or discrete time. Its complete description is usually too complicated to be applied to practical situations. Fortunately, a well-accepted set of simplifying properties like stationarity and ergodicity allows the modeling of many problems in so different areas as Biology, Economics, and Communications.

There are plenty of books on random processes,<sup>2</sup> each one following some preferred order and notation, but covering essentially the same topics. This chapter is just one more attempt to present the subject in a compact manner. It is structured in the usual way: probability is first introduced, then described through random variables; within this framework, stochastic processes are presented, then associated with processing systems. Due to space limitations, proofs were avoided, and examples were kept at a minimum. No attempt was made to cover many families of probability distributions, for example. The preferred path was to define clear and unambiguously the concepts and entities associated to the subject and whenever possible give them simple and intuitive interpretations. Even risking to seem redundant, the author decided to explicitly duplicate the formulations related to random processes and sequences (i.e., continuous- and discrete-time random processes); the idea was to provide always a direct response to a consulting reader, instead of suggesting modifications in the given expressions.

Writing technical material always poses a difficult problem: which level of detail and depth will make the text useful? Our goal was making the text approachable for an undergraduate student as well as a consistent reference for more advanced students or even researchers (re)visiting random processes. The author tried to be especially careful with the notation consistency throughout the chapter in order to avoid confusion and ambiguity (which may easily occur in advanced texts). The choices of covered topics and order of presentation reflect several years of teaching the subject, and obviously match those of some preferred books. A selected list of didactic references on statistics [1,2], random variables

<sup>1</sup>Of course, other independent variables (e.g., space) can substitute for time in this context.

<sup>2</sup>Even if the literature sometimes prefers to employ “stochastic” for processes and “random” for signals, the expression “random processes” became common use and will be used throughout the chapter.

and processes [3,4], and applications [5,6] is given at the end of the chapter. We hope you enjoy the reading.

### 1.04.2 Probability

Probabilistic models are useful to describe and study phenomena that cannot be precisely predicted. To establish a precise framework for the concept of probability, one should define a chance **experiment**, of which each **trial** yields an **outcome**  $s$ . The set of all possible outcomes is the **sample space**  $S$ . In this context, one speaks of the **probability** that one trial of the experiment yields an outcome  $s$  that belongs to a desired set  $A \subset S$  (when one says the **event**  $A$  has occurred), as illustrated in Figure 4.1.

There are two different views of probability: the subjectivist and the objectivist. For subjectivists, the probability measures someone's degree of belief on the occurrence of a given event, while for objectivists it results from concrete reality. Polemics aside, objectivism can be more rewarding didactically.

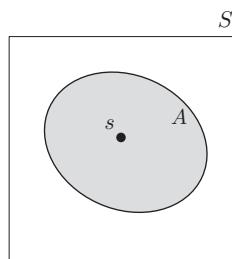

From the objectivist view point, one of the possible ways to define probability is the so-called **classical** or **a priori** approach: given an experiment whose possible outcomes  $s$  are equally likely, the probability of an event  $A$  is defined as the ratio between the number  $N(A)$  of acceptable outcomes (elements of  $A$ ) and the number  $N(S)$  of possible outcomes (elements of  $S$ ):

$$P(A) = \frac{N(A)}{N(S)}. \quad (4.1)$$

The experiment of flipping a fair coin, with  $S = \{\text{head}, \text{tail}\}$ , is an example in which the probabilities of both individual outcomes can be theoretically set:  $P(\{\text{head}\}) = P(\{\text{tail}\}) = 0.5$ .

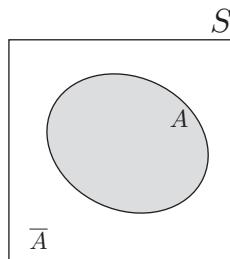

Another way to define probability is the **relative frequency** or **a posteriori** approach: the probability that the event  $A$  occurs after one trial of a given experiment can be obtained by taking the limit of the ratio between the number  $n_A$  of successes (i.e., occurrences of  $A$ ) and the number  $n$  of experiment trials, when the repeats go to infinity:

$$P(A) = \lim_{n \rightarrow \infty} \frac{n_A}{n}. \quad (4.2)$$

**FIGURE 4.1**

Sample space  $S$ , event  $A$ , and outcome  $s$ .

**FIGURE 4.2**

Event  $A$  and its complement  $\bar{A}$ .

In the ideal coin flip experiment, one is expected to find equal probabilities for head and tail. On the other hand, this pragmatic approach allows modeling the non-ideal case, provided the experiment can be repeated.

A pure **mathematical** definition can provide a sufficiently general framework to encompass every conceptual choice: the **axiomatic** approach develops a complete probability theory from three **axioms**:

1.  $P(A) \geq 0$ .
2.  $P(S) = 1$ .
3. Given  $A_m$ ,  $1 \leq m \leq M$ , such that  $A_m \cap A_{m'} = \emptyset \forall m' \neq m$ ,  $1 \leq m' \leq M$ , then  $P\left(\bigcup_{m=1}^M A_m\right) = \sum_{m=1}^M P(A_m)$ .

Referring to an experiment with sample space  $S$ :

- The events  $A_m$ ,  $1 \leq m \leq M$ , are said to be **mutually exclusive** when the occurrence of one prevents the occurrence of the others. They are the subject of the third axiom.
- The **complement**  $\bar{A}$  of a given event  $A$ , illustrated in Figure 4.2, is determined by the non-occurrence of  $A$ , i.e.,  $\bar{A} = S - A$ . From this definition,  $P(\bar{A}) = 1 - P(A)$ . Complementary events are also mutually exclusive.
- An event  $A = \emptyset$  is called **impossible**. From this definition,  $P(A) = 0$ .
- An event  $A = S$  is called **certain**. From this definition,  $P(A) = 1$ .

It should be emphasized that all events  $A$  related to a given experiment are completely determined by the sample space  $S$ , since by definition  $A \subset S$ . Therefore, a set  $B$  of outcomes not in  $S$  is mapped to an event  $B \cap S = \emptyset$ . For instance, for the experiment of rolling a fair die,  $S = \{1, 2, 3, 4, 5, 6\}$ ; the event corresponding to  $B = \{7\}$  (showing a 7) is  $B \cap S = \emptyset$ .

According to the experiment, sample spaces may be **countable** or **uncountable**.<sup>3</sup> For example, the sample space of the coin flip experiment is countable. On the other hand, the sample space of the experiment that consists in sampling with no preference any real number from the interval  $S = (0, 100]$

<sup>3</sup>One could think of mixed cases, but this discussion is better conveyed in the random variable framework, which comprises every possible mapping from the original experiment to a subset of the real numbers.

is uncountable. Given an individual outcome  $s \in S$ , defining  $A = \{s\}$ ,

$$P(A) \begin{cases} \neq 0, & \text{if } S \text{ is countable;} \\ = 0, & \text{if } S \text{ is uncountable.} \end{cases} \quad (4.3)$$

As a consequence, one should not be surprised to find an event  $A \neq \emptyset$  with  $P(A) = 0$  or an event  $A \neq S$  with  $P(A) = 1$ . In the  $(0, 100]$  interval sampling experiment,  $A = \{50\} \neq \emptyset$  has  $P(A) = 0$ ; and  $\bar{A} \neq S$  has  $P(\bar{A}) = 1$ .

### 1.04.2.1 Joint, conditional, and total probability—Bayes' rule

The **joint probability** of a set of events  $A_m$ ,  $1 \leq m \leq M$ , is the probability of their simultaneous occurrence  $\bigcap_{m=1}^M A_m$ . Referring to Figure 4.3, given two events  $A$  and  $B$ , their joint probability can be found as

$$P(A \cap B) = P(A) + P(B) - P(A \cup B). \quad (4.4)$$

By rewriting this equation as

$$P(A \cup B) = P(A) + P(B) - P(A \cap B), \quad (4.5)$$

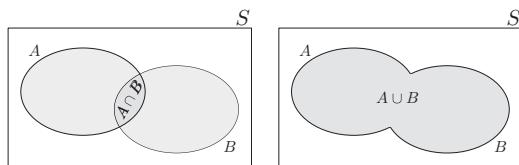

one finds an intuitive result: the term  $P(A \cap B)$  is included twice in  $P(A) + P(B)$ , and should thus be discounted. Moreover, when  $A$  and  $B$  are mutually exclusive, we arrive at the third axiom. In the die experiment, defining  $A = \{s \in S | s \text{ is even}\} = \{2, 4, 6\}$  and  $B = \{s \in S | s > 3\} = \{4, 5, 6\}$ :  $P(A) = 1/2$ ,  $P(B) = 1/2$ ,  $P(A \cap B) = P(\{4, 6\}) = 1/3$ , and  $P(A \cup B) = P(\{2, 4, 5, 6\}) = 2/3$ .

The **conditional probability**  $P(A|B)$  is the probability of event  $A$  conditioned to the occurrence of event  $B$ , and can be computed as

$$P(A|B) = \frac{P(A \cap B)}{P(B)}, \quad P(B) > 0. \quad (4.6)$$

The value of  $P(A \cap B)$  accounts for the uncertainty of both  $A$  and  $B$ ; the term  $P(B)$  discounts the uncertainty of  $B$ , since it is certain in this context. In fact, the conditioning event  $B$  is the new (reduced) sample space for the experiment. By rewriting this equation as

$$P(A \cap B) = P(A|B)P(B), \quad (4.7)$$

**FIGURE 4.3**

$A \cap B$  and  $A \cup B$ .

one gets another interpretation: the joint probability of  $A$  and  $B$  combines the uncertainty of  $B$  with the uncertainty of  $A$  when  $B$  is known to occur. Using the example in the last paragraph,  $P(A|B) = [P(\{4, 6\}) \text{ in sample space } B] = 2/3$ .

Since  $P(A \cap B) = P(B \cap A) = P(B|A)P(A)$ , the **Bayes Rule** follows straightforwardly:

$$P(A|B) = \frac{P(B|A)P(A)}{P(B)}. \quad (4.8)$$

This formula allows computing one conditional probability  $P(A|B)$  from its reverse  $P(B|A)$ . Using again the example in the last paragraph, one would arrive at the same result for  $P(A|B)$  using  $P(B|A) = [P(\{4, 6\}) \text{ in sample space } A] = 2/3$  in the last equation.

If the sample space  $S$  is partitioned into  $M$  disjoint sets  $A_m$ ,  $1 \leq m \leq M$ , such that  $A_m \cap A_{m'} = \emptyset \forall m' \neq m$ ,  $1 \leq m' \leq M$ , then any event  $B \subset S$  can be written as  $B = \bigcup_{m=1}^M (B \cap A_m)$ . Since  $B \cap A_m$ ,  $1 \leq m \leq M$ , are disjoint sets,

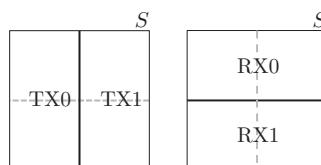

$$P(B) = \sum_{m=1}^M P(B|A_m)P(A_m), \quad (4.9)$$

which is called the **total probability** of  $B$ .

For a single event of interest  $A$ , for example, the application of Eq. (4.9) to Eq. (4.8) yields

$$P(A|B) = \frac{P(B|A)P(A)}{P(B|A)P(A) + P(B|\bar{A})P(\bar{A})}. \quad (4.10)$$

Within the Bayes context,  $P(A)$  and  $P(A|B)$  are usually known as the **a priori** and **a posteriori probabilities** of  $A$ , respectively;  $P(B|A)$  is called **likelihood** in the estimation context, and also **transition probability** in the communications context. In the latter case,  $A = \{a\}$  could refer to a symbol  $a$  sent by the transmitter and  $B = \{b\}$ , to a symbol  $b$  recognized by the receiver. Knowing  $P(B|A)$ , the probability of recognizing  $b$  when  $a$  is sent (which models the communication channel), and  $P(A)$ , the a priori probability of the transmitter to send  $a$ , allows to compute  $P(A|B)$ , the probability of  $a$  having been sent given that  $b$  has been recognized. In the case of binary communication, we could partition the sample space either in the events TX0 (0 transmitted) and TX1 (1 transmitted), or in the events RX0 (0 recognized) and RX1 (1 recognized), as illustrated in Figure 4.4; the event “error” would be  $E = (TX0 \cap RX1) \cup (TX1 \cap RX0)$ .

**FIGURE 4.4**

Binary communication example: partitions of  $S$  regarding transmission and reception.

### 1.04.2.2 Probabilistic independence

The events  $A_m$ ,  $1 \leq m \leq M$  are said to be **mutually independent** when the occurrence of one does not affect the occurrence of any combination of the others.

For two events  $A$  and  $B$ , three equivalent tests can be employed: they are independent if and only if.

1.  $P(A|B) = P(A)$ , or
2.  $P(B|A) = P(B)$ , or
3.  $P(A \cap B) = P(A)P(B)$ .

The first two conditions follow directly from the definition of independence. Using any of them in Eq. (4.6) one arrives at the third one. The reader is invited to return to Eq. (4.7) and conclude that  $B$  and  $A|B$  are independent events. Consider the experiment of rolling a special die with the numbers 1, 2, and 3 stamped in black on three faces and stamped in red on the other three; the events  $A = \{1\}$  and  $B = \{s \in S | s \text{ is a red number}\}$  are mutually independent.

Algorithmically, the best choice for testing the mutual independence of more than two events is using the third condition for every combination of  $2, 3, \dots, M$  events among  $A_1, A_2, \dots, A_M$ .

As a final observation, mutually exclusive events are not mutually independent; on the contrary, one could say they are maximally dependent, since the occurrence of one precludes the occurrence of the other.

### 1.04.2.3 Combined experiments—Bernoulli trials

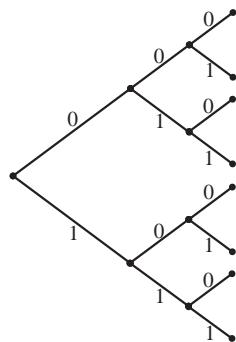

The theory we have discussed so far can be applied when more than one experiment is performed at a time. The generalization to the **multiple experiment** case can be easily done by using cartesian products.

Consider the experiments  $E_m$  with their respective sample spaces  $S_m$ ,  $1 \leq m \leq M$ . Define the combined experiment  $E$  such that each of its trials is composed by one trial of each  $E_m$ . An outcome of  $E$  is the  $M$ -tuple  $(s_1, s_2, \dots, s_M)$ , where  $s_m \in S_m$ ,  $1 \leq m \leq M$ , and the sample space of  $E$  can be written as  $S = S_1 \times S_2 \times \dots \times S_M$ . Analogously, any event of  $E$  can be expressed as  $A = A_1 \times A_2 \times \dots \times A_M$ , where  $A_m$  is a properly chosen event of  $E_m$ ,  $1 \leq m \leq M$ .

In the special case when the sub-experiments are mutually independent, i.e., the outcomes of one do not affect the outcomes of the others, we have  $P(A) = \prod_{m=1}^M P(A_m)$ . However, this is not the general case. Consider the experiment of randomly selecting a card from a 52-card deck, repeated twice: if the first card drawn is replaced, the sub-experiments are independent; if not, the first outcome affects the second experiment. For example, for  $A = \{\text{ace of spades, ace of spades}\}$ ,  $P(A) = (1/52)^2$  if the first card is replaced, and  $P(A) = 0$  if not.

At this point, an interesting counting experiment (called **Bernoulli trials**) can be defined. Take a random experiment  $E$  with sample space  $S$  and a desired event  $A$  (success) with  $P(A) = p$ , which also defines  $\bar{A}$  (failure) with  $P(\bar{A}) = 1 - p$ . What is the probability of getting exactly  $k$  successes in  $N$  independent repeats of  $E$ ? The solution can be easily found by noticing that the desired result is composed by  $k$  successes and  $N - k$  failures, which may occur in  $\binom{N}{k}$  different orders. Then,

$$P(k \text{ successes after } N \text{ trials}) = \binom{N}{k} p^k (1-p)^{N-k}. \quad (4.11)$$

**FIGURE 4.5**

Three consecutive bits sent through a binary communication system.

When  $N \rightarrow \infty$ ,  $p \rightarrow 0$ , and  $Np \rightarrow$  a constant,

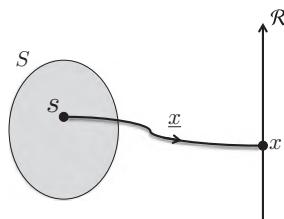

$$P(k \text{ successes after } N \text{ trials}) \rightarrow \frac{(Np)^k e^{-Np}}{k!}. \quad (4.12)$$

Returning to the card deck experiment (with replacement): the probability of selecting exactly 2 aces of spades after 300 repeats is approximately 5.09% according to Eq. (4.11), while Eq. (4.12) provides the approximate value 5.20%. In a binary communication system where 0 and 1 are randomly transmitted with equal probabilities, the probability that exactly 2 bits 1 are sent among 3 bits transmitted is 0.25%; this result can be easily checked by inspection of Figure 4.5.

### 1.04.3 Random variable

Mapping each outcome of a random experiment to a real number provides a different framework for the study of probabilistic models, amenable to simple interpretation and easy mathematical manipulation. This mapping is performed by the so-called random variable.

Given a random experiment with sample space  $S$ , a **random variable** is any function  $\underline{x}(s)$  that maps each  $s \in S$  into some  $x \in \mathcal{R}$  (see Figure 4.6). The image of this transformation with domain  $S$  and

**FIGURE 4.6**

Sample space  $S$  mapped into  $\mathcal{R}$  via random variable  $\underline{x}(s)$ .

co-domain  $\mathcal{R}$ , which results of the convenient choice of the mapping function, can be seen as the sample space of  $\underline{x}$ ; any event  $A$  of  $\underline{x}$  can be described as a subset of  $\mathcal{R}$ ; and each mapped outcome  $x$  is called a sample of  $\underline{x}$ . The following conditions should be satisfied by a random variable  $\underline{x}$ :

1.  $\{\underline{x} \leq x\}$  is an event  $\forall x \in \mathcal{R}$ ;
2.  $P(\{\underline{x} = -\infty\}) = P(\{\underline{x} = \infty\}) = 0$ .

We will see later that these conditions allow the proper definition of the cumulative probability distribution function of  $\underline{x}$ .

As seen in Section 1.04.2, sample spaces (and events) can be countable or uncountable, according to the nature of the random experiment's individual outcomes. After mapped into subsets of  $\mathcal{R}$ , countable events remain countable—e.g., one could associate with the coin flip experiment a random variable  $\underline{v}$  such that  $\underline{v}(\text{head}) = 0$  and  $\underline{v}(\text{tail}) = 1$ . On the other hand, uncountable events may or may not remain uncountable. Consider the following four distinct definitions of a random variable  $\underline{i}$  associated with the  $(0, 100]$  interval experiment described immediately before Eq. (4.3):

1.  $\underline{i}_1(s) = s$ ;
2.  $\underline{i}_2(s) = \begin{cases} -1, & s \leq 50; \\ 1, & s > 50; \end{cases}$
3.  $\underline{i}_3(s) = \begin{cases} s, & s \leq 50; \\ 100, & s > 50; \end{cases}$
4.  $\underline{i}_4(s) = \min[s, 50]$ .

The sample space of:

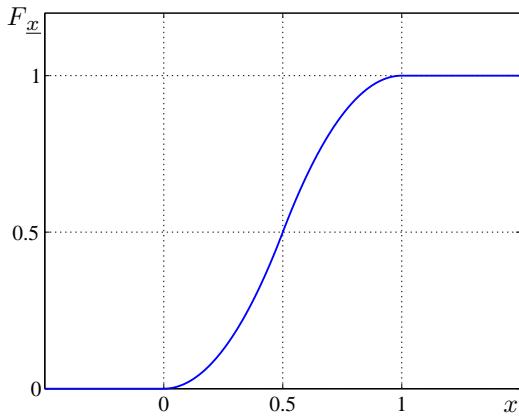

1.  $\underline{i}_1, (0, 100]$ , is uncountable;
2.  $\underline{i}_2, \{-1, 1\}$ , is countable;
3.  $\underline{i}_3, (0, 50] \cup \{100\}$ , is part uncountable, part countable;
4.  $\underline{i}_4, (0, 50]$ , even if continuous, may be difficult to classify.

The classification of sample spaces as countable or uncountable leads directly to the classification of random variables as discrete, continuous, or mixed. A **discrete** random variable  $\underline{d}$  has a countable sample space  $S_{\underline{d}}$ , and has  $P(\{\underline{d} = d\}) > 0, \forall d \in S_{\underline{d}}$ —this is the case of  $\underline{v}$  and  $\underline{i}_2$  defined above. A **continuous** random variable  $\underline{c}$  has an uncountable sample space  $S_{\underline{c}}$ , and (to avoid ambiguity) has  $P(\{\underline{c} = c\}) = 0, \forall c \in S_{\underline{c}}$ —this is the case of  $\underline{i}_1$  defined above. A **mixed** variable  $\underline{m}$  has a sample space  $S_{\underline{m}}$  composed by the union of real intervals with continuously distributed probabilities, within which  $P(\{\underline{m} = m\}) = 0$ , and discrete real values with finite probabilities  $P(\{\underline{m} = m\}) > 0$ —this is the case of  $\underline{i}_3$  and  $\underline{i}_4$  defined above. Specifically, since  $P(0 < \underline{i}_4 < 50) = P(\underline{i}_4 = 50) = 50\%$ ,  $S_{\underline{i}_4}$  should rather be treated as part uncountable, part countable than as simply uncountable.

### 1.04.3.1 Probability distributions

From the conditions that must be satisfied by any random variable  $\underline{x}$ , an overall description of its probability distribution can be provided by the so-called **cumulative probability distribution function** (shortened to **CDF**),

$$F_{\underline{x}}(x) = P(\{\underline{x} \leq x\}). \quad (4.13)$$

**FIGURE 4.7**

Example of cumulative probability distribution function.

Since  $P(\underline{x} = -\infty) = 0$ ,  $F_{\underline{x}}(-\infty) = 0$ . It is obvious that  $F_{\underline{x}}(\infty) = 1$ ; but since  $P(\{\underline{x} = \infty\}) = 0$ ,  $P(\{\underline{x} < \infty\}) = 1$ . Moreover,  $0 \leq F_{\underline{x}}(x) \leq 1$  and is a non-decreasing function of  $x$ , i.e.,  $F_{\underline{x}}(x_1) \leq F_{\underline{x}}(x_2)$  if  $x_1 < x_2$ . Also,  $F_{\underline{x}}(x^+) = F_{\underline{x}}(x)$ , i.e.,  $F_{\underline{x}}(x)$  is continuous from the right; this will be important in the treatment of discrete random variables. A typical CDF is depicted in Figure 4.7. One can use the CDF to calculate probabilities by noticing that

$$P(\{x_1 < \underline{x} \leq x_2\}) = F_{\underline{x}}(x_2) - F_{\underline{x}}(x_1). \quad (4.14)$$

For the random variable  $\underline{x}$  whose distribution is described in Figure 4.7, one can easily check by inspection that  $P(\underline{x} \leq \frac{1}{2}) = 50\%$ .

The CDF of the random variable  $i_1$  associated above with the  $(0, 100]$  interval sampling experiment is

$$F_{i_1}(i_1) = \begin{cases} 0, & i_1 \leq 0; \\ i_1, & 0 < i_1 \leq 100; \\ 1, & i_1 > 100. \end{cases} \quad (4.15)$$

The CDF of the random variable  $v$  associated above with the coin flip experiment is

$$F_v(v) = \begin{cases} 0, & v < 0; \\ 0.5, & 0 \leq v < 1; \\ 1, & v \geq 1. \end{cases} \quad (4.16)$$

Given a random variable  $\underline{x}$ , any single value  $x_0$  such that  $P(\{\underline{x} = x_0\}) = p > 0$  contributes a step<sup>4</sup> of amplitude  $p$  to  $F_{\underline{x}}(x)$ . Then, it is easy to conclude that for a discrete random variable  $\underline{d}$  with

<sup>4</sup>Unit step function:  $u(x) = \begin{cases} 0, & x < 0; \\ 1, & x \geq 0. \end{cases}$

$$S_{\underline{d}} = \{\dots, d_{i-1}, d_i, d_{i+1}, \dots\},$$

$$F_{\underline{d}}(d) = \sum_i P(\{\underline{d} = d_i\}) u(d - d_i). \quad (4.17)$$

An even more informative function that can be derived from the CDF to describe the probability distribution of a random variable  $\underline{x}$  is the so-called **probability density function** (shortened to **PDF**),

$$f_{\underline{x}}(x) = \frac{dF_{\underline{x}}(x)}{dx}. \quad (4.18)$$

Since  $F_{\underline{x}}(x)$  is a non-decreasing function of  $x$ , it follows that  $f_{\underline{x}}(x) \geq 0$ . From the definition,

$$F_{\underline{x}}(x) = \int_{-\infty}^{x^+} f_{\underline{x}}(\tilde{x}) d\tilde{x}. \quad (4.19)$$

Then,

$$\int_{-\infty}^{\infty} f_{\underline{x}}(x) dx = 1. \quad (4.20)$$

The PDF corresponding to the CDF shown in Figure 4.7 is depicted in Figure 4.8. One can use the PDF to calculate probabilities by noticing that

$$P(\{x_1 < \underline{x} \leq x_2\}) = \int_{x_1^+}^{x_2^+} f_{\underline{x}}(x) dx. \quad (4.21)$$

Again, for the random variable  $\underline{x}$  whose distribution is described in Figure 4.8, one can easily check by inspection that  $(\underline{x} \leq \frac{1}{2}) = 50\%$ .

The PDF of the random variable  $\underline{i}_1$  associated above with the  $(0, 100]$  interval sampling experiment is

$$f_{\underline{i}_1}(i_1) = \begin{cases} 1, & 0 < i_1 \leq 100; \\ 0, & \text{otherwise.} \end{cases} \quad (4.22)$$

The PDF of the random variable  $\underline{v}$  associated above with the coin flip experiment is

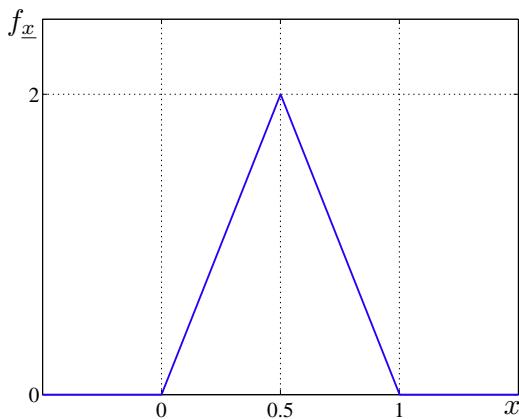

$$f_{\underline{v}}(v) = \begin{cases} \infty, & v = 0 \text{ or } v = 1; \\ 0, & \text{otherwise,} \end{cases} \quad (4.23)$$

which is not well-defined. But coherently with what has been seen for the CDF, given a random variable  $\underline{x}$ , any single value  $x_0$  such that  $P(\{\underline{x} = x_0\}) = p > 0$  contributes an impulse<sup>5</sup> of area  $p$  to  $f_{\underline{x}}(x)$ . Then, it is easy to conclude that for a discrete random variable  $\underline{d}$  with  $S_{\underline{d}} = \{\dots, d_{i-1}, d_i, d_{i+1}, \dots\}$ ,

$$f_{\underline{d}}(d) = \sum_i P(\{\underline{d} = d_i\}) \delta(d - d_i). \quad (4.24)$$

---

<sup>5</sup>Unit impulse distribution, or Dirac delta: For  $x \in \mathcal{R}$ ,  $\delta(x) = 0 \forall x \neq 0$  and  $\int_{-\infty}^{\infty} \delta(x) dx = 1$ .

**FIGURE 4.8**

Example of probability density function.

In particular, for the coin flip experiment the PDF is  $f_v(v) = 0.5\delta(v) + 0.5\delta(v - 1)$ .

In the case of discrete random variables, in order to avoid the impulses in the PDF, one can operate directly on the so-called **mass probability function**<sup>6</sup>:

$$P_d(d) = P(\{d = d\}). \quad (4.25)$$

In this case,

$$F_d(d) = \sum_{i|d_i \leq d} P_d(d_i). \quad (4.26)$$

This chapter favors an integrate framework for continuous and discrete variables, based on CDFs and PDFs.

It is usual in the literature referring (for short) to the CDF as “the distribution” and to the PDF as “the density” of the random variable. This text avoids this loose terminology, since the word “distribution” better applies to the overall probabilistic behavior of the random variable, no matter in the form of a CDF or a PDF.

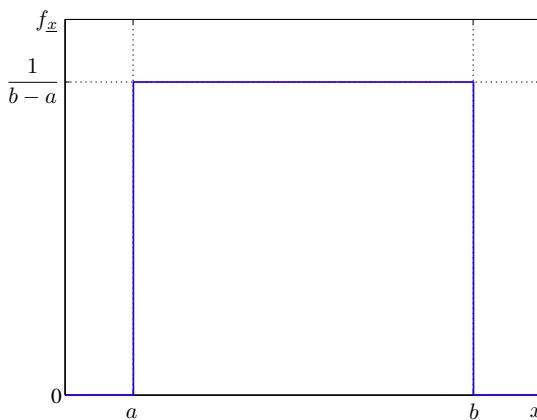

### 1.04.3.2 Usual distributions

The simplest continuous distribution is the so-called **uniform**. A random variable  $\underline{x}$  is said to be uniformly distributed between  $a$  and  $b > a$  if its PDF is

$$f_{\underline{x}}(x) = \begin{cases} \frac{1}{b-a}, & a \leq x \leq b; \\ 0, & \text{otherwise,} \end{cases} \quad (4.27)$$

---

<sup>6</sup>This unusual notation is employed here for the sake of compatibility with the other definitions.

**FIGURE 4.9**

Uniform probability distribution.

depicted in Figure 4.9. Notice that the inclusion or not of the interval bounds is unimportant here, since the variable is continuous. The error produced by uniform quantization of real numbers is an example of uniform random variable.

Perhaps the most recurrent continuous distribution is the so-called **Gaussian** (or **normal**). A Gaussian random variable  $\underline{x}$  is described by the PDF

$$f_{\underline{x}}(x) = \frac{1}{\sqrt{2\pi\sigma_{\underline{x}}^2}} e^{-\frac{(x-\bar{x})^2}{2\sigma_{\underline{x}}^2}}. \quad (4.28)$$

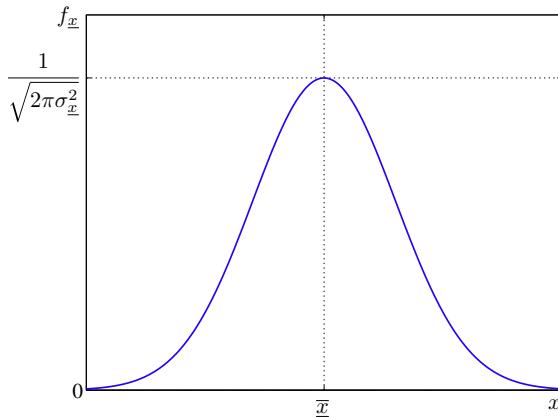

As seen in Figure 4.10, this function is symmetrical around  $\bar{x}$ , with spread controlled by  $\sigma_{\underline{x}}$ . These parameters, respectively called statistical mean and standard deviation of  $\underline{x}$ , will be precisely defined in Section 1.04.3.4. The Gaussian distribution arises from the combination of several independent random phenomena, and is often associated with noise models.

There is no closed expression for the Gaussian CDF, which is usually tabulated for a normalized Gaussian random variable  $\tilde{x}$  with  $\bar{x} = 0$  and  $\sigma_{\tilde{x}}^2 = 1$  such that

$$f_{\tilde{x}}(\tilde{x}) = \frac{1}{\sqrt{2\pi}} e^{-\frac{\tilde{x}^2}{2}}. \quad (4.29)$$

In order to compute  $p = P(\{x_1 < \underline{x} \leq x_2\})$  for a Gaussian random variable  $\underline{x}$ , one can build an auxiliary variable  $\tilde{x} = \frac{\underline{x}-\bar{x}}{\sigma_{\underline{x}}}$  such that  $p = P(\{\tilde{x}_1 < \tilde{x} \leq \tilde{x}_2\}) = F_{\tilde{x}}(\tilde{x}_2) - F_{\tilde{x}}(\tilde{x}_1)$ , which can then be approximated by tabulated values of  $F_{\tilde{x}}(\tilde{x})$ .

**Example 1.** The values  $r$  of a 10%-resistor series produced by a component industry can be modeled by a Gaussian random variable  $\underline{r}$  with  $\sigma_{\underline{r}} = \frac{1}{30}\bar{r}$ . What is the probability of producing a resistor within  $\pm 1\%$  of  $\bar{r}$ ?

**FIGURE 4.10**

Gaussian probability distribution.

**Solution 1.** The normalized counterpart of  $r$  is  $\tilde{r} = \frac{r - \bar{r}}{\frac{1}{30}\bar{r}}$ . Then,

$$P(\{0.99\bar{r} \leq r \leq 1.01\bar{r}\}) = P(\{-0.3 \leq \tilde{r} \leq 0.3\}) = F_{\tilde{r}}(0.3) - F_{\tilde{r}}(-0.3) \approx 0.2358. \quad (4.30)$$

Notice once more that since the variable is continuous, the inclusion or not of the interval bounds has no influence on the result.

In Section 1.04.2.3, an important discrete random variable was implicitly defined. A random variable  $\underline{x}$  that follows the so-called **binomial** distribution is described by

$$f_{\underline{x}}(x) = \sum_{k=0}^N \binom{N}{k} p^k (1-p)^{N-k} \delta(x - k), \quad (4.31)$$

and counts the number of occurrences of an event  $A$  which has probability  $p$ , after  $N$  independent repeats of a random experiment. Games of chance are related to binomial random variables.

The so-called **Poisson** distribution, described by

$$f_{\underline{x}}(x) = e^{-\lambda T} \sum_{k=0}^{\infty} \frac{(\lambda T)^k}{k!} \delta(x - k), \quad (4.32)$$

counts the number of occurrences of an event  $A$  that follows a mean rate of  $\lambda$  occurrences per unit time, during the time interval  $T$ . Traffic studies are related to Poisson random variables.

It is simple to derive the Poisson distribution from the binomial distribution. If an event  $A$  may occur with no preference anytime during a time interval  $(t_0, t_0 + T_0)$ , the probability that  $A$  occurs within the time interval  $[t, t + T] \subset (t_0, t_0 + T_0)$  is  $\frac{T}{T_0}$ . If  $A$  occurs  $N$  times in  $(t_0, t_0 + T_0)$ , the probability that

it falls exactly  $k$  times in  $[t, t + T] \subset (t_0, t_0 + T_0)$  is  $\binom{N}{k} p^k (1-p)^{N-k}$ . If  $T_0 \rightarrow \infty$ ,  $p \rightarrow 0$ ; if  $A$

follows a mean rate of  $\lambda = \frac{N}{T_0}$  occurrences per unit time, then  $N \rightarrow \infty$  and the probability of exact  $k$  occurrences in a time interval of duration  $T$  becomes  $e^{-\lambda T} \sum_{k=0}^{\infty} \frac{(\lambda T)^k}{k!}$ , where  $\lambda T$  substituted for  $Np$ . If a central office receives 100 telephone calls per minute in the mean, the probability that more than 1 call arrive during 1s is  $1 - e^{-\frac{100}{60}} (1 - e^{-\frac{100}{60}}) \approx 49.6\%$ .

Due to space restrictions, this chapter does not detail other random distributions, which can be easily found in the literature.

### 1.04.3.3 Conditional distribution

In many instances, one is interested in studying the behavior of a given random variable  $\underline{x}$  under some constraints. A **conditional distribution** can be built to this effect, if the event  $B \subset \mathcal{R}$  summarizes those constraints. The corresponding CDF of  $\underline{x}$  conditioned to  $B$  can be computed as

$$F_{\underline{x}}(x|B) = P(\{\underline{x} \leq x | B\}) = \frac{P(\{\underline{x} \leq x\} \cap B)}{P(B)}. \quad (4.33)$$

The related PDF is simply

$$f_{\underline{x}}(x|B) = \frac{dF_{\underline{x}}(x|B)}{dx}. \quad (4.34)$$

Conditional probabilities can be straightforwardly computed from conditional CDFs or PDFs.

When the conditioning event is an interval  $B = (a, b]$ , it can be easily deduced that

$$F_{\underline{x}}(x|B) = \begin{cases} 0, & x \leq a; \\ \frac{F_{\underline{x}}(x) - F_{\underline{x}}(a)}{F_{\underline{x}}(b) - F_{\underline{x}}(a)}, & a < x \leq b; \\ 1, & x > b; \end{cases} \quad (4.35)$$

and

$$f_{\underline{x}}(x|B) = \begin{cases} \frac{f_{\underline{x}}(x)}{\int_a^b f_{\underline{x}}(x) dx}, & a < x \leq b; \\ 0, & \text{otherwise.} \end{cases} \quad (4.36)$$

Both sentences in Eq. (4.36) can be easily interpreted:

- Within  $(a, b]$ , the conditional PDF has the same shape of the original one; the normalization factor  $\int_a^b f_{\underline{x}}(x) dx$  ensures  $P((a, b]) = 100\%$  in the restricted sample space  $(a, b]$ .
- By definition, there is null probability of getting  $x$  outside  $(a, b]$ .

As an example, the random variable  $H$  defined by the non-negative outcomes of a normalized Gaussian variable follows the PDF

$$f_{\underline{h}}(h) = \sqrt{\frac{2}{\pi}} e^{-\frac{h^2}{2}} u(h). \quad (4.37)$$

The results shown in this section can be promptly generalized to any conditioning event.

### 1.04.3.4 Statistical moments

The concept of mean does not need any special introduction: the single value that substituted for each member in a set of numbers produces the same total. In the context of probability, following a frequentist path, one could define the arithmetic mean of infinite samples of a random variable  $\underline{x}$  as its **statistical mean**  $\bar{x}$  or its **expected value**  $E[\underline{x}]$ .

Recall the random variable  $\underline{v}$  associated with the fair coin flip experiment, with  $P_{\underline{v}}(0) = P_{\underline{v}}(1) = 0.5$ . After infinite repeats of the experiment, one gets 50% of heads ( $\underline{v} = 0$ ) and 50% of tails ( $\underline{v} = 1$ ); then, the mean outcome will be<sup>7</sup>  $E[\underline{v}] = 0.5$ . If another variable  $\underline{v}'$  is associated with an unfair coin with probabilities  $P_{\underline{v}'}(0) = 0.4$  and  $P_{\underline{v}'}(1) = 0.6$ , the same reasoning leads to  $E[\underline{v}'] = 0.6$ . Instead of averaging infinite outcomes, just summing the possible values of the random variable weighted by their respective probabilities also yields its statistical mean. Thus we can state that for any discrete random variable  $\underline{d}$  with sample space  $S = \{\dots, d_{i-1}, d_i, d_{i+1}, \dots\}$ ,

$$E[\underline{d}] = \sum_i d_i P_{\underline{d}}(d_i). \quad (4.38)$$

This result can be generalized. Given a continuous random variable  $\underline{x}$ , the probability of drawing a value in the interval  $dx$  around  $x_0$  is given by  $f_{\underline{x}}(x_0)dx$ . The weighted sum of every  $x \in \mathcal{R}$  is simply

$$E[\underline{x}] = \int_{-\infty}^{\infty} x f_{\underline{x}}(x) dx. \quad (4.39)$$

By substituting the PDF of a discrete variable  $\underline{d}$  (see Eq. (4.24)) into this expression, one arrives at Eq. (4.38). Then, Eq. (4.39) is the analytic expression for the expected value of any random variable  $\underline{x}$ .

Suppose another random variable  $g(\underline{x})$  is built as a function of  $\underline{x}$ . Since the probability of getting the value  $x_0$  is the same as getting the respective  $g(x_0)$ , we can deduce that

$$E[g(\underline{x})] = \int_{-\infty}^{\infty} g(x) f_{\underline{x}}(x) dx. \quad (4.40)$$

A complete family of measures based on expected values can be associated with a random variable. The so-called *n*th-order **moment** of  $\underline{x}$  (about the origin) is defined as

$$m_n = E[\underline{x}^n], \quad n \in \mathbb{Z}. \quad (4.41)$$

The first two moments of  $\underline{x}$  are:

- $m_1 = \bar{x}$ , i.e., the **mean** of  $\underline{x}$ , given by the centroid of  $f_{\underline{x}}(x)$ .
- $m_2 = \underline{x}^2$ , i.e., the **mean square value** of  $\underline{x}$ .

A modified family of parameters can be formed by computing the moments about the mean. The so-called *n*th-order **central moment** of  $\underline{x}$  is defined as

$$\mu_n = E[(\underline{x} - \bar{x})^n], \quad n \in \mathbb{Z}. \quad (4.42)$$

Subtracting the statistical mean from a random variable can be interpreted as disregarding its “deterministic” part (represented by its statistical mean) Three special cases:

---

<sup>7</sup>Notice that the expected value of a random variable is not necessarily meaningful for the associated experiment.

- $\mu_2 = \sigma_{\underline{x}}^2$ , known as the **variance** of  $\underline{x}$ , which measures the spread of  $f_{\underline{x}}(x)$  around  $\bar{x}$ . The so-called **standard deviation**  $\sigma_{\underline{x}} = \sqrt{\mu_2}$  is a convenient measure with the same dimension of  $\underline{x}$ .
- $\mu_3$ , whose standardized version  $\frac{\mu_3}{\sigma_{\underline{x}}^3}$  is the so-called **skewness** of  $\underline{x}$ , which measures the asymmetry of  $f_{\underline{x}}(x)$ .
- $\mu_4$ , whose standardized version<sup>8</sup> minus three  $\frac{\mu_4}{\sigma_{\underline{x}}^4} - 3$  is the so-called **kurtosis** of  $\underline{x}$ , which measures the peakedness of  $f_{\underline{x}}(x)$ . One can say the distributions are measured against the Gaussian, which has a null kurtosis.

Of course, analogous definitions apply to the moments computed over conditional distributions.

<b>Table 4.1</b> Statistical Distribution of $\underline{d}$	
$d$	$P_d$
-1	0.2
0	0.5
1	0.3

A useful expression, which will be recalled in the context of random processes, relates three of the measures defined above:

$$\sigma_{\underline{x}}^2 = \bar{x}^2 - \underline{x}^2. \quad (4.43)$$

Rewritten as

$$\bar{x}^2 = \underline{x}^2 + \sigma_{\underline{x}}^2, \quad (4.44)$$

it allows to split the overall “intensity” of  $\underline{x}$ , measured by its mean square value, into a deterministic part, represented by  $\bar{x}^2$ , and a random part, represented by  $\sigma_{\underline{x}}^2$ .

As an example, consider a discrete random variable  $\underline{d}$  distributed as shown in Table 4.1. Their respective parameters are:

- mean  $\bar{d} = 0.1$ , indicating the PDF of  $\underline{d}$  is shifted to the right of the origin;
- mean square value  $\bar{d}^2 = 1$ , which measures the intensity of  $\underline{d}$ ;
- variance  $\sigma_{\underline{d}}^2 = 0.49$ , which measures the random part of the intensity of  $\underline{d}$ ;
- standard deviation  $\sigma_{\underline{d}} = 0.7$ , which measures the spread of  $\underline{d}$  around its mean;
- skewness  $\frac{\mu_3}{\sigma_{\underline{d}}^3} \approx -0.14$ , indicating the PDF of  $\underline{d}$  is left-tailed;
- kurtosis  $\frac{\mu_4}{\sigma_{\underline{d}}^4} - 3 \approx -0.96$ , indicating the PDF of  $\underline{d}$  is less peaky than the PDF of a Gaussian variable.

At this point, we can discuss two simple transformations of a random variable  $\underline{x}$  whose effects can be summarized by low-order moments:

- A random variable  $y = \underline{x} + x_0$  can be formed by adding a fixed offset  $x_0$  to each sample of  $\underline{x}$ . As a consequence of this operation, the new PDF is a shifted version of the original one:  $f_y(y) = f_{\underline{x}}(y - x_0)$ , thus adding  $x_0$  to the mean of  $\underline{x}$ :  $\bar{y} = \bar{x} + x_0$ .

---

<sup>8</sup>The classical definition does not subtract three.

- A random variable  $\underline{y} = \alpha \underline{x}$  can be formed by scaling by  $\alpha$  each sample of  $\underline{x}$ . As a consequence of this operation, the new PDF is a scaled version of the original one:  $f_{\underline{y}}(y) = \frac{1}{\alpha} f_{\underline{x}}\left(\frac{y}{\alpha}\right)$ , thus scaling by  $\alpha$  the standard deviation of  $\underline{x}$ :  $\sigma_{\underline{y}} = \alpha \sigma_{\underline{x}}$ .

Such transformations do not change the shape (and therefore the type) of the original distribution. In particular, one can generate:

- a zero-mean version of  $\underline{x}$  by making  $\underline{y} = \underline{x} - \bar{\underline{x}}$ , which disregards the deterministic part of  $\underline{x}$ ;
- a unit-standard deviation version of  $\underline{x}$  by making  $\underline{y} = \frac{\underline{x}}{\sigma_{\underline{x}}}$ , which enforces a standard statistical variability to  $\underline{x}$ ;
- a normalized version of  $\underline{x}$  by making  $\underline{y} = \frac{\underline{x} - \bar{\underline{x}}}{\sigma_{\underline{x}}}$ , which combines both effects.

**Table 4.2** Statistical Distribution of  $\underline{d}$

$\tilde{d}$	$P_{\tilde{d}}$
-11/7	0.2
-1/7	0.5
9/7	0.3

We already defined a normalized Gaussian distribution in Section 1.04.3.2. The normalized version  $\underline{d}$  of the random variable  $\underline{d}$  of the last example would be distributed as shown in Table 4.2.

The main importance of these expectation-based parameters is to provide a partial description of an underlying distribution without the need to resource to the PDF. In a practical situation in which only a few samples of a random variable are available, as opposed to its PDF and related moments, it is easier to get more reliable estimates for the latter (especially low-order ones) than for the PDF itself. The same rationale applies to the use of certain auxiliary inequalities that avoid the direct computation of probabilities on a random variable (which otherwise would require the knowledge or estimation of its PDF) by providing upper bounds for them based on low-order moments. Two such inequalities are:

- Markov's inequality for a non-negative random variable  $\underline{x}$ :  $P(\{\underline{x} \geq a\}) \leq \frac{\bar{\underline{x}}}{a}$ ,  $\forall a > 0$ .
- Chebyshev's inequality for a random variable  $\underline{x}$ :  $P(\{|\underline{x} - \bar{\underline{x}}| \geq a\}) \leq \frac{\sigma_{\underline{x}}^2}{a^2}$ ,  $\forall a > 0$ .

The derivation of Markov's inequality is quite simple:

$$\begin{aligned} P(\underline{x} \geq a) &= \int_a^{\infty} f_{\underline{x}}(x) dx = \int_{-\infty}^{\infty} f_{\underline{x}}(x) u(x-a) dx \\ &\leq \int_{-\infty}^{\infty} \frac{x}{a} f_{\underline{x}}(x) u(x-a) dx \leq \int_{-\infty}^{\infty} \frac{x}{a} f_{\underline{x}}(x) dx = \frac{E[\underline{x}]}{a}. \end{aligned} \quad (4.45)$$

Chebyshev's inequality follows directly by substituting  $(x - \bar{x})^2 \geq a^2$  for  $x \geq a$  in Markov's inequality. As an example, the probability of getting a sample  $g > 3$  from the normalized Gaussian random variable  $\underline{g}$  is  $P(\{\underline{g} > 3\}) \approx 0.0013$ ; Chebyshev's inequality predicts  $P(\{\underline{g} > 3\}) \leq \frac{1}{9}$ , an upper bound almost 100 times greater than the actual probability.

Two representations of the distribution of a random variable in alternative domains provide interesting links with its statistical moments. The so-called **characteristic function** of a random variable  $\underline{x}$  is defined as

$$\Phi_{\underline{x}}(\omega) = E[e^{j\omega\underline{x}}], \quad \omega \in \mathcal{R}, \quad (4.46)$$

and inter-relates the moments  $m_n$  by successive differentiations:

$$m_n = (-j)^n \left. \frac{d^n \Phi_{\underline{x}}(\omega)}{d\omega^n} \right|_{\omega=0}. \quad (4.47)$$

The so-called **moment generating function** of a random variable  $\underline{x}$  is defined as

$$M_{\underline{x}}(v) = E[e^{v\underline{x}}], \quad v \in \mathcal{R}, \quad (4.48)$$

and provides a more direct way to compute  $m_n$ :

$$m_n = \left. \frac{d^n M_{\underline{x}}(v)}{dv^n} \right|_{v=0}. \quad (4.49)$$

### 1.04.3.5 Transformation of random variables

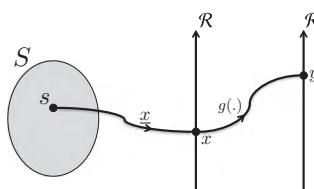

Consider the problem of describing a random variable  $\underline{y} = g(\underline{x})$  obtained by transformation of another random variable  $\underline{x}$ , illustrated in Figure 4.11. By definition,

$$F_{\underline{y}}(y) = P(\{\underline{y} \leq y\}) = P(\{g(\underline{x}) \leq y\}). \quad (4.50)$$

If  $\underline{x}$  is a continuous random variable and  $g(\cdot)$  is a differentiable function, the sentence  $g(x) \leq y$  is equivalent to a set of sentences in the form  $h_1(y) < x \leq h_2(y)$ . Since  $P(\{h_1(y) < x \leq h_2(y)\}) = F_{\underline{x}}(h_2(y)) - F_{\underline{x}}(h_1(y))$ , then  $F_{\underline{y}}(y)$  can be expressed as a function of  $F_{\underline{x}}(x)$ .

Fortunately, an intuitive formula expresses  $f_{\underline{y}}(y)$  as a function of  $f_{\underline{x}}(x)$ :

$$f_{\underline{y}}(y) = \sum_n \frac{f_{\underline{x}}(x_n)}{\left| \frac{dg(x)}{dx} \right|_{x=x_n}}, \quad \text{with } y = g(x_n). \quad (4.51)$$

**FIGURE 4.11**

Random variable  $\underline{x}$  mapped into random variable  $\underline{y}$ .

Given that the transformation  $g(\cdot)$  is not necessarily monotonic,  $x_n$  are all possible values mapped to  $y$ ; therefore, their contributions must be summed up. It is reasonable that  $f_y(y)$  must be directly proportional to  $f_x(x)$ : the more frequent a given  $x_0$ , the more frequent its respective  $y_0 = g(x_0)$ . By its turn, the term  $\left| \frac{dg(x)}{dx} \right|$  accounts for the distortion imposed to  $f_x(x)$  by  $g(x)$ . For example, if this transformation is almost constant in a given region, no matter if increasing or decreasing, then  $\left| \frac{dg(x)}{dx} \right|$  in the denominator will be close to zero; this just reflects the fact that a wide range of  $x$  values will be mapped into a narrow range of values of  $y$ , which will then become denser than  $x$  in that region.

As an example, consider that a continuous random variable  $x$  is transformed into a new variable  $y = x^2$ . For the CDF of  $y$ ,

$$\underline{y} \leq y \Rightarrow \underline{x}^2 \leq y \Rightarrow -\sqrt{y} \leq \underline{x} \leq \sqrt{y} \Rightarrow F_y(y) = F_x(\sqrt{y}) - F_x(-\sqrt{y}). \quad (4.52)$$

By Eq. (4.51), or by differentiation of Eq. (4.52), one arrives at the PDF of  $y$ :

$$f_y(y) = \frac{f_x(\sqrt{y}) + f_x(-\sqrt{y})}{\sqrt{y}}. \quad (4.53)$$

The case when real intervals of  $x$  are mapped into single values of  $y$  requires an additional care to treat the nonzero individual probabilities of the resulting values of the new variable. However, the case of a discrete random variable  $x$  with  $S = \{\dots, x_{i-1}, x_i, x_{i+1}, \dots\}$  being transformed is trivial:

$$f_y(y) = \sum_i P_y(y_i) \delta(y - y_i), \text{ with } y_i = g(x_{i_n}) \text{ and } P_y(y_i) = \sum_n P_x(x_{i_n}). \quad (4.54)$$

Again,  $x_{i_n}$  are all possible values mapped to  $y_i$ .

An interesting application of transformations of random variables is to obtain samples of a given random variable  $y$  from samples of another random variable  $x$ , both with known distributions. Assume that exists  $y = g(x)$  such that  $F_y(y = g(x)) = F_x(x)$ . Then,  $y = F_y^{-1}F_x(x)$ , which requires only the invertibility of  $F_y(y)$ .

### 1.04.3.6 Multiple random variable distributions

A single random experiment  $E$  (composed or not) may give rise to a set of  $N$  random variables, if each individual outcome  $s \in S$  is mapped into several real values  $x_1, x_2, \dots, x_N$ . Consider, for example, the random experiment of sampling the climate conditions at every point on the globe; daily mean temperature  $t$  and relative air humidity  $h$  can be considered as two random variables that serve as numerical summarizing measures. One must generalize the probability distribution descriptions to cope with this multiple random variable situation: it should be clear that the set of  $N$  individual probability distribution descriptions, one for each distinct random variable, provides less information than their joint probability distribution description, since the former cannot convey information about their mutual influences.

We start by defining a **multiple or vector random variable** as the function  $\underline{\mathbf{x}}$  that maps  $s \in S$  into  $\underline{\mathbf{x}} \in \mathcal{R}^N$ , such that

$$\underline{\mathbf{x}} = \begin{bmatrix} \underline{x}_1 \\ \underline{x}_2 \\ \vdots \\ \underline{x}_N \end{bmatrix} \quad (4.55)$$

and

$$\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_N \end{bmatrix}. \quad (4.56)$$

Notice that  $x_1, x_2, \dots, x_N$  are jointly sampled from  $\underline{x}_1, \underline{x}_2, \dots, \underline{x}_N$ .

The **joint cumulative probability distribution function** of  $\underline{x}_1, \underline{x}_2, \dots, \underline{x}_N$ , or simply the CDF of  $\underline{\mathbf{x}}$ , can be defined as

$$F_{\underline{\mathbf{x}}}(\mathbf{x}) = F_{\underline{x}_1, \underline{x}_2, \dots, \underline{x}_N}(x_1, x_2, \dots, x_N) = P(\{\underline{x}_1 \leq x_1\} \cap \{\underline{x}_2 \leq x_2\} \cap \dots \cap \{\underline{x}_N \leq x_N\}). \quad (4.57)$$

The following relevant properties of the joint CDF can be easily deduced:

- $F_{\underline{\mathbf{x}}}(\dots, x_{n-1}, -\infty, x_{n+1}, \dots) = 0$ , since  $P(\{x_n \leq -\infty\}) = 0$  for any  $1 \leq n \leq N$ .
- $F_{\underline{\mathbf{x}}}(\infty, \infty, \dots, \infty) = 1$ , since this condition encompasses the complete  $S$ .
- $0 \leq F_{\underline{\mathbf{x}}}(\mathbf{x}) \leq 1$  and is a nondecreasing function of  $x_n$ ,  $1 \leq n \leq N$ , by construction.

Define  $\underline{\mathbf{x}}_i$  containing  $N_i$  variables of interest among the random variables in  $\underline{\mathbf{x}}$ , and leave the remaining  $N - N_i$  **nuisance** variables in  $\underline{\mathbf{x}}_n$ . The so-called **marginal CDF** of  $\underline{x}_{i_1}, \underline{x}_{i_2}, \dots, \underline{x}_{i_{N_i}}$  separately describes these variables' distribution from the knowledge of the CDF of  $\underline{\mathbf{x}}$ :

$$F_{\underline{\mathbf{x}}_i}(\mathbf{x}_i) = F_{\underline{\mathbf{x}}}(\mathbf{x})|_{x_{n_1}=x_{n_2}=\dots=x_{n_{N-N_i}}=\infty}. \quad (4.58)$$

One says the variables  $x_{n_1}, x_{n_2}, \dots, x_{n_{N-N_i}}$  have been **marginalized** out: the condition  $x_{n_m} \leq \infty$  simply means they must be in the sample space, thus one does not need to care about them anymore.

The CDF of a discrete random variable  $\underline{\mathbf{d}}$  with  $S_{\underline{\mathbf{d}}} = \{\dots, \mathbf{d}_{i-1}, \mathbf{d}_i, \mathbf{d}_{i+1}, \dots\}$ , analogously to the single variable case, is composed by steps at the admissible  $N$ -tuples:

$$F_{\underline{\mathbf{d}}}(\mathbf{d}) = \sum_i P_{\underline{\mathbf{d}}}(\mathbf{d}_i) u(d_1 - d_{1i}) u(d_2 - d_{2i}) \dots u(d_N - d_{Ni}). \quad (4.59)$$

The **joint probability density function** of  $\underline{x}_1, \underline{x}_2, \dots, \underline{x}_N$ , or simply the PDF of  $\underline{\mathbf{x}}$ , can be defined as

$$f_{\underline{\mathbf{x}}}(\mathbf{x}) = f_{\underline{x}_1, \underline{x}_2, \dots, \underline{x}_N}(x_1, x_2, \dots, x_N) = \frac{\partial^N F_{\underline{\mathbf{x}}}(\mathbf{x})}{\partial x_1 \partial x_2 \dots \partial x_N}. \quad (4.60)$$

Since  $F_{\underline{\mathbf{x}}}(\mathbf{x})$  is a non-decreasing function of  $x_n$ ,  $1 \leq n \leq N$ , it follows that  $f_{\underline{\mathbf{x}}}(\mathbf{x}) \geq 0$ . From the definition,

$$F_{\underline{\mathbf{x}}}(\mathbf{x}) = \int_{-\infty}^{x_N} \dots \int_{-\infty}^{x_2} \int_{-\infty}^{x_1} f_{\underline{\mathbf{x}}}(\tilde{\mathbf{x}}) d\tilde{x}_1 d\tilde{x}_2 \dots d\tilde{x}_N. \quad (4.61)$$

Then,

$$\int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f_{\underline{x}}(\mathbf{x}) dx_1 dx_2 \cdots dx_N = 1. \quad (4.62)$$

The probability of any event  $B \in \mathcal{R}^N$  can be computed as

$$P(B) = \int_{\mathbf{x} \in B} f_{\underline{x}}(\mathbf{x}) dx_1 dx_2 \cdots dx_N. \quad (4.63)$$

Once more we can marginalize the nuisance variables  $x_{n_1}, x_{n_2}, \dots, x_{n_{N-N_i}}$  to obtain the **marginal PDF** of  $\underline{x}_i$  from the PDF of  $\underline{x}$ :

$$f_{\underline{x}_i}(\mathbf{x}_i) = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f_{\underline{x}}(\mathbf{x}) dx_{n_1} dx_{n_2} \cdots dx_{n_{N-N_i}}. \quad (4.64)$$

Notice that if  $\underline{x}_i$  and  $\underline{x}_n$  are statistically dependent, the marginalization of  $\underline{x}_n$  does not “eliminate” the effect of  $\underline{x}_n$  on  $\underline{x}_i$ : the integration is performed over  $\underline{x}$ , which describes their mutual influences. For a discrete random variable  $\underline{d}$  with  $S_{\underline{d}} = \{\dots, \mathbf{d}_{i-1}, \mathbf{d}_i, \mathbf{d}_{i+1}, \dots\}$  consists of impulses at the admissible  $N$ -tuples:

$$f_{\underline{d}}(\mathbf{d}) = \sum_i P_{\underline{d}}(\mathbf{d}_i) \delta(d_1 - d_{1i}) \delta(d_2 - d_{2i}) \cdots \delta(d_N - d_{Ni}). \quad (4.65)$$

Suppose, for example, that we want to find the joint and marginal CDFs and PDFs of two random variables  $\underline{x}$  and  $\underline{y}$  jointly uniformly distributed in the region  $0 \leq y \leq x \leq 1$ , i.e., such that

$$f_{\underline{x}, \underline{y}}(x, y) = \begin{cases} 2, & 0 \leq y \leq x \leq 1; \\ 0, & \text{otherwise.} \end{cases} \quad (4.66)$$

The marginalization of  $\underline{y}$  yields

$$f_{\underline{x}}(x) = \int_{-\infty}^{\infty} f_{\underline{x}, \underline{y}}(x, y) dy = \int_0^x 2 dy = \begin{cases} 2x, & 0 \leq x \leq 1; \\ 0, & \text{otherwise.} \end{cases} \quad (4.67)$$

The marginalization of  $\underline{x}$  yields

$$f_{\underline{y}}(y) = \int_{-\infty}^{\infty} f_{\underline{x}, \underline{y}}(x, y) dx = \int_y^1 2 dx = \begin{cases} 2(1-y), & 0 \leq y \leq 1; \\ 0, & \text{otherwise.} \end{cases} \quad (4.68)$$

By definition,

$$F_{\underline{x}, \underline{y}}(x, y) = \int_{-\infty}^y \int_{-\infty}^x f_{\underline{x}, \underline{y}}(\tilde{x}, \tilde{y}) d\tilde{x} d\tilde{y} = \begin{cases} 0, & x < 0 \text{ or } y < 0; \\ y(2x - y), & 0 \leq y \leq x \leq 1; \\ x^2, & 0 \leq x \leq 1 \text{ and } y > x; \\ y(2 - y), & 0 \leq y \leq 1 \text{ and } x > 1; \\ 1, & x > 1 \text{ and } y > 1. \end{cases} \quad (4.69)$$

The reader is invited to sketch the admissible region  $0 \leq y \leq x \leq 1$  on the  $(x, y)$  plane and try to solve Eq. (4.69) by visual inspection. The marginal CDF of  $\underline{x}$  is given by

$$F_{\underline{x}}(x) = F_{\underline{x}, \underline{y}}(x, \infty) = \begin{cases} 0, & x < 0; \\ x^2, & 0 \leq x \leq 1; \\ 1, & x > 1, \end{cases} \quad (4.70)$$

which could also have been obtained by direct integration of  $f_{\underline{x}}(x)$ . The marginal CDF of  $\underline{y}$  is given by

$$F_{\underline{y}}(y) = F_{\underline{x}, \underline{y}}(\infty, y) = \begin{cases} 0, & y < 0; \\ y(2-y), & 0 \leq y \leq 1; \\ 1, & y > 1, \end{cases} \quad (4.71)$$

which could also have been obtained by direct integration of  $f_{\underline{y}}(y)$ .

Similarly to the univariate case discussed in Section 1.04.3.3, the **conditional distribution** of a vector random variable  $\underline{x}$  restricted by a conditioning event  $B \in \mathcal{R}^N$  can be described by its respective CDF

$$F_{\underline{x}}(\underline{x}|B) = \frac{P(\{\underline{x}_1 \leq x_1\} \cap \{\underline{x}_2 \leq x_2\} \cap \dots \cap \{\underline{x}_N \leq x_N\} \cap B)}{P(B)} \quad (4.72)$$

and PDF

$$f_{\underline{x}}(\underline{x}|B) = \frac{\partial^N F_{\underline{x}}(\underline{x}|B)}{\partial x_1 \partial x_2 \dots \partial x_N}. \quad (4.73)$$

A special case arises when  $B$  imposes a point conditioning: Define  $\underline{x}_B$  containing  $N_B$  variables among those in  $\underline{x}$ , such that  $B = \{\underline{x}_B = \underline{x}_B\}$ . It can be shown that

$$f_{\underline{x}}(\underline{x}|B) = \frac{f_{\underline{x}}(\underline{x})}{f_{\underline{x}_B}(\underline{x}_B)}, \quad (4.74)$$

an intuitive result in light of Eq. (4.6)—to which one may directly refer in the case of discrete random variables. Returning to the last example, the point-conditioned PDFs can be shown to be

$$f_{\underline{x}}(x|\underline{y} = y) = \begin{cases} \frac{1}{1-y}, & 0 \leq y \leq x \leq 1; \\ 0, & \text{otherwise}; \end{cases} \quad (4.75)$$

and

$$f_{\underline{y}}(y|\underline{x} = x) = \begin{cases} \frac{1}{x}, & 0 \leq y \leq x \leq 1; \\ 0, & \text{otherwise}. \end{cases} \quad (4.76)$$

### 1.04.3.7 Statistically independent random variables

Based on the concept of statistical independence, discussed in Section 1.04.2.2, the mutual **statistical independence** of a set of random variables means that the probabilistic behavior of each one is not affected by the probabilistic behavior of the others. Formally, the random variables  $\underline{x}_1, \underline{x}_2, \dots, \underline{x}_N$  are independent if any of the following conditions is fulfilled:

- $F_{\underline{\mathbf{x}}}(\underline{\mathbf{x}}) = \prod_{n=1}^N F_{x_n}(x_n)$ , or
- $f_{\underline{\mathbf{x}}}(\underline{\mathbf{x}}) = \prod_{n=1}^N f_{x_n}(x_n)$ , or
- $F_{x_n}(x_n | \text{any condition on the remaining variables}) = F_{x_n}(x_n)$ ,  $\forall 1 \leq n \leq N$ , or
- $f_{x_n}(x_n | \text{any condition on the remaining variables}) = f_{x_n}(x_n)$ ,  $\forall 1 \leq n \leq N$ .

Returning to the example developed in Section 1.04.3.6,  $x$  and  $y$  are clearly statistically dependent. However, if they were jointly uniformly distributed in the region defined by  $0 \leq x \leq 1$ ,  $0 \leq y \leq 1$ , they would be statistically independent—this verification is left to the reader.

The PDF of a random variable  $\underline{y} = \sum_{n=1}^N f_{x_n}(x_n)$  composed by the sum of  $N$  independent variables  $x_n$  can be computed as<sup>9</sup>

$$f_{\underline{y}}(y) = (f_{x_1} * f_{x_2} * \dots * f_{x_N})(y). \quad (4.77)$$

### 1.04.3.8 Joint statistical moments

The definition of **statistical mean** can be directly extended to a vector random variable  $\underline{\mathbf{x}}$  with known PDF. The **expected value** of a real scalar function  $g(\underline{\mathbf{x}})$  is given by:

$$E[g(\underline{\mathbf{x}})] = \int_{-\infty}^{\infty} \dots \int_{-\infty}^{\infty} g(\underline{\mathbf{x}}) f_{\underline{\mathbf{x}}}(\underline{\mathbf{x}}) dx_1 dx_2 \dots dx_N. \quad (4.78)$$

We can analogously proceed to the definition of  $N$ -variable joint statistical moments. However, due to the more specific usefulness of the  $N > 2$  cases, only 2-variable moments will be presented.

An  $(n+k)$ th-order **joint moment** of  $\underline{x}$  and  $\underline{y}$  (about the origin) has the general form

$$m_{n,k} = E[\underline{x}^n \underline{y}^k], \quad n, k \in \mathbb{Z}. \quad (4.79)$$

The most important case corresponds to  $m = n = 1$ :  $m_{11} = R_{\underline{x}\underline{y}}$  is called the **statistical correlation** between  $\underline{x}$  and  $\underline{y}$ . Under a frequentist perspective,  $R_{\underline{x}\underline{y}}$  is the average of infinite products of samples  $x$  and  $y$  jointly drawn from  $f_{\underline{x},\underline{y}}(x, y)$ , which links the correlation to an inner product between the random variables. Indeed, when  $R_{\underline{x}\underline{y}} = 0$ ,  $\underline{x}$  and  $\underline{y}$  are called **orthogonal**. One can say the correlation quantifies the overall linear relationship between the two variables. Moreover, when  $R_{\underline{x}\underline{y}} = \bar{x}\bar{y}$ ,  $\underline{x}$  and  $\underline{y}$  are called mutually **uncorrelated**; this “separability” in the mean is weaker than the distribution separability implied by the independence. In fact, if  $\underline{x}$  and  $\underline{y}$  are independent,

$$\begin{aligned} R_{\underline{x}\underline{y}} &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} xy f_{\underline{x},\underline{y}}(x, y) dx dy = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} xy f_{\underline{x}}(x) f_{\underline{y}}(y) dx dy \\ &= \int_{-\infty}^{\infty} xf_{\underline{x}}(x) dx \int_{-\infty}^{\infty} yf_{\underline{y}}(y) dy = \bar{x}\bar{y}, \end{aligned} \quad (4.80)$$

i.e., they are also uncorrelated. The converse is not necessarily true.

An  $(n+k)$ th-order **joint central moment** of  $\underline{x}$  and  $\underline{y}$ , computed about the mean, has the general form

$$\mu_{nk} = E[((\underline{x} - \bar{x})^n (\underline{y} - \bar{y})^k)], \quad n, k \in \mathbb{Z}. \quad (4.81)$$

---

<sup>9</sup>Convolution integral:  $(a * b)(y) = \int_{-\infty}^{\infty} a(\tilde{y})b(y - \tilde{y})d\tilde{y}$ .

Once more, the case  $m = n = 1$  is specially important:  $\mu_{11} = C_{\underline{x}\underline{y}}$  is called the **statistical covariance** between  $\underline{x}$  and  $\underline{y}$ , which quantifies the linear relationship between their random parts. Since<sup>10</sup>  $C_{\underline{x}\underline{y}} = R_{\underline{x}\underline{y}} - \bar{x}\bar{y}$ ,  $\underline{x}$  and  $\underline{y}$  are uncorrelated when  $C_{\underline{x}\underline{y}} = 0$ . If  $C_{\underline{x}\underline{y}} > 0$ , one says  $\underline{x}$  and  $\underline{y}$  are positively correlated, i.e., the variations of their statistical samples tend to occur in the same direction; if  $C_{\underline{x}\underline{y}} < 0$ , one says  $\underline{x}$  and  $\underline{y}$  are negatively correlated, i.e., the variations of their statistical samples tend to occur in opposite directions. For example, the age and the annual medical expenses of an individual are expected to be positively correlated random variables. A normalized covariance can be computed as the correlation between the normalized versions of  $\underline{x}$  and  $\underline{y}$ :

$$\rho_{\underline{x}\underline{y}} = \frac{C_{\underline{x}\underline{y}}}{\sigma_{\underline{x}}\sigma_{\underline{y}}} = E \left[ \frac{\underline{x} - \bar{x}}{\sigma_{\underline{x}}} \cdot \frac{\underline{y} - \bar{y}}{\sigma_{\underline{y}}} \right], \quad (4.82)$$

known as the **correlation coefficient** between  $\underline{x}$  and  $\underline{y}$ ,  $-1 \leq \rho_{\underline{x}\underline{y}} \leq 1$ , and can be interpreted as the percentage of correlation between  $x$  and  $y$ . Recalling the inner product interpretation, the correlation coefficient can be seen as the cosine of the angle between the statistical variations of the two random variables.

Table 4.3 Statistical Distribution of $\underline{d}$		
$d_1$	$d_2$	$P_{d_1, d_2}$
-1	1	0.3
1	-1	0.6
1	1	0.1

Consider, for example, the discrete variables  $\underline{d}_1$  and  $\underline{d}_2$  jointly distributed as shown in Table 4.3. Their joint second-order parameters are:

- correlation  $R_{\underline{x}\underline{y}} = -0.80$ , indicating  $\underline{d}_1$  and  $\underline{d}_2$  are not orthogonal;
- covariance  $C_{\underline{x}\underline{y}} = -0.72$ , indicating  $\underline{d}_1$  and  $\underline{d}_2$  tend to evolve in opposite directions;
- correlation coefficient  $\rho_{\underline{x}\underline{y}} \approx -0.80$ , indicating this negative correlation is relatively strong.

Returning to  $N$ -dimensional random variables, the **characteristic function** of a vector random variable  $\underline{x}$  is defined as

$$\Phi_{\underline{x}}(\omega_1, \omega_2, \dots, \omega_N) = E[e^{j(\omega_1\underline{x}_1 + \omega_2\underline{x}_2 + \dots + \omega_N\underline{x}_N)}], \quad \omega_1, \omega_2, \dots, \omega_N \in \mathcal{R}, \quad (4.83)$$

and inter-relates the moments of order  $m_{n_1, n_2, \dots, n_N}$  by:

$$m_{n_1, n_2, \dots, n_N} = (-j)^{n_1+n_2+\dots+n_N} \left. \frac{\partial^{n_1+n_2+\dots+n_N} \Phi_{\underline{x}}(\omega_1, \omega_2, \dots, \omega_N)}{\partial \omega_1^{n_1} \partial \omega_2^{n_2} \dots \partial \omega_N^{n_N}} \right|_{\omega_1=\omega_2=\dots=\omega_N=0}. \quad (4.84)$$

The **moment generating function** of a vector random variable  $\underline{x}$  is defined as

$$M_{\underline{x}}(v_1, v_2, \dots, v_N) = E[e^{v_1\underline{x}_1 + v_2\underline{x}_2 + \dots + v_N\underline{x}_N}], \quad v_1, v_2, \dots, v_N \in \mathcal{R}, \quad (4.85)$$

<sup>10</sup>Equation (4.43) can be seen as the next expression computed for  $\underline{x} = \underline{y}$ , since  $R_{\underline{x}\underline{x}} = \bar{x^2}$  and  $C_{\underline{x}\underline{x}} = \sigma_x^2$ .

and allows the computation of  $m_{n_1, n_2, \dots, n_N}$  as:

$$m_{n_1, n_2, \dots, n_N} = \frac{\partial^{n_1+n_2+\dots+n_N} M_{\underline{x}}(\nu_1, \nu_2, \dots, \nu_N)}{\partial \nu_1^{n_1} \nu_2^{n_2} \cdots \partial \nu_N^{n_N}} \Bigg|_{\nu_1=\nu_2=\dots=\nu_N=0}. \quad (4.86)$$

### 1.04.3.9 Central limit theorem

A result that partially justifies the ubiquitous use of Gaussian models, the **Central Limit Theorem** (CLT) states that (under mild conditions in practice) the distribution of a sum  $\underline{y} = \sum_{n=1}^N \underline{x}_n$  of  $N$  independent variables  $\underline{x}_n$  approaches a Gaussian distribution as  $N \rightarrow \infty$ . Having completely avoided the CLT proof, we can at least recall that in this case,  $f_{\underline{y}}(y) = \lim_{N \rightarrow \infty} f_{\underline{y}}(y) = (f_{\underline{x}_1} * f_{\underline{x}_2} * \cdots * f_{\underline{x}_N})(y)$  (see Eq. (4.77)). Of course,  $\bar{y} = \sum_{n=1}^N \bar{x}_n$  and, by the independence property,  $\sigma_{\underline{y}}^2 = \sum_{n=1}^N \sigma_{\underline{x}_n}^2$ .

Gaussian approximations for finite- $N$  models are useful for sufficiently high  $N$ , but due to the shape of the Gaussian distribution, the approximation error grows as  $y$  distances from  $\bar{y}$ .

The reader is invited to verify the validity of the approximation provided by the CLT for successive sums of independent  $\underline{x}_n$  uniformly distributed in  $[0, 1]$ .

Interestingly, the CLT also applies to the sum of discrete distributions: even if  $f_{\underline{y}}(y)$  remains impulsive, the shape of  $F_{\underline{y}}(y)$  approaches the shape of the CDF of a Gaussian random variable as  $N$  grows.

### 1.04.3.10 Multivariate Gaussian distribution

The PDF of an  $N$ -dimensional Gaussian variable is defined as

$$f_{\underline{x}}(\underline{x}) = \frac{1}{\sqrt{(2\pi)^N \det(\mathbf{C}_{\underline{x}})}} e^{-\frac{(\underline{x}-\bar{\underline{x}})^T \mathbf{C}_{\underline{x}}^{-1} (\underline{x}-\bar{\underline{x}})}{2}}, \quad (4.87)$$

where  $\bar{\underline{x}}$  is an  $N \times 1$  vector with elements  $\{\bar{\underline{x}}\}_n = \bar{x}_n$ ,  $1 \leq n \leq N$ , and  $\mathbf{C}_{\underline{x}}$  is an  $N \times N$  matrix with elements  $\{\mathbf{C}_{\underline{x}}\}_{mn} = C_{\underline{x}_m \underline{x}_n}$ ,  $1 \leq m, n \leq N$ , such that any related marginal distribution remains Gaussian. As a consequence, by Eq. (4.74), any conditional distribution  $f_{\underline{x}}(\underline{x}|B)$  with point conditioning  $B$  is also Gaussian.

By this definition, we can see the Gaussian distribution is completely defined by its first- and second-order moments, which means that if  $N$  jointly distributed random variables are known to be Gaussian, estimating their **mean-vector**  $\bar{\underline{x}}$  and their **covariance-matrix**  $\mathbf{C}_{\underline{x}}$  is equivalent to estimate their overall PDF. Moreover, if  $\underline{x}_m$  and  $\underline{x}_n$  are mutually uncorrelated,  $\forall m \neq n$ , then  $\mathbf{C}_{\underline{x}}$  is diagonal, and the joint PDF becomes  $f_{\underline{x}}(\underline{x}) = \prod_{n=1}^N f_{\underline{x}_n}(x_n)$ , i.e.,  $\underline{x}_n$  will be mutually independent. This is a strong result inherent to Gaussian distributions.

### 1.04.3.11 Transformation of vector random variables

The treatment of a general multiple random variable  $\underline{y} = \mathbf{T}(\underline{x})$  resulting from the application of the transformation  $\mathbf{T}(\cdot)$  to the multiple variable  $\underline{x}$  always starts by enforcing  $F_{\underline{x}}(\underline{x}) = F_{\underline{y}}(\underline{y})$ , with  $\underline{y} = \mathbf{T}(\underline{x})$ .

The special case when  $\mathbf{T}$  is invertible, i.e.,  $\underline{\mathbf{x}} = \mathbf{T}^{-1}(\underline{\mathbf{y}})$  (or  $\underline{x}_n = T_n^{-1}(\underline{\mathbf{y}})$ ,  $1 \leq n \leq N$ ), follows a closed expression:

$$f_{\underline{\mathbf{y}}}(\underline{\mathbf{y}}) = f_{\underline{\mathbf{x}}}(\underline{\mathbf{x}} = \mathbf{T}^{-1}(\underline{\mathbf{y}}))|J|, \quad (4.88)$$

where

$$J = \det \left( \begin{bmatrix} \frac{\partial T_1^{-1}}{\partial y_1} & \frac{\partial T_1^{-1}}{\partial y_2} & \cdots & \frac{\partial T_1^{-1}}{\partial y_N} \\ \frac{\partial T_2^{-1}}{\partial y_1} & \frac{\partial T_2^{-1}}{\partial y_2} & \cdots & \frac{\partial T_2^{-1}}{\partial y_N} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial T_N^{-1}}{\partial y_1} & \frac{\partial T_N^{-1}}{\partial y_2} & \cdots & \frac{\partial T_N^{-1}}{\partial y_N} \end{bmatrix} \right). \quad (4.89)$$

The reader should notice that this expression with  $N = 1$  reduces to Eq. (4.51) particularized to the invertible case.

Given the multiple random variable  $\underline{\mathbf{x}}$  with known mean-vector  $\bar{\mathbf{x}}$  and covariance-matrix  $\mathbf{C}_{\underline{\mathbf{x}}}$ , its linear transformation  $\underline{\mathbf{y}} = \mathbf{T}\underline{\mathbf{x}}$  will have:

- a mean-vector  $\bar{\mathbf{y}} = \mathbf{T}\bar{\mathbf{x}}$ ,
- a covariance-matrix  $\mathbf{C}_{\underline{\mathbf{y}}} = \mathbf{T}\mathbf{C}_{\underline{\mathbf{x}}}\mathbf{T}^T$ .

It is possible to show that the linear transformation  $\underline{\mathbf{y}}$  of an  $N$ -dimensional Gaussian random variable  $\underline{\mathbf{x}}$  is also Gaussian. Therefore, in this case the two expressions above completely determine the PDF of the transformed variable.

The generation of samples that follow a desired multivariate probabilistic distribution from samples that follow another known multivariate probabilistic distribution applies the same reasoning followed in the univariate case to the multivariate framework. The reader is invited to show that given the pair  $x_1, x_2$  of samples from the random variables  $\underline{x}_1, \underline{x}_2$ , jointly uniform in the region  $0 \leq x \leq 1, 0 \leq y \leq 1$ , it is possible to generate the pair  $y_1, y_2$  of samples from the random variables  $\underline{y}_1, \underline{y}_2$ , jointly Gaussian with the desired parameters  $\bar{y}_1, \sigma_{y_1}^2, \bar{y}_2, \sigma_{y_2}^2$ , and  $\rho_{y_1 y_2}$  by making

$$\begin{cases} y_1 = \bar{y}_1 + \sigma_{y_1} \sqrt{-2 \ln x_1} \cos(2\pi x_2), \\ y_2 = \bar{y}_2 + \rho_{y_1 y_2} \sigma_{y_2} \sqrt{-2 \ln x_1} \cos(2\pi x_2) + \sigma_{y_2} \sqrt{1 - \rho_{y_1 y_2}^2} \sqrt{-2 \ln x_1} \sin(2\pi x_2). \end{cases} \quad (4.90)$$

### 1.04.3.12 Complex random variables

At first sight, defining a complex random variable  $\underline{z}$  may seem impossible, since the seminal event  $\{\underline{z} \leq z\}$  makes no sense. However, in the vector random variable framework this issue can be circumvented if one jointly describes the real and imaginary parts (or magnitude and phase) of  $\underline{z}$ .

The single complex random variable  $\underline{z} = \underline{x} + j\underline{y}$ ,  $x, y \in \mathcal{R}$ , is completely represented by  $f_{\underline{x}, \underline{y}}(x, y)$ , which allows one to compute the expected value of a scalar function  $g(\underline{z})$  as  $E[g(\underline{z})] = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} g(z) f_{\underline{x}, \underline{y}}(x, y) dx dy$ . Moreover, we can devise general definitions for the mean and variance of  $\underline{z}$  as, respectively:

- $\bar{\underline{z}} = \bar{\underline{x}} + j\bar{\underline{y}}$ ;
- $\sigma_{\underline{z}}^2 = E[|\underline{z} - \bar{\underline{z}}|^2] = \sigma_{\underline{x}}^2 + \sigma_{\underline{y}}^2$ , which measures the spread of  $\underline{z}$  about its mean in the complex plan.

An  $N$ -dimensional complex random variable  $\underline{z} = \underline{x} + j\underline{y}$  can be easily tackled through a properly defined joint distribution, e.g.,  $f_{\underline{x}, \underline{y}}(\underline{x}, \underline{y})$ . The individual variables  $z_n$ ,  $1 \leq n \leq N$ , will be independent when

$$f_{\underline{x}, \underline{y}}(\underline{x}, \underline{y}) = \prod_{n=1}^N f_{x_n, y_n}(x_n, y_n). \quad (4.91)$$

The following definitions must be generalized to cope with complex random variables:

- correlation:  $R_{z_1 z_2} = E[z_1^* z_2]$ ;
- covariance:  $C_{z_1 z_2} = E[(z_1 - \bar{z}_1)^*(z_2 - \bar{z}_2)]$ .

Now,  $C_{z_1 z_2} = R_{z_1 z_2} - \bar{z}_1^* \bar{z}_2$ . As before,  $z_1$  and  $z_2$  will be:

- orthogonal when  $R_{z_1 z_2} = 0$ ;
- uncorrelated when  $C_{z_1 z_2} = 0$ .

### 1.04.3.13 An application: estimators

One of the most encompassing applications of vector random variables is the so-called **parameter estimation**, per se an area supported by its own theory. The typical framework comprises using a finite set of measured data from a given phenomenon to estimate the parameters<sup>11</sup> of its underlying model.

A set  $\underline{x}_1, \underline{x}_2, \dots, \underline{x}_N$  of  $N$  independent identically distributed (**iid**) random variables such that

$$f_{\underline{x}}(\underline{x}) = \prod_{n=1}^N f_{\underline{x}}(x_n) \quad (4.92)$$

can describe an  $N$ -size **random sample** of a population modeled by  $f_{\underline{x}}(x)$ . Any function  $g(\underline{x})$  (called a **statistic** of  $\underline{x}$ ) can constitute a **point estimator**  $\hat{\theta}$  of some parameter  $\theta$  such that given an  $N$ -size sample  $x_1, x_2, \dots, x_N$  of  $\underline{x}$ , one can compute an estimate  $\hat{\theta} = g(\underline{x})$  of  $\theta$ .

A classical example of point estimator for a fixed parameter is the so-called **sample mean**, which estimates  $\theta = \bar{x}$  by the arithmetic mean of the available samples  $x_n$ ,  $n = 1, 2, \dots, N$ :

$$\hat{\bar{x}}_N = \frac{1}{N} \sum_{n=1}^N x_n. \quad (4.93)$$

Not always defining a desired estimator is trivial task as in the previous example. In general, resorting to a proper analytical criterion is necessary. Suppose we are given the so-called likelihood function of  $\theta$ ,  $L(\theta) = f_{\underline{x}}(\underline{x}|\theta)$ , which provides a probabilistic model for  $\underline{x}$  as an explicit function of  $\theta$ . Given the sample  $\underline{x}$ , the so-called **maximum likelihood** (ML) estimator  $\hat{\theta}_{\text{ML}}$  computes an estimate of  $\theta$  by direct maximization of  $L(\theta)$ . This operation is meant to find the value of  $\theta$  that would make the available sample  $\underline{x}$  most probable.

---

<sup>11</sup>We will tackle only scalar parameters, without loss of generality.

Sometimes the parameter  $\theta$  itself can be a sample of a random variable  $\underline{\theta}$  described by an a priori PDF  $f_{\underline{\theta}}(\theta)$ . For example, suppose one wants to estimate the mean value of a shipment of components received from a given factory; since the components may come from several production units, we can think of a statistical model for their nominal values. In such situations, any reliable information on the parameter distribution can be taken in account to better tune the estimator formulation; these so-called **Bayesian estimators** rely on the a posteriori PDF of  $\theta$ :

$$f_{\underline{\theta}}(\theta|\mathbf{x}) = \frac{f_{\underline{\mathbf{x}}, \underline{\theta}}(\mathbf{x}, \theta)}{f_{\underline{\mathbf{x}}}(\mathbf{x})} \propto L(\theta) f_{\underline{\theta}}(\theta). \quad (4.94)$$

Given a sample  $\mathbf{x}$ , the so-called **maximum a posteriori** (MAP) estimator  $\hat{\underline{\theta}}_{\text{MAP}}$  computes an estimate of  $\theta$  as the mode of  $f_{\underline{\theta}}(\theta|\mathbf{x})$ . This choice is meant to find the most probable  $\theta$  that would have produced the available data  $\mathbf{x}$ . Several applications favor the **posterior mean** estimator, which for a given sample  $\mathbf{x}$  computes  $\hat{\underline{\theta}}_{\text{PM}} = E[\underline{\theta}|\mathbf{x}]$ , over the MAP estimator.

The quality of an estimator  $\underline{\theta}$  can be assessed through some of its statistical properties.<sup>12</sup> An overall measure of the estimator performance is its **mean square error**  $\text{MSE}(\hat{\underline{\theta}}) = E[(\theta - \hat{\underline{\theta}})^2]$ , which can be decomposed in two parts:

$$\text{MSE}(\hat{\underline{\theta}}) = b^2(\hat{\underline{\theta}}) + \sigma_{\hat{\underline{\theta}}}^2, \quad (4.95)$$

where  $b(\hat{\underline{\theta}}) = E[\theta - \hat{\underline{\theta}}]$  is the estimator **bias** and  $\sigma_{\hat{\underline{\theta}}}^2$  is its **variance**. The bias measures the deterministic part of the error, i.e., how much the estimates deviate from the target in the mean, thus providing an **accuracy** measure: the smaller its bias, the more accurate the estimator. The variance, by its turn, measures the random part of the error, i.e., how much the estimates spread about their mean, thus providing a **precision** measure: the smaller its variance, the more precise the estimator. Another property attributable to an estimator is **consistency**<sup>13</sup>:  $\hat{\underline{\theta}}$  is said to be consistent when  $\lim_{N \rightarrow \infty} P(|\hat{\underline{\theta}} - \theta| \geq \epsilon) = 0, \forall \epsilon > 0$ . Using the Chebyshev inequality (see Section 1.04.3.4), one finds that an unbiased estimator with  $\lim_{N \rightarrow \infty} \sigma_{\hat{\underline{\theta}}}^2 = 0$  is consistent. It can be shown that the sample mean defined in Eq. (4.93) has  $b(\hat{\underline{x}}_N) = 0$  (thus is unbiased) and  $\sigma_{\hat{\underline{x}}_N}^2 = \frac{\sigma_x^2}{N}$  (thus is consistent). The similarly built estimator for  $\sigma_x^2$ , the **unbiased sample variance**, computes

$$\widehat{\sigma}_{\underline{x}}^2 = \frac{1}{N-1} \sum_{n=1}^N \left( x_n - \hat{\underline{x}}_N \right)^2. \quad (4.96)$$

The reader is invited to prove that this estimator is unbiased, while its more intuitive form with denominator  $N$  instead of  $N-1$  is not.

One could argue how much reliable a point estimation is. In fact, if the range of  $\theta$  is continuous, one can deduce that  $P(\{\hat{\underline{\theta}} = \theta\}) = 0$ . However, perhaps we would feel safer if the output of an estimator were something like “ $\theta_1 \leq \theta \leq \theta_2$  with probability  $p$ .”  $\theta_1$  and  $\theta_2$  are the confidence limits and  $p$  is the confidence of this **interval estimate**.

<sup>12</sup>For the sake of simplicity, we refer only to the estimation of a fixed parameter  $\theta$ .

<sup>13</sup>There are other definitions of consistency.

**Example 2.** Suppose we use a 10-size sample mean to estimate  $\bar{x}$  of a unit-variance Gaussian random variable  $\underline{x}$ . Determine the 95%-confidence interval for the estimates.

**Solution 2.** It is easy to find that  $\hat{\bar{x}}_{10}$  is a Gaussian random variable with  $E[\hat{\bar{x}}_{10}] = \bar{x}$  and  $\sigma_{\hat{\bar{x}}_{10}}^2 = 0.1$ . We should find  $a$  such that  $P(\{\hat{\bar{x}}_{10} - a \leq \bar{x} \leq \hat{\bar{x}}_{10} + a\}) = 0.95$ , or  $P(|\bar{x} - \hat{\bar{x}}_{10}| \leq a) = 0.95$ . For the associated normalized Gaussian random variable,  $P\left(\left\{-1.96 \leq \frac{\bar{x} - \hat{\bar{x}}_{10}}{1/\sqrt{10}} \leq 1.96\right\}\right) \approx 0.95$ . Then,  $a \approx 0.62$ .

## 1.04.4 Random process

If the outcomes  $s$  of a given random experiment are amenable to variation in time  $t$ , each one can be mapped by some  $\underline{x}(s(t))$  into a real function  $x(t)$ . This is a direct generalization of the random variable. As a result, we get an infinite **ensemble** of time-varying **sample functions** or **realizations**  $x(t)$  which form the so-called **stochastic** or **random process**  $\underline{x}(t)$ . For a fixed  $t_0$ ,  $x(t_0)$  reduces to a single random variable, thus a random process can be seen as a time-ordered multiple random variable. An example of random process is the simultaneous observation of air humidity at every point of the globe,  $\underline{h}(t)$ : each realization  $h(t)$  describes the humidity variation in time at a randomly chosen place on the earth whereas the random variable  $\underline{h}(t_0)$  describes the distribution of air humidity over the earth at instant  $t_0$ . A similar construction in the discrete time  $n$  domain would produce  $\underline{x}[n]$  composed of realizations  $x[n]$ . If the hourly measures of air humidity substitute for its continuous measure in the former example, we get a new random process  $\underline{h}[n]$ .

As seen, there can be **continuous-** or **discrete-time** random processes. Since random variables have already been classified as continuous or discrete, one analogously refers to **continuous-valued** and **discrete-valued** random processes. Combining these two classifications according to time and value is bound to result ambiguous or awkwardly lengthy; when this complete categorization is necessary, one favors the nomenclature **random process** for the continuous-time case and **random sequence** for the discrete-time case, using the words “continuous” and “discrete” only with reference to amplitude values.<sup>14</sup> In the former examples, the continuous random process  $\underline{h}(t)$  and random sequence  $\underline{h}[n]$  would model the idealized actual air humidity as a physical variable, whereas the practical digitized measures of air humidity would be modeled by their discrete counterparts.

### 1.04.4.1 Distributions of random processes and sequences

One could think of the complete description of a random process or sequence as a joint CDF (or PDF) encompassing every possible instant of time  $t$  or  $n$ , respectively, which is obviously impractical. However, their partial representation by  $L$ th-order distributions (employing a slightly modified notation to include the reference to time) can be useful. The CDF of a random process  $\underline{x}(t)$  can be defined as

$$F_{\underline{x}}(x_1, x_2, \dots, x_L; t_1, t_2, \dots, t_L) = P(\{\underline{x}(t_1) \leq x_1, \underline{x}(t_2) \leq x_2, \dots, \underline{x}(t_L) \leq x_L\}), \quad (4.97)$$

<sup>14</sup>In this text, for completeness we opted for always explicitly writing both formulations, for processes and sequences.

with an associated PDF

$$f_{\underline{x}}(x_1, x_2, \dots, x_L; t_1, t_2, \dots, t_L) = \frac{\partial^L F_{\underline{x}}(x_1, x_2, \dots, x_L; t_1, \dots, t_L)}{\partial x_1 \partial x_2 \dots \partial x_L}. \quad (4.98)$$

The CDF of a random sequence  $\underline{x}[n]$  can be defined as

$$F_{\underline{x}}(x_1, x_2, \dots, x_L; n_1, n_2, \dots, n_L) = P(\{x[n_1] \leq x_1, x[n_2] \leq x_2, \dots, x[n_L] \leq x_L\}), \quad (4.99)$$

with an associated PDF

$$f_{\underline{x}}(x_1, x_2, \dots, x_L; n_1, n_2, \dots, n_L) = \frac{\partial^L F_{\underline{x}}(x_1, x_2, \dots, x_L; n_1, n_2, \dots, n_L)}{\partial x_1 \partial x_2 \dots \partial x_L}. \quad (4.100)$$

This convention can be easily extended to the joint distributions of  $M$  random processes  $x_m(t)$ ,  $m = 1, 2, \dots, M$  (sequences  $x_m[n]$ ,  $m = 1, 2, \dots, M$ ), as will be seen in the next subsection. The notation for point-conditioned distributions can also be promptly inferred (see Section 1.04.4.12).

### 1.04.4.2 Statistical independence

As with random variables, the mutual independence of random processes or sequences is tested by the complete separability of their respective distributions. The random processes  $x_m(t)$ ,  $m = 1, 2, \dots, M$ , are independent when

$$\begin{aligned} & f_{x_1, x_2, \dots, x_M}(x_{11}, x_{12}, \dots, x_{1L_1}, x_{21}, x_{22}, \dots, x_{2L_2}, \dots, x_{M1}, x_{M2}, \dots, x_{ML_M}; \\ & t_{11}, t_{12}, \dots, t_{1L_1}, t_{21}, t_{22}, \dots, t_{2L_2}, \dots, t_{M1}, t_{M2}, \dots, t_{ML_M}) \\ &= \prod_{m=1}^M f_{x_m}(x_{m1}, x_{m2}, \dots, x_{mL_m}; t_{m1}, t_{m2}, \dots, t_{mL_m}) \end{aligned} \quad (4.101)$$

for any choice of time instants. Similarly, the random sequences  $x_m[n]$ ,  $m = 1, 2, \dots, M$ , are independent when

$$\begin{aligned} & f_{x_1, x_2, \dots, x_M}(x_{11}, x_{12}, \dots, x_{1L_1}, x_{21}, x_{22}, \dots, x_{2L_2}, \dots, x_{M1}, x_{M2}, \dots, x_{ML_M}; \\ & n_{11}, n_{12}, \dots, n_{1L_1}, n_{21}, n_{22}, \dots, n_{2L_2}, \dots, n_{M1}, n_{M2}, \dots, n_{ML_M}) \\ &= \prod_{m=1}^M f_{x_m}(x_{m1}, x_{m2}, \dots, x_{mL_m}; n_{m1}, n_{m2}, \dots, n_{mL_m}) \end{aligned} \quad (4.102)$$

for any choice of time instants.

### 1.04.4.3 First- and second-order moments for random processes and sequences

It is not necessary to redefine moments in the context of random processes and sequences, since we will always be tackling a set of random variables as in Section 1.04.3.8. But it is useful to revisit the first- and second-order cases with a slightly modified notation to include time information.

For a random process  $\underline{x}(t)$ , the following definitions apply:

- the **mean**  $\bar{x}(t) = E[\underline{x}(t)]$ ;
- the **mean square value or mean instantaneous power**  $\bar{x}^2(t) = E[\underline{x}^2(t)]$ ;
- the **variance**  $\sigma_{\underline{x}}^2(t) = E[(\underline{x}(t) - \bar{x}(t))^2]$ ;
- the **auto-correlation**  $R_{xx}(t_1, t_2) = E[\underline{x}(t_1)\underline{x}(t_2)]$ ;
- the **auto-covariance**  $C_{xx}(t_1, t_2) = E[(\underline{x}(t_1) - \bar{x}(t_1))(\underline{x}(t_2) - \bar{x}(t_2))]$ .

As seen for random variables,

$$\sigma_{\underline{x}}^2(t) = \bar{x}^2(t) - \bar{x}^2(t) \Rightarrow \bar{x}^2(t) = \bar{x}^2(t) + \sigma_{\underline{x}}^2(t), \quad (4.103)$$

which means that the mean instantaneous power of the process is the sum of a deterministic parcel with a random parcel.

Analogously, for a random sequence  $\underline{x}[n]$ , the following definitions apply:

- the **mean**  $\bar{x}[n] = E[\underline{x}[n]]$ ;
- the **mean square value or mean instantaneous power**  $\bar{x}^2[n] = E[\underline{x}^2[n]]$ ;
- the **variance**  $\sigma_{\underline{x}}^2[n] = E[(\underline{x}[n] - \bar{x}[n])^2]$ ;
- the **auto-correlation**  $R_{xx}[n_1, n_2] = E[\underline{x}[n_1]\underline{x}[n_2]]$ ;
- the **auto-covariance**  $C_{xx}[n_1, n_2] = E[(\underline{x}[n_1] - \bar{x}[n_1])(\underline{x}[n_2] - \bar{x}[n_2])]$ .

Again,

$$\sigma_{\underline{x}}^2[n] = \bar{x}^2[n] - \bar{x}^2[n] \Rightarrow \bar{x}^2[n] = \bar{x}^2[n] + \sigma_{\underline{x}}^2[n], \quad (4.104)$$

i.e., the mean instantaneous power of the sequence is the sum of a deterministic parcel with a random parcel.

Given two random processes  $\underline{x}(t)$  and  $\underline{y}(t)$ , one defines:

- the **cross-correlation**  $R_{xy}(t_1, t_2) = E[\underline{x}(t_1)\underline{y}(t_2)]$ ;
- the **cross-covariance**  $C_{xy}(t_1, t_2) = E[(\underline{x}(t_1) - \bar{x}(t_1))(\underline{y}(t_2) - \bar{y}(t_2))]$ .

The processes  $\underline{x}(t)$  and  $\underline{y}(t)$  are said to be mutually:

- **orthogonal** when  $R_{xy}(t_1, t_2) = 0, \forall t_1 \neq t_2$ ;
- **uncorrelated** when  $C_{xy}(t_1, t_2) = 0$ , which is the same as  $R_{xy}(t_1, t_2) = \bar{x}(t_1)\bar{y}(t_2) \forall t_1 \neq t_2$ .

The mean instantaneous power of  $(\underline{x}(t) + \underline{y}(t))$  is given by

$$E[(\underline{x}(t) + \underline{y}(t))^2] = \bar{x}^2(t) + 2E[\underline{x}(t)\underline{y}(t)] + \bar{y}^2(t), \quad (4.105)$$

which suggests the definition of  $E[\underline{x}(t)\underline{y}(t)]$  as the **mean instantaneous cross power** between  $\underline{x}(t)$  and  $\underline{y}(t)$ .

Analogously, given two random sequences  $\underline{x}[n]$  and  $\underline{y}[n]$ , one defines:

- the **cross-correlation**  $R_{xy}[n_1, n_2] = E[\underline{x}[n_1]\underline{y}[n_2]]$ ;
- the **cross-covariance**  $C_{xy}[n_1, n_2] = E[(\underline{x}[n_1] - \bar{x}[n_1])(\underline{y}[n_2] - \bar{y}[n_2])]$ .

The sequences  $\underline{x}[n]$  and  $\underline{y}[n]$  are said to be mutually:

- **orthogonal** when  $R_{xy}[n_1, n_2] = 0, \forall n_1 \neq n_2$ ;

- **uncorrelated** when  $C_{\underline{x}\underline{y}}[n_1, n_2] = 0$ , which is the same as  $R_{\underline{x}\underline{y}}[n_1, n_2] = \bar{\underline{x}}[n_1] \bar{\underline{y}}[n_2] \forall n_1 \neq n_2$ .

The mean instantaneous power of  $(\underline{x}[n] + \underline{y}[n])$  is given by

$$E[(\underline{x}[n] + \underline{y}[n])^2] = \bar{\underline{x}}^2[n] + 2E[\underline{x}[n]\underline{y}[n]] + \bar{\underline{y}}^2[n], \quad (4.106)$$

which suggests the definition of  $E[\underline{x}[n]\underline{y}[n]]$  as the **mean instantaneous cross power** between  $\underline{x}[n]$  and  $\underline{y}[n]$ .

The interpretation of this “cross power” is not difficult: it accounts for the constructive or destructive interaction of the two involved processes (sequences) as dictated by their mutual correlation.

We will dedicate some space later to the properties of second-order moments.

#### 1.04.4.4 Stationarity

The stationarity of random processes and sequences refers to the time-invariance of their statistical properties, which turns their treatment considerably easier.

**Strict-sense** is the strongest class of stationarity. A strict-sense stationary (SSS) random process  $\underline{x}(t)$  (sequence  $\underline{x}[n]$ ) bears exactly the same statistical properties as  $\underline{x}(t + \Delta t)$ ,  $\forall \Delta t \in \mathcal{R}$  ( $\underline{x}[n + \Delta n]$ ,  $\forall \Delta n \in \mathcal{Z}$ ), which means that its associated joint distribution for any set of time instants does not change when they are all shifted by the same time lag. A random process (sequence) in which each realization is a constant sampled from some statistical distribution in time is SSS.

Under this perspective, we can define that a random process  $\underline{x}(t)$  is **Lth-order** stationary when

$$F_{\underline{x}}(x_1, x_2, \dots, x_L; t_1, t_2, \dots, t_L) = F_{\underline{x}}(x_1, x_2, \dots, x_L; t_1 + \Delta t, t_2 + \Delta t, \dots, t_L + \Delta t) \quad (4.107)$$

or, alternatively,

$$f_{\underline{x}}(x_1, x_2, \dots, x_L; t_1, t_2, \dots, t_L) = f_{\underline{x}}(x_1, x_2, \dots, x_L; t_1 + \Delta t, t_2 + \Delta t, \dots, t_L + \Delta t). \quad (4.108)$$

Analogously, a random sequence  $\underline{x}[n]$  is **Lth-order** stationary when

$$F_{\underline{x}}(x_1, x_2, \dots, x_L; n_1, n_2, \dots, n_L) = F_{\underline{x}}(x_1, x_2, \dots, x_L; n_1 + \Delta n, n_2 + \Delta n, \dots, n_L + \Delta n) \quad (4.109)$$

or, alternatively,

$$f_{\underline{x}}(x_1, x_2, \dots, x_L; n_1, n_2, \dots, n_L) = f_{\underline{x}}(x_1, x_2, \dots, x_L; n_1 + \Delta n, n_2 + \Delta n, \dots, n_L + \Delta n). \quad (4.110)$$

We can say that an SSS random process or sequence is stationary for any order  $L$ . Moreover,  $L$ th-order stationarity implies  $(L - 1)$ th-order stationarity, by marginalization at both sides of any of the four equations above.

First-order stationarity says the statistical distribution at any individual instant of time  $t$  ( $n$ ) is the same, i.e.,  $f_{\underline{x}}(\underline{x}; t)$  does not depend on  $t$  ( $f_{\underline{x}}(\underline{x}; n)$  does not depend on  $n$ ). A natural consequence is the time-invariance of its statistical mean:  $\bar{\underline{x}}(t) = \bar{\underline{x}}$  ( $\bar{\underline{x}}[n] = \bar{\underline{x}}$ ). Second-order stationarity says the joint statistical distribution at any two time instants  $t$  and  $t + \tau$  for a fixed  $\tau$  ( $n$  and  $n + k$  for a fixed  $k$ ) is the same. A natural consequence is the time-invariance of its auto-correlation, which can depend only of the time lag between the two time instants:  $R_{\underline{x}\underline{x}}(t, t + \tau) = R_{\underline{x}\underline{x}}(\tau)$  ( $R_{\underline{x}\underline{x}}[n, n + k] = R_{\underline{x}\underline{x}}[k]$ ).

A weaker class of stationarity called **wide-sense** is much used in practice for its simple testability. A random process  $\underline{x}(t)$  (sequence  $\underline{x}[n]$ ) is said to be wide-sense stationary (WSS) when its mean and auto-correlation are time-invariant. Such conditions do not imply stationarity of any order, although second-order stationarity implies wide-sense stationarity. As an extension of such definition, one says that two processes  $\underline{x}(t)$  and  $\underline{y}(t)$  (sequences  $\underline{x}[n]$  and  $\underline{y}[n]$ ) are jointly WSS when they are individually WSS and their cross-correlation is time-invariant, i.e., can depend only of the time lag between the two time instants:  $R_{\underline{x}\underline{y}}(t, t + \tau) = R_{\underline{x}\underline{y}}(\tau)$  ( $R_{\underline{x}\underline{y}}[n, n + k] = R_{\underline{x}\underline{y}}[k]$ ).

#### 1.04.4.5 Properties of correlation functions for WSS processes and sequences

Wide-sense stationarity in random processes and sequences induces several interesting properties, some of which are listed below. For processes,

- $|R_{\underline{x}\underline{x}}(\tau)| \leq R_{\underline{x}\underline{x}}(0);$
- $R_{\underline{x}\underline{x}}(-\tau) = R_{\underline{x}\underline{x}}(\tau);$
- If  $\lim_{\tau \rightarrow \infty} R_{\underline{x}\underline{x}}(\tau) = B$ ,  $B = \bar{x}^2$ ;
- If  $\underline{x}(t)$  has a periodic component,  $R_{\underline{x}\underline{x}}(\tau)$  has the same periodic component;
- $R_{\underline{x}\underline{y}}(-\tau) = R_{\underline{y}\underline{x}}(\tau);$
- $R_{\underline{x}\underline{y}}(\tau) \leq \sqrt{R_{\underline{x}\underline{x}}(0)R_{\underline{y}\underline{y}}(0)};$
- $R_{\underline{x}\underline{y}}(\tau) \leq \frac{R_{\underline{x}\underline{x}}(0) + R_{\underline{y}\underline{y}}(0)}{2}.$

For sequences,

- $|R_{\underline{x}\underline{x}}[k]| \leq R_{\underline{x}\underline{x}}[0];$
- $R_{\underline{x}\underline{x}}[-k] = R_{\underline{x}\underline{x}}[k];$
- If  $\lim_{k \rightarrow \infty} R_{\underline{x}\underline{x}}[k] = B$ ,  $B = \bar{x}^2$ ;
- If  $\underline{x}[n]$  has a periodic component,  $R_{\underline{x}\underline{x}}[k]$  has the same periodic component;
- $R_{\underline{x}\underline{y}}[-k] = R_{\underline{y}\underline{x}}[k];$
- $R_{\underline{x}\underline{y}}[k] \leq \sqrt{R_{\underline{x}\underline{x}}[0]R_{\underline{y}\underline{y}}[0]};$
- $R_{\underline{x}\underline{y}}[k] \leq \frac{R_{\underline{x}\underline{x}}[0] + R_{\underline{y}\underline{y}}[0]}{2}.$

Even if the properties are not proven here, some interesting observations can be traced about them:

- The statistical behavior of the process (sequence) at a given instant of time is maximally correlated with itself, an intuitive result.
- The autocorrelation commutes.
- The statistical behaviors of a WSS process (sequence) with no periodic components at two time instants separated by  $\tau \rightarrow \infty$  ( $k \rightarrow \infty$ ) are uncorrelated. Then, the autocorrelation tends to the product of two identical statistical means.
- Periodic components in the process (sequence) cause the correlation maximum and surrounding behavior to repeat at each fundamental period.
- The arithmetic and geometric mean properties are in a certain sense linked to the first property. The second property is more stringent than the first.

#### 1.04.4.6 Time averages of random processes and sequences

The proper use of random processes and sequences to model practical problems depends on the careful understanding of both their statistical and time variations. The main difference between these two contexts, which must be kept in mind, is the fact that time is inexorably ordered, thus allowing the inclusion in the model of some deterministic (predictable) time-structure. When we examine the statistical auto-correlation between two time instants of a random process or sequence, we learn how the statistical samples taken at those instants follow each other. In a WSS process or sequence, this measure for different lags can convey an idea of statistical periodicity.<sup>15</sup> But what if one is concerned with the time structure and characteristics of each (or some) individual realization of a given process or sequence? The use of time averages can provide this complementary description.

The time average of a given continuous-time function  $f(t)$  can be defined as

$$A[f(t)] = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T f(t) dt. \quad (4.111)$$

Given the random process  $\underline{x}(t)$ , the **time average** of any of its realizations  $x(t)$  is

$$\bar{x} = A[x(t)]. \quad (4.112)$$

The **average power** of  $x(t)$  is

$$\mathcal{P}_{xx} = A[x^2(t)]. \quad (4.113)$$

The **time auto-correlation** of  $x(t)$  for a lag  $\tau$  is defined as

$$\mathcal{R}_{xx}(\tau) = A[x(t)x(t + \tau)]. \quad (4.114)$$

The **time cross-correlation** between the realizations  $x(t)$  of process  $\underline{x}(t)$  and  $y(t)$  of process  $\underline{y}(t)$  for a lag  $\tau$  is defined as

$$\mathcal{R}_{xy}(\tau) = A[x(t)y(t + \tau)]. \quad (4.115)$$

As in the statistical case, an **average cross power** between  $x(t)$  and  $y(t)$ , which accounts for their mutual constructive or destructive interferences due to their time structure, can be defined as

$$\mathcal{P}_{xy} = A[x(t)y(t)]. \quad (4.116)$$

Computed for the complete ensemble, such measures produce the random variables  $\bar{x}$ ,  $\mathcal{P}_{xx}$ ,  $\mathcal{R}_{xx}(\tau)$ ,  $\mathcal{R}_{xy}(\tau)$ , and  $\mathcal{P}_{xy}$ , respectively. Under mild convergence conditions,

$$E[\bar{x}] = E[A[\underline{x}(t)]] = A[E[\underline{x}(t)]] = A[\bar{x}(t)], \quad (4.117)$$

$$E[\mathcal{P}_{xx}] = E[A[\underline{x}^2(t)]] = A[E[\underline{x}^2(t)]] = A[\bar{x}^2(t)], \quad (4.118)$$

$$E[\mathcal{R}_{xx}(\tau)] = E[A[\underline{x}(t)\underline{x}(t + \tau)]] = A[E[\underline{x}(t)\underline{x}(t + \tau)]] = A[R_{xx}(t, t + \tau)], \quad (4.119)$$

$$E[\mathcal{R}_{xy}(\tau)] = E[A[\underline{x}(t)\underline{y}(t + \tau)]] = A[E[\underline{x}(t)\underline{y}(t + \tau)]] = A[R_{xy}(t, t + \tau)], \quad (4.120)$$

---

<sup>15</sup>We hinted this point when discussing the properties of second-order moments, in Section 1.04.4.5.

and

$$\mathbb{E}[\underline{\mathcal{P}}_{xy}] = \mathbb{E}[A[\underline{x}(t)\underline{y}(t)]] = A[\mathbb{E}[\underline{x}(t)\underline{y}(t)]], \quad (4.121)$$

which are respectively the overall mean value, mean power, and auto-correlation (for lag  $\tau$ ) of process  $\underline{x}(t)$ , and cross-correlation (for lag  $\tau$ ) and mean cross power between processes  $\underline{x}(t)$  and  $\underline{y}(t)$ .

The time average of a given discrete-time function  $f[n]$  can be defined as

$$A[f[n]] = \lim_{N \rightarrow \infty} \frac{1}{2N+1} \sum_{n=-N}^N f[n]. \quad (4.122)$$

Given the random sequence  $\underline{x}[n]$ , the **time average** of any of its realizations  $x[n]$  is

$$\bar{x} = A[x[n]]. \quad (4.123)$$

The **average power** of  $x[n]$  is

$$\underline{\mathcal{P}}_{xx} = A[x^2[n]]. \quad (4.124)$$

The **time auto-correlation** of  $x[n]$  for lag  $k$  is defined as

$$\mathcal{R}_{xx}[k] = A[x[n]x[n+k]]. \quad (4.125)$$

The **time cross-correlation** between the realizations  $x[n]$  of sequence  $\underline{x}[n]$  and  $y[n]$  of sequence  $\underline{y}[n]$  for lag  $k$  is defined as

$$\mathcal{R}_{xy} = A[x[n]y[n+k]]. \quad (4.126)$$

As in the statistical case, an **average cross power** between  $x[n]$  and  $y[n]$ , which accounts for their mutual constructive or destructive interferences due to their time structure, can be defined as

$$\underline{\mathcal{P}}_{xy} = A[x[n]y[n]]. \quad (4.127)$$

Computed for the complete ensemble, such measures produce the random variables  $\bar{x}$ ,  $\underline{\mathcal{P}}_{xx}$ ,  $\mathcal{R}_{xx}[k]$ ,  $\underline{\mathcal{R}}_{xy}[k]$ , and  $\underline{\mathcal{P}}_{xy}$ , respectively. Under mild convergence conditions,

$$\mathbb{E}[\bar{x}] = \mathbb{E}[A[\underline{x}[n]]] = A[\mathbb{E}[\underline{x}[n]]] = A[\bar{x}[n]], \quad (4.128)$$

$$\mathbb{E}[\underline{\mathcal{P}}_{xx}] = \mathbb{E}[A[\underline{x}^2[n]]] = A[\mathbb{E}[\underline{x}^2[n]]] = A[\bar{x}^2[n]], \quad (4.129)$$

$$\mathbb{E}[\mathcal{R}_{xx}[k]] = \mathbb{E}[A[\underline{x}[n]\underline{x}[n+k]]] = A[\mathbb{E}[\underline{x}[n]\underline{x}[n+k]]] = A[R_{xx}[n, n+k]], \quad (4.130)$$

$$\mathbb{E}[\underline{\mathcal{R}}_{xy}[k]] = \mathbb{E}[A[\underline{x}[n]\underline{y}[n+k]]] = A[\mathbb{E}[\underline{x}[n]\underline{y}[n+k]]] = A[R_{xy}[n, n+k]], \quad (4.131)$$

and

$$\mathbb{E}[\underline{\mathcal{P}}_{xy}] = \mathbb{E}[A[\underline{x}[n]\underline{y}[n]]] = A[\mathbb{E}[\underline{x}[n]\underline{y}[n]]], \quad (4.132)$$

which are respectively the overall mean value, mean power, and auto-correlation (for lag  $k$ ) of sequence  $\underline{x}[n]$ , and cross-correlation (for lag  $k$ ) and mean cross power between sequences  $\underline{x}[n]$  and  $\underline{y}[n]$ .

As an example, consider that a deterministic signal  $s(t) \neq 0$  (with  $A[s(t)] = 0$ ) is additively contaminated by random noise  $n(t)$  which can be modeled as a realization of the WSS random process  $\underline{n}(t)$  (with  $\bar{n}(t) = 0$  and  $\bar{n}^2(t) = \sigma_n^2$ ), thus yielding the random signal  $x(t) = s(t) + n(t)$ . The corresponding process  $\underline{x}(t) = s(t) + \underline{n}(t)$  is obviously not WSS, since  $\bar{x}(t) = s(t)$ . Furthermore, (following the nomenclature we have adopted) we can compute its:

- mean instantaneous power  $\overline{\underline{x}^2}(t) = s^2(t) + \sigma_n^2$ ;
- mean power  $\mathcal{P}_{xx} = A[s^2(t)] + A[n^2(t)]$ ;
- overall mean power  $E[\mathcal{P}_{xx}] = A[s^2(t)] + \sigma_n^2$ .

Defining the signal-to-noise ratio (SNR) as the ratio between signal and noise powers, we can conclude that  $\text{SNR}_{\underline{x}} = \frac{A[s^2(t)]}{\sigma_n^2}$ .

Now, suppose that two differently contaminated versions of  $s(t)$  are available:  $x_1(t) = s(t) + n_1(t)$  and  $x_2(t) = s(t) + n_2(t)$ , and that the underlying noise processes  $\underline{n}_1(t)$  and  $\underline{n}_2(t)$  are jointly WSS and uncorrelated, with  $\overline{\underline{n}_1}(t) = \overline{\underline{n}_2}(t) = 0$ ,  $\overline{\underline{n}_1^2}(t) = \sigma_{n_1}^2$ , and  $\overline{\underline{n}_2^2}(t) = \sigma_{n_2}^2$ . If an average signal  $x_m(t) = \frac{x_1(t)+x_2(t)}{2}$  is computed, we can guarantee  $\text{SNR}_{\underline{x}_m} > \text{SNR}_{\underline{x}_1}$  and  $\text{SNR}_{\underline{x}_m} > \text{SNR}_{\underline{x}_2}$  (i.e., noise is reduced) as long as  $\frac{1}{3} < \frac{\sigma_{n_1}^2}{\sigma_{n_2}^2} < 3$ .

#### 1.04.4.7 Ergodicity

The so-called **ergodicity** is a property that allows interchanging statistic and temporal characteristics of some random processes (sequences)—which are then called ergodic. There are several levels of ergodicity, some of which are discussed below.

A random process  $\underline{x}(t)$  with constant statistical mean is said to be mean-ergodic when any time average  $\overline{\underline{x}}$  is equal to  $\underline{\underline{x}}$  with probability 1, which requires  $\sigma_{\overline{\underline{x}}}^2 = 0$ . If  $\underline{x}(t)$  is WSS, a necessary and sufficient condition for mean-ergodicity is

$$\lim_{T \rightarrow \infty} \frac{1}{T} \int_0^{2T} C_{\underline{x}\underline{x}}(\tau) \left(1 - \frac{\tau}{2T}\right) d\tau = 0. \quad (4.133)$$

A random process  $\underline{x}(t)$  with time-invariant auto-correlation is said to be auto-correlation-ergodic when any time auto-correlation  $\mathcal{R}_{xx}(\tau)$  is equal to  $R_{\underline{x}\underline{x}}(\tau)$  with probability 1, which requires  $\sigma_{\mathcal{R}_{xx}(\tau)}^2 = 0$ . Two processes  $\underline{x}(t)$  and  $\underline{y}(t)$  with time-invariant cross-correlation are cross-correlation-ergodic when any time cross-correlation  $\mathcal{R}_{xy}(\tau)$  is equal to  $R_{\underline{x}\underline{y}}(\tau)$  with probability 1, which requires  $\sigma_{\mathcal{R}_{xy}(\tau)}^2 = 0$ . Conditions for correlation-ergodicity of random processes involve 4th-order moments.

A random sequence  $\underline{x}[n]$  with constant statistical mean is said to be mean-ergodic when any time average  $\overline{\underline{x}}$  is equal to  $\underline{\underline{x}}$  with probability 1, which requires  $\sigma_{\overline{\underline{x}}}^2 = 0$ . If  $\underline{x}[n]$  is WSS, a necessary and sufficient condition for mean-ergodicity is

$$\lim_{M \rightarrow \infty} \frac{1}{2M+1} \sum_{k=-M}^M C_{\underline{x}\underline{x}}[k] \left(1 - \frac{|k|}{2M+1}\right) = 0. \quad (4.134)$$

A random sequence  $\underline{x}[n]$  with time-invariant auto-correlation is said to be auto-correlation-ergodic when any time auto-correlation  $\mathcal{R}_{xx}[k]$  is equal to  $R_{\underline{x}\underline{x}}[k]$  with probability 1, which requires  $\sigma_{\mathcal{R}_{xx}[k]}^2 = 0$ . Two sequences  $\underline{x}[n]$  and  $\underline{y}[n]$  with time-invariant cross-correlation are cross-correlation-ergodic when any time cross-correlation  $\mathcal{R}_{xy}[k]$  is equal to  $R_{\underline{x}\underline{y}}[k]$  with probability 1, which requires  $\sigma_{\mathcal{R}_{xy}[k]}^2 = 0$ . Conditions for correlation-ergodicity of random sequences involve 4th-order moments.

A process (sequence) that is mean- and auto-correlation-ergodic is called **wide-sense ergodic**. Two wide-sense ergodic processes (sequences) that are cross-correlation-ergodic are called **jointly wide-sense ergodic**.

A process (sequence) is **distribution-ergodic** when is ergodic for every moment.

The SSS random process (sequence) formed by random constant realizations is not ergodic in any sense. From Eqs. (4.133) and (4.134), a WSS process  $\underline{x}(t)$  (sequence  $\underline{x}[n]$ ), statistically uncorrelated at any different time instants  $t_1$  and  $t_2$  ( $n_1$  and  $n_2$ ), i.e., with  $C_{\underline{x}\underline{x}}(t_2 - t_1) = \delta(t_2 - t_1)$  ( $C_{\underline{x}\underline{x}}[n_2 - n_1] = \delta[n_2 - n_1]$ ), is mean-ergodic.

In practical real-life situations, quite often just a single realization of an underlying random process (sequence) is available. In such cases, if the latter is known to be ergodic, we can make use of the complete powerful statistical modeling framework described in this chapter. But how can one guarantee the property is enjoyed by a process (sequence) of which an only sample function is known? This is not so stringent a requirement: in fact, one needs just to be sure that there can be an ergodic process (sequence) of which that time function is a realization. Strictly speaking, a given music recording  $s(t)$  additively contaminated by background noise  $d(t)$  cannot be modeled as a realization of a mean-ergodic process,<sup>16</sup> since each member of the ensemble would combine the same  $s(t)$  with a different  $d(t)$ . The random process which describes the noisy signal can be written as  $\underline{x}(t) = s(t) + \underline{d}(t)$ ; thus,  $\bar{x}(t) = s(t)$ , while in practice we know that  $\bar{x} = 0$ .

#### 1.04.4.8 An encompassing example

Define the random sequences  $\underline{x}_1[n] = \underline{a}_1 \cos(\Omega_0 n + \underline{\phi}_1)$  and  $\underline{x}_2[n] = \underline{a}_2 \sin(\Omega_0 n + \underline{\phi}_2)$ , such that:

- $\underline{a}_1$  is a random variable with mean  $\bar{\underline{a}}_1$  and variance  $\sigma_{\underline{a}_1}^2$ ;
- $\underline{a}_2$  is a random variable with mean  $\bar{\underline{a}}_2$  and variance  $\sigma_{\underline{a}_2}^2$ ;
- $(-\pi \leq \Omega_0 < \pi)$  rad/sample is a real constant;
- $\underline{\phi}_1$  is a random variable uniformly distributed between  $-\pi$  and  $\pi$  rad;
- $\underline{\phi}_2$  is a random variable uniformly distributed between  $-\pi$  and  $\pi$  rad;
- $\underline{a}_1, \underline{a}_2, \underline{\phi}_1$ , and  $\underline{\phi}_2$  are mutually independent.

Compute their time and statistical means, mean powers, auto-correlations, cross-correlations, and mean cross-powers; and discuss their correlation, orthogonality, stationarity, and ergodicity.

**Solution 3.** Time-averages:

$$\bar{x}_1 = A[x_1[n]] = a_1 A[\cos(\Omega_0 n + \phi_1)] = 0. \quad (4.135)$$

$$\bar{x}_2 = A[x_2[n]] = a_2 A[\sin(\Omega_0 n + \phi_2)] = 0. \quad (4.136)$$

$$\begin{aligned} R_{x_1 x_1}[k] &= A[x_1[n]x_1[n+k]] = a_1^2 A[\cos(\Omega_0 n + \phi_1)\cos(\Omega_0 n + \Omega_0 k + \phi_1)] \\ &= a_1^2 A \left[ \frac{\cos(2\Omega_0 n + \Omega_0 k + 2\phi_1) + \cos(\Omega_0 k)}{2} \right] = \frac{a_1^2}{2} \cos(\Omega_0 k); \end{aligned} \quad (4.137)$$

---

<sup>16</sup>Even if the author has done so many times.

then,

$$\mathcal{P}_{x_1 x_1} = R_{x_1 x_1}[0] = \frac{a_1^2}{2}. \quad (4.138)$$

$$\begin{aligned} \mathcal{R}_{x_2 x_2}[k] &= A[x_2[n]x_2[n+k]] = a_2^2 A[\sin(\Omega_0 n + \phi_2) \sin(\Omega_0 n + \Omega_0 k + \phi_2)] \\ &= a_2^2 A \left[ \frac{\cos(\Omega_0 k) - \cos(2\Omega_0 n + \Omega_0 k + 2\phi_2)}{2} \right] = \frac{a_2^2}{2} \cos(\Omega_0 k); \end{aligned} \quad (4.139)$$

then,

$$\mathcal{P}_{x_2 x_2} = \mathcal{R}_{x_2 x_2}[0] = \frac{a_2^2}{2}. \quad (4.140)$$

$$\begin{aligned} \mathcal{R}_{x_1 x_2}[k] &= A[x_1[n]x_2[n+k]] = a_1 a_2 A[\cos(\Omega_0 n + \phi_1) \sin(\Omega_0 n + \Omega_0 k + \phi_2)] \\ &= a_1 a_2 A \left[ \frac{\sin(2\Omega_0 n + \Omega_0 k + \phi_1 + \phi_2) - \sin(\phi_1 - \phi_2 - \Omega_0 k)}{2} \right] \\ &= \frac{a_1 a_2}{2} \sin(\Omega_0 k + \phi_2 - \phi_1); \end{aligned} \quad (4.141)$$

then,

$$\mathcal{P}_{x_1 x_2} = \mathcal{R}_{x_1 x_2}[0] = \frac{a_1 a_2}{2} \sin(\phi_2 - \phi_1). \quad (4.142)$$

Expected values:

$$\begin{aligned} \bar{x}_1 &= E[\underline{x}_1[n]] = E[\underline{a}_1] E[\cos(\Omega_0 n + \underline{\phi}_1)] \\ &= \bar{a}_1 \int_{-\pi}^{\pi} \frac{1}{2\pi} \cos(\Omega_0 n + \phi_1) d\phi_1 = \bar{a}_1 \cdot 0 = 0. \end{aligned} \quad (4.143)$$

$$\begin{aligned} \bar{x}_2 &= E[x_2[n]] = E[\underline{a}_2] E[\sin(\Omega_0 n + \underline{\phi}_2)] \\ &= \bar{a}_2 \int_{-\pi}^{\pi} \frac{1}{2\pi} \sin(\Omega_0 n + \phi_2) d\phi_2 = \bar{a}_2 \cdot 0 = 0. \end{aligned} \quad (4.144)$$

$$\begin{aligned} R_{\underline{x}_1 \underline{x}_1}[n, n+k] &= E[\underline{x}_1[n]\underline{x}_1[n+k]] = E[\underline{a}_1^2] E[\cos(\Omega_0 n + \underline{\phi}_1) \cos(\Omega_0 n + \Omega_0 k + \underline{\phi}_1)] \\ &= \frac{\bar{a}_1^2 + \sigma_{\underline{a}_1}^2}{2} E \left[ \frac{\cos(2\Omega_0 n + \Omega_0 k + 2\underline{\phi}_1) + \cos(\Omega_0 k)}{2} \right] \\ &= \frac{\bar{a}_1^2 + \sigma_{\underline{a}_1}^2}{2} \cos(\Omega_0 k); \end{aligned} \quad (4.145)$$

then,

$$\bar{x}_1^2 = R_{\underline{x}_1 \underline{x}_1}[n, n] = \frac{\bar{a}_1^2 + \sigma_{\underline{a}_1}^2}{2}. \quad (4.146)$$

$$\begin{aligned}
R_{\underline{x}_2 \underline{x}_2}[n, n+k] &= E[\underline{x}_2[n] \underline{x}_2[n+k]] = E[\underline{a}_2^2] E[\sin(\Omega_0 n + \underline{\phi}_2) \sin(\Omega_0 n + \Omega_0 k + \underline{\phi}_2)] \\
&= \frac{\underline{a}_2^2 + \sigma_{\underline{a}_2}^2}{2} E\left[\frac{\cos(\Omega_0 k) - \cos(2\Omega_0 n + \Omega_0 k + 2\underline{\phi}_2)}{2}\right] \\
&= \frac{\underline{a}_2^2 + \sigma_{\underline{a}_2}^2}{2} \cos(\Omega_0 k);
\end{aligned} \tag{4.147}$$

then,

$$\overline{\underline{x}_2^2} = R_{\underline{x}_2 \underline{x}_2}[n, n] = \frac{\underline{a}_2^2 + \sigma_{\underline{a}_2}^2}{2}. \tag{4.148}$$

$$\begin{aligned}
R_{\underline{x}_1 \underline{x}_2}[n, n+k] &= E[\underline{x}_1[n] \underline{x}_2[n+k]] = E[\underline{a}_1] E[\underline{a}_2] \\
&\quad E[\cos(\Omega_0 n + \underline{\phi}_1)] E[\sin(\Omega_0 n + \Omega_0 k + \underline{\phi}_2)] \\
&= \overline{\underline{a}_1 \underline{a}_2} \cdot 0.0 = 0.
\end{aligned} \tag{4.149}$$

Conclusions:

- Since  $\overline{\underline{x}_1}$  and  $R_{\underline{x}_1 \underline{x}_1}[n, n+k]$  do not depend on  $n$ ,  $\underline{x}_1[n]$  is WSS.
- Since  $\overline{\underline{x}_2}$  and  $R_{\underline{x}_2 \underline{x}_2}[n, n+k]$  do not depend on  $n$ ,  $\underline{x}_2[n]$  is WSS.
- Since  $\underline{x}_1[n]$  is WSS,  $\underline{x}_2[n]$  is WSS, and  $R_{\underline{x}_1 \underline{x}_2}[n, n+k]$  does not depend on  $n$ ,  $\underline{x}_1[n]$  and  $\underline{x}_2[n]$  are jointly WSS.
- Since  $R_{\underline{x}_1 \underline{x}_2}[n, n+k] = \overline{\underline{x}_1 \underline{x}_2}$ ,  $\underline{x}_1[n]$  and  $\underline{x}_2[n]$  are uncorrelated.
- Since  $R_{\underline{x}_1 \underline{x}_2}[n, n+k] = 0$ ,  $\underline{x}_1[n]$  and  $\underline{x}_2[n]$  are orthogonal.
- Since  $\overline{\underline{x}_1} = \overline{\underline{x}_1}$ ,  $\underline{x}_1[n]$  is mean-ergodic.
- Since  $\overline{\underline{x}_2} = \overline{\underline{x}_2}$ ,  $\underline{x}_2[n]$  is mean-ergodic.

#### 1.04.4.9 Gaussian processes and sequences

A very special case of random processes (sequences) are the Gaussian-distributed. The corresponding  $L$ th-order PDFs can be written (see Section 1.04.3.10).

- for processes as

$$f_{\underline{x}}(x_1, x_2, \dots, x_L; t_1, t_2, \dots, t_L) = \frac{1}{\sqrt{(2\pi)^L \det(\mathbf{C}_{\underline{x}})}} e^{-\frac{(\mathbf{x}-\bar{\mathbf{x}})^T \mathbf{C}_{\underline{x}}^{-1} (\mathbf{x}-\bar{\mathbf{x}})}{2}}, \tag{4.150}$$

where  $\bar{\mathbf{x}}$  is the  $L \times 1$  mean-vector with elements  $\{\bar{x}_l\}_l = \bar{x}(t_l)$ , for  $1 \leq l \leq L$ , and  $\mathbf{C}_{\underline{x}}$  is the  $L \times L$  covariance-matrix with elements  $\{\mathbf{C}_{\underline{x}}\}_{l_1 l_2} = C_{\underline{x} \underline{x}}(t_{l_1}, t_{l_2})$ , for  $1 \leq l_1, l_2 \leq L$ ;

- for sequences as

$$f_{\underline{x}}(x_1, x_2, \dots, x_L; n_1, n_2, \dots, n_L) = \frac{1}{\sqrt{(2\pi)^L \det(\mathbf{C}_{\underline{x}})}} e^{-\frac{(\mathbf{x}-\bar{\mathbf{x}})^T \mathbf{C}_{\underline{x}}^{-1} (\mathbf{x}-\bar{\mathbf{x}})}{2}}, \tag{4.151}$$

where  $\underline{\bar{x}}$  is the  $L \times 1$  mean-vector with elements  $\{\underline{\bar{x}}\}_l = \bar{x}[n_l]$ , for  $1 \leq l \leq L$ , and  $\mathbf{C}_{\underline{x}}$  is the  $L \times L$  covariance-matrix with elements  $\{\mathbf{C}_{\underline{x}}\}_{l_1 l_2} = C_{\underline{x}\underline{x}}[n_{l_1}, n_{l_2}]$ , for  $1 \leq l_1, l_2 \leq L$ .

From the definition above:

- A WSS Gaussian random process (sequence) is SSS: Since the PDF of a Gaussian process (sequence) is entirely described by first- and second-order moments, if these moments do not depend on  $t(n)$ , the PDF itself does not depend on  $t(n)$ .
- Uncorrelated Gaussian processes (sequences) are independent: A joint PDF of two uncorrelated Gaussian processes (sequences) can be easily factorized as the product of their individual PDFs, since the covariance-matrix becomes block diagonal.

These two strong properties turn Gaussian models mathematically simpler to tackle, and the strict-sense stationarity and independence conditions easier to meet in practice.

The reader is invited to show that a stationary Gaussian process (sequence) whose auto-correlation is absolutely integrable in  $\tau$  (summable in  $k$ ) is ergodic.

#### 1.04.4.10 Poisson random process

Poisson is an example of discrete random process that we have already defined in Section 1.04.3.2. Each realization  $x(t)$  of  $\underline{x}(t)$  counts the occurrences along time of a certain event whose mean occurrence rate is  $\lambda$  per time unit, provided that.

- there are no simultaneous occurrences;
- occurrence times are independent.

It can model the entry of clients in a store, for example. By convention:

- $\underline{x}(0) = 0$ , i.e., the count starts in  $t = 0$ ;
- $\underline{x}(t_0 > 0)$  provides the count between  $t = 0$  and  $t = t_0$ ;
- $-\underline{x}(t_0 > 0)$  provides the count between  $t = t_0$  and  $t = 0$ .

Time origin can be shifted if necessary.

From Eq. (4.32), the first-order PDF of a Poisson process is given by

$$f_{\underline{x}}(x; t) = \sum_{k=0}^{\infty} \frac{(\lambda t)^k e^{-\lambda t}}{k!} \delta(x - k). \quad (4.152)$$

Applying the definition iteratively, one can show that for  $t_1 \leq t_2 \leq \dots \leq t_L$ , the corresponding  $L$ th-order PDF is

$$f_{\underline{x}}(x_1, x_2, \dots, x_L; t_1, t_2, \dots, t_L) = \begin{cases} \sum_{k_1=0}^{\infty} \sum_{k_2=k_1}^{\infty} \cdots \sum_{k_L=k_{L-1}}^{\infty} \frac{(\lambda t_1)^{k_1}}{k_1!} \prod_{l=2}^L \frac{[\lambda(t_l-t_{l-1})]^{k_l-k_{l-1}}}{(k_l-k_{l-1})!} \\ e^{-\lambda t_L} \delta(x_1 - k_1) \delta(x_2 - k_2) \cdots \delta(x_L - k_L), & k_1 \leq k_2 \leq \dots \leq k_L; \\ 0, & \text{otherwise.} \end{cases} \quad (4.153)$$

#### 1.04.4.11 Complex random processes and sequences

Analogously to what has been done for random variables, real random processes and sequences can be generalized to handle the complex case.

A complex random process can be described as  $\underline{z}(t) = \underline{x}(t) + j\underline{y}(t)$ , where  $\underline{x}(t)$  and  $\underline{y}(t)$  are real random processes. It is stationary in some sense as long as  $\underline{x}(t)$  e  $\underline{y}(t)$  are jointly stationary in that sense. The remaining definitions related to process stationarity are kept the same.

For a complex random process  $\underline{z}(t)$ , the following definitions apply:

- the **mean**  $\bar{\underline{z}}(t) = \bar{\underline{x}}(t) + \bar{\underline{y}}(t)$ ;
- the **mean instantaneous power**  $\overline{|\underline{z}|^2}(t) = \overline{|\underline{x}|^2}(t) + \overline{|\underline{y}|^2}(t)$ ;
- the **variance**  $\sigma_{\underline{z}}^2(t) = E[(|\underline{z}(t) - \bar{\underline{z}}(t)|^2)] = \sigma_{\underline{x}}^2(t) + \sigma_{\underline{y}}^2(t)$ ;
- the **auto-correlation**  $R_{\underline{z}\underline{z}}(t_1, t_2) = E[\underline{z}^*(t_1)\underline{z}(t_2)]$ ;
- the **auto-covariance**  $C_{\underline{z}\underline{z}}(t_1, t_2) = E[(\underline{z}(t_1) - \bar{\underline{z}}(t_1))^*(\underline{z}(t_2) - \bar{\underline{z}}(t_2))]$ .

Given two random processes  $\underline{z}_1(t)$  and  $\underline{z}_2(t)$ , one defines:

- the **mean instantaneous cross power**  $E[\underline{z}_1^*(t)\underline{z}_2(t)]$ ;
- the **cross-correlation**  $R_{\underline{z}_1\underline{z}_2}(t_1, t_2) = E[\underline{z}_1^*(t_1)\underline{z}_2(t_2)]$ ;
- the **cross-covariance**  $C_{\underline{z}_1\underline{z}_2}(t_1, t_2) = E[(\underline{z}_1(t_1) - \bar{\underline{z}}_1(t_1))^*(\underline{z}_2(t_2) - \bar{\underline{z}}_2(t_2))]$ .

The processes  $\underline{z}_1(t)$  and  $\underline{z}_2(t)$  are said to be mutually:

- **orthogonal** when  $R_{\underline{z}_1\underline{z}_2}(t_1, t_2) = 0, \forall t_1 \neq t_2$ ;
- **uncorrelated** when  $C_{\underline{z}_1\underline{z}_2}(t_1, t_2) = 0$ , which is the same as  $R_{\underline{z}_1\underline{z}_2}(t_1, t_2) = \bar{\underline{z}}_1^*(t_1)\bar{\underline{z}}_2(t_2) \forall t_1 \neq t_2$ .

For a random sequence  $\underline{z}[n]$ , the following definitions apply:

- the **mean**  $\bar{\underline{z}}[n] = \bar{\underline{x}}[n] + \bar{\underline{y}}[n]$ ;
- the **mean instantaneous power**  $\overline{|\underline{z}|^2}[n] = \overline{|\underline{x}|^2}[n] + \overline{|\underline{y}|^2}[n]$ ;
- the **variance**  $\sigma_{\underline{z}}^2[n] = E[(|\underline{z}[n] - \bar{\underline{z}}[n]|^2)] = \sigma_{\underline{x}}^2[n] + \sigma_{\underline{y}}^2[n]$ ;
- the **auto-correlation**  $R_{\underline{z}\underline{z}}[n_1, n_2] = E[\underline{z}^*[n_1]\underline{z}[n_2]]$ ;
- the **auto-covariance**  $C_{\underline{z}\underline{z}}[n_1, n_2] = E[(\underline{z}[n_1] - \bar{\underline{z}}[n_1])^*(\underline{z}[n_2] - \bar{\underline{z}}[n_2])]$ .

Given two random processes  $\underline{z}_1[n]$  and  $\underline{z}_2[n]$ , one defines:

- the **mean instantaneous cross power**  $E[\underline{z}_1^*[n]\underline{z}_2[n]]$ ;
- the **cross-correlation**  $R_{\underline{z}_1\underline{z}_2}[n_1, n_2] = E[\underline{z}_1^*[n_1]\underline{z}_2[n_2]]$ ;
- the **cross-covariance**  $C_{\underline{z}_1\underline{z}_2}[n_1, n_2] = E[(\underline{z}_1[n_1] - \bar{\underline{z}}_1[n_1])^*(\underline{z}_2[n_2] - \bar{\underline{z}}_2[n_2])]$ .

The processes  $\underline{z}_1[n]$  and  $\underline{z}_2[n]$  are said to be mutually:

- **orthogonal** when  $R_{\underline{z}_1\underline{z}_2}[n_1, n_2] = 0, \forall n_1 \neq n_2$ ;
- **uncorrelated** when  $C_{\underline{z}_1\underline{z}_2}[n_1, n_2] = 0$ , which is the same as  $R_{\underline{z}_1\underline{z}_2}[n_1, n_2] = \bar{\underline{z}}_1^*[n_1]\bar{\underline{z}}_2[n_2] \forall n_1 \neq n_2$ .

### 1.04.4.12 Markov chains

The simplest random processes (sequences) are those whose statistics at a given time are independent from every other time: a first-order distribution suffices to describe them. A less trivial model is found when the statistical time interdependency assumes a special recursive behavior such that the knowledge of a past conditioning state summarizes all previous history of the process (sequence). For the so-called **Markov** random process (sequence), the knowledge of the past does not affect the expectation of the future when the present is known.

Mathematically, a random process  $\underline{x}(t)$  is said to be a Markov process when for  $t_{n-1} < t_n$ ,

$$f_{\underline{x}}(x_{t_n}; t_n | x_t; \text{all } t \leq t_{n-1}) = f_{\underline{x}}(x_{t_n}; t_n | x_{t_{n-1}}; t_{n-1}), \quad (4.154)$$

or for  $t_1 < t_2 < \dots < t_{n-1} < t_n$ ,

$$f_{\underline{x}}(x_{t_n}; t_n | x_{t_{n-1}}, \dots, x_{t_2}, x_{t_1}; t_{n-1}, \dots, t_2, t_1) = f_{\underline{x}}(x_{t_n}; t_n | x_{t_{n-1}}; t_{n-1}). \quad (4.155)$$

We will restrict ourselves to the discrete-time case. A random sequence  $\underline{x}[n]$  is said to be a Markov sequence when

$$f_{\underline{x}}(x_n; n | x_{n-1}, \dots, x_1, x_0; n-1, \dots, 1, 0) = f_X(x_n; n | x_{n-1}; n-1), \quad (4.156)$$

which can be seen as a **transition PDF**. From the definition, one arrives at the **chain rule**

$$f_{\underline{x}}(x_0, x_1, \dots, x_n; 0, 1, \dots, n) = f_{\underline{x}}(x_n; n | x_{n-1}; n-1) \cdots f_{\underline{x}}(x_1; 1 | x_0; 0) f_{\underline{x}}(x_0; 0), \quad (4.157)$$

which means that the overall Markov sequence can be statistically described for  $n \geq 0$  from the knowledge of its distribution at  $n = 0$  and its subsequent transition distributions. Some interesting properties can be deduced from the expressions above:

- Since  $f_{\underline{x}}(x_n; n | x_{n+1}, x_{n+2}, \dots, x_{n+k}; n+1, n+2, \dots, n+k) = f_{\underline{x}}(x_n; n | x_{n+1}; n+1)$ , a time-reversed Markov sequence is also a Markov sequence.
- For  $n_1 < n_2 < n_3$ ,  $f_{\underline{x}}(x_{n_1}, x_{n_3}; n_1, n_3 | x_{n_2}; n_2) = f_{\underline{x}}(x_{n_3}; n_3 | x_{n_2}; n_2) f_{\underline{x}}(x_{n_1}; n_1 | x_{n_2}; n_2)$ .

A much important property of Markov sequences is the so-called **Chapman-Kolmogorov equation**: for  $n_1 < n_2 < n_3$ ,

$$f_{\underline{x}}(x_{n_3}; n_3 | x_{n_1}; n_1) = \int_{-\infty}^{\infty} f_{\underline{x}}(x_{n_3}; n_3 | x_{n_2}; n_2) f_{\underline{x}}(x_{n_2}; n_2 | x_{n_1}; n_1) dx_{n_2}, \quad (4.158)$$

which provides a recursive way to compute arbitrary transition PDFs.

We can say a Markov sequence  $\underline{x}[n]$  is **stationary** when  $f_{\underline{x}}(x_n; n)$  and  $f_{\underline{x}}(x_n; n | x_{n-1}; n-1)$  are shift-invariant. In this case, the overall sequence can be obtained from  $f_{\underline{x}}(x_1, x_2; 1, 2)$ . A less trivial (and quite useful) model is provided by **homogeneous** Markov sequences, which are characterized only by a shift-invariant transition distribution; they are not stationary in general, but can be asymptotically stationary (i.e., for  $n \rightarrow \infty$ ) under certain conditions.

Discrete Markov processes and sequences are called **Markov chains**, which can assume a countable number of random states  $a_i$  described by their **state probabilities** ( $P(\underline{x}[n] = a_i) = p_i[n]$  for sequences) and **transition probabilities** ( $P(\underline{x}[n_2] = a_j | \underline{x}[n_1] = a_i) = \Pi_{ij}[n_1, n_2]$ ,  $n_1 < n_2$  for sequences). Discrete-time Markov chains enjoy the following properties, for  $n_1 < n_2 < n_3$ :

- $\sum_j \Pi_{ij}[n_1, n_2] = 1$ , which totalizes all possible ways to left state  $a_i$  in  $n_1$ ;
- $\sum_i p_i[n_1] \Pi_{ij}[n_1, n_2] = p_j[n_2]$ , which totalizes all possible ways to arrive at state  $a_j$  in  $n_2$ ;
- $\Pi_{il}[n_1, n_3] = \sum_j \Pi_{ij}[n_1, n_2] \Pi_{jl}[n_2, n_3]$  (**Chapman-Kolmogorov equation**).

If the chain has a finite number of states, a matrix notation can be employed. The state probability vector  $\mathbf{p}[n]$ , with elements  $\{\mathbf{p}_i[n]\} = p_i[n]$ , and the transition probability matrix  $\boldsymbol{\Pi}[n_1, n_2]$ , with elements  $\{\boldsymbol{\Pi}_{ij}[n_1, n_2]\} = \Pi_{ij}[n_1, n_2]$ , are related by  $\mathbf{p}[n_2] = \boldsymbol{\Pi}^T[n_1, n_2] \mathbf{p}[n_1]$ .

The special class of homogeneous Markov chains enjoys the following additional properties:

- $\Pi_{ij}[n_1, n_2] = \Pi_{ij}[k], k = n_2 - n_1$ ;
- $\Pi_{il}[k_2 + k_1] = \sum_j \Pi_{ij}[k_1] \Pi_{jl}[k_2]$ .

Accordingly, the transition probability matrix becomes  $\boldsymbol{\Pi}[k]$ . Defining  $\boldsymbol{\Pi}[1] = \boldsymbol{\Pi}$ ,

$$\mathbf{p}[n] = \boldsymbol{\Pi}^T \mathbf{p}[n-1] = (\boldsymbol{\Pi}^T)^n \mathbf{p}[0], \quad (4.159)$$

i.e.,  $\boldsymbol{\Pi}[n] = \boldsymbol{\Pi}^n$ . When asymptotic stationarity is reachable, one can find the **steady-state probability vector**  $\mathbf{p} = \mathbf{p}[\infty]$  such that  $\mathbf{p} = \boldsymbol{\Pi} \mathbf{p}$ .

Consider, for example, the homogeneous Markov chain  $\underline{x}[n]$  depicted in Figure 4.12, with states 1 and 2, state probabilities  $P(\underline{x}[n] = 1) = p_1[n]$  and  $P(\underline{x}[n] = 2) = p_2[n]$ , and transition probabilities  $P(\underline{x}[n] = 2 | \underline{x}[n-1] = 1) = \Pi_{12}[1] = a$  and  $P(\underline{x}[n] = 1 | \underline{x}[n-1] = 2) = \Pi_{21}[1] = b$ . Its corresponding one-sample transition matrix is

$$\boldsymbol{\Pi}[1] = \boldsymbol{\Pi} = \begin{bmatrix} 1-a & a \\ b & 1-b \end{bmatrix}, \quad (4.160)$$

such that

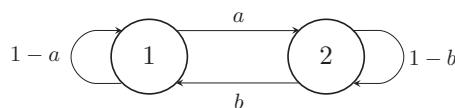

$$\boldsymbol{\Pi}[k] = \boldsymbol{\Pi}^k = \begin{bmatrix} \frac{b+a(1-a-b)^k}{a+b} & \frac{a-a(1-a-b)^k}{a+b} \\ \frac{b-b(1-a-b)^k}{a+b} & \frac{a+b(1-a-b)^k}{a+b} \end{bmatrix}. \quad (4.161)$$

It can also be shown that the chain reaches the steady-state probability vector

$$\lim_{n \rightarrow \infty} \mathbf{p}[n] = \lim_{n \rightarrow \infty} \begin{bmatrix} p_1[n] \\ p_2[n] \end{bmatrix} = \begin{bmatrix} \frac{b}{a+b} \\ \frac{a}{a+b} \end{bmatrix}. \quad (4.162)$$

#### 1.04.4.13 Spectral description of random processes and sequences

At first sight, the direct conversion of each realization  $x(t)$  ( $x[n]$ ) to the frequency domain seems the easiest way to spectrally characterize a random process  $\underline{x}(t)$  (sequence  $\underline{x}[n]$ ). However, it is difficult to

**FIGURE 4.12**

Homogeneous Markov chain with two states.

guarantee the existence of the Fourier transform

$$X(j\omega) = \mathcal{F}[x(t)] \triangleq \int_{-\infty}^{\infty} x(t)e^{-j\omega t} dt \quad (4.163)$$

(in the case of random processes) or

$$X(e^{j\Omega}) = \mathcal{F}[x[n]] \triangleq \sum_{n=-\infty}^{\infty} x[n]e^{-j\Omega n} \quad (4.164)$$

(in the case of random sequences) for every realization. And even if possible, we would get a random spectrum of limited applicability. In Section 1.04.4.5, we have found that the auto-correlation conveys information about every sinusoidal component found in the process (sequence). A correct interpretation of the Fourier transform<sup>17</sup> suggests that the auto-correlation in fact conveys information about the overall spectrum of the process (sequence). Furthermore, it is a better behaved function than the individual realizations, and thus amenable to be Fourier transformed.

In Section 1.04.4.6, Eq. (4.118), we defined the overall mean power of the random process  $\underline{x}(t)$ , which for the general complex case, becomes

$$\overline{\underline{\mathcal{P}}_{xx}} = A[\mathbb{E}[|\underline{x}^2(t)|]]. \quad (4.165)$$

It can be shown that

$$\overline{\underline{\mathcal{P}}_{xx}} = \frac{1}{2\pi} \int_{-\infty}^{\infty} \lim_{T \rightarrow \infty} \frac{\mathbb{E}[|\underline{X}_T(j\omega)|^2]}{2T} d\omega, \quad (4.166)$$

where

$$\underline{X}_T(j\omega) = \mathcal{F}[\underline{x}_T(t)] \quad (4.167)$$

and

$$\underline{x}_T(t) = \begin{cases} x(t), & -T < t < T; \\ 0, & \text{otherwise.} \end{cases} \quad (4.168)$$

We can then define a **power spectral density**

$$S_{\underline{xx}}(j\omega) = \lim_{T \rightarrow \infty} \frac{\mathbb{E}[|\underline{X}_T(j\omega)|^2]}{2T}, \quad (4.169)$$

such that  $\overline{\underline{\mathcal{P}}_{xx}} = \frac{1}{2\pi} \int_{-\infty}^{\infty} S_{\underline{xx}}(j\omega) d\omega$ . Some additional algebraic manipulation yields

$$S_{\underline{xx}}(j\omega) = \mathcal{F}[A[R_{\underline{xx}}(t, t + \tau)]], \quad (4.170)$$

which directly relates the auto-correlation to the power spectral density of the process, as predicted. From the expressions above,  $S_{\underline{xx}}(j\omega)$  is a non-negative real function of  $\omega$ . Furthermore, if  $\underline{x}(t)$  is real, then  $S_{\underline{xx}}(j\omega)$  is an even function of  $\omega$ .

---

<sup>17</sup>The Fourier transform represents a time signal as a linear combination of continuously distributed sinusoids.

In Section 1.04.4.6, Eq. (4.121), we also defined the overall mean cross-power between the processes  $\underline{x}(t)$  and  $\underline{y}(t)$ , which for the general complex case, becomes

$$\overline{\mathcal{P}_{xy}} = A[\mathbb{E}[\underline{x}^*(t)\underline{y}(t)]] \quad (4.171)$$

Following the same steps as above, we arrive at

$$\overline{\mathcal{P}_{xy}} = \frac{1}{2\pi} \int_{-\infty}^{\infty} \lim_{T \rightarrow \infty} \frac{\mathbb{E}[X_T^*(j\omega)Y_T(j\omega)]}{2T} d\omega, \quad (4.172)$$

where  $X_T(j\omega)$  is defined as before,

$$Y_T(j\omega) = \mathcal{F}[\underline{y}_T(t)] \quad (4.173)$$

and

$$y_T(t) = \begin{cases} y(t), & -T < t < T; \\ 0, & \text{otherwise.} \end{cases} \quad (4.174)$$

We can then define the corresponding **cross-power spectral density**

$$S_{\underline{x}\underline{y}}(j\omega) = \lim_{T \rightarrow \infty} \frac{\mathbb{E}[X_T^*(j\omega)Y_T(j\omega)]}{2T}, \quad (4.175)$$

such that  $\overline{\mathcal{P}_{xy}} = \frac{1}{2\pi} \int_{-\infty}^{\infty} S_{\underline{x}\underline{y}}(j\omega) d\omega$ . In terms of the cross-correlation, the cross-power spectral density can be written as

$$S_{\underline{x}\underline{y}}(j\omega) = \mathcal{F}[A[R_{\underline{x}\underline{y}}(t, t + \tau)]] \quad (4.176)$$

As expected, the cross-power density of orthogonal processes is zero. From the expressions above,  $S_{\underline{x}\underline{y}}(j\omega) = S_{\underline{y}\underline{x}}^*(j\omega)$ . Furthermore, if  $x(t)$  and  $y(t)$  are real, then the real part of  $S_{\underline{x}\underline{y}}(j\omega)$  is even and the imaginary part of  $S_{\underline{x}\underline{y}}(j\omega)$  is odd.

It should be noticed that in the WSS case,  $\overline{\mathcal{P}_{xx}} = \mathbb{E}[|\underline{x}^2(t)|]$ ,  $\overline{\mathcal{P}_{xy}} = \mathbb{E}[\underline{x}^*(t)\underline{y}(t)]$ ,  $S_{\underline{x}\underline{x}}(j\omega) = \mathcal{F}[R_{\underline{x}\underline{x}}(\tau)]$ , and  $S_{\underline{x}\underline{y}}(j\omega) = \mathcal{F}[R_{\underline{x}\underline{y}}(\tau)]$ .

A similar development can be done for random sequences. In Section 1.04.4.6, Eq. (4.129), we defined the overall mean power of the random sequence  $\underline{x}[n]$ , which for the general complex case, becomes

$$\overline{\mathcal{P}_{xx}} = A[\mathbb{E}[|\underline{x}^2[n]|]] \quad (4.177)$$

It can be shown that

$$\overline{\mathcal{P}_{xx}} = \frac{1}{2\pi} \int_{-\pi}^{\pi} \lim_{N \rightarrow \infty} \frac{\mathbb{E}[|\underline{X}_N(e^{j\Omega})|^2]}{2N + 1} d\Omega, \quad (4.178)$$

where

$$\underline{X}_N(e^{j\Omega}) = \mathcal{F}[\underline{x}_N[n]] \quad (4.179)$$

and

$$x_N[n] = \begin{cases} x[n], & -N \leq n \leq N; \\ 0, & \text{otherwise.} \end{cases} \quad (4.180)$$

We can then define a **power spectral density**

$$S_{\underline{x}\underline{x}}(e^{j\Omega}) = \lim_{N \rightarrow \infty} \frac{E[|X_N(e^{j\Omega})|^2]}{2N + 1}, \quad (4.181)$$

such that  $\overline{\mathcal{P}_{xx}} = \frac{1}{2\pi} \int_{-\pi}^{\pi} S_{\underline{x}\underline{x}}(e^{j\Omega}) d\Omega$ . Some additional algebraic manipulation yields

$$S_{\underline{x}\underline{x}}(e^{j\Omega}) = \mathcal{F}[A[R_{\underline{x}\underline{x}}[n, n+k]]], \quad (4.182)$$

which directly relates the auto-correlation to the power spectral density of the random sequence, as expected. From the expressions above,  $S_{\underline{x}\underline{x}}(e^{j\Omega})$  is a non-negative real function of  $\Omega$ . Furthermore, if  $x[n]$  is real, then  $S_{\underline{x}\underline{x}}(e^{j\Omega})$  is an even function of  $\Omega$ .

In Section 1.04.4.6, Eq. (4.132), we also defined the overall mean cross-power between the random sequences  $\underline{x}[n]$  and  $\underline{y}[n]$ , which for the general complex case, becomes

$$\overline{\mathcal{P}_{xy}} = A[E[\underline{x}^*[n]\underline{y}[n]]]. \quad (4.183)$$

Following the same steps as above, we arrive at

$$\overline{\mathcal{P}_{xy}} = \frac{1}{2\pi} \int_{-\pi}^{\pi} \lim_{N \rightarrow \infty} \frac{E[X_N^*(e^{j\Omega})Y_N(e^{j\Omega})]}{2N + 1} d\Omega, \quad (4.184)$$

where  $X_N(e^{j\Omega})$  is defined as before,

$$Y_N(e^{j\Omega}) = \mathcal{F}[\underline{y}_N[n]] \quad (4.185)$$

and

$$y_N[n] = \begin{cases} y[n], & -N \leq n \leq N; \\ 0, & \text{otherwise.} \end{cases} \quad (4.186)$$

We can then define the corresponding **cross-power spectral density**

$$S_{\underline{x}\underline{y}}(e^{j\Omega}) = \lim_{N \rightarrow \infty} \frac{E[X_N^*(e^{j\Omega})Y_N(e^{j\Omega})]}{2N + 1}, \quad (4.187)$$

such that  $\overline{\mathcal{P}_{xy}} = \frac{1}{2\pi} \int_{-\pi}^{\pi} S_{\underline{x}\underline{y}}(e^{j\Omega}) d\Omega$ . In terms of the cross-correlation, the cross-power spectral density can be written as

$$S_{\underline{x}\underline{y}}(e^{j\Omega}) = \mathcal{F}[A[R_{\underline{x}\underline{y}}[n, n+k]]]. \quad (4.188)$$

As expected, the cross-power density of orthogonal processes is zero. From the expressions above,  $S_{\underline{x}\underline{y}}(j\omega) = S_{\underline{y}\underline{x}}^*(e^{j\Omega})$ . Furthermore, if  $\underline{x}[n]$  and  $\underline{y}[n]$  are real, then the real part of  $S_{\underline{x}\underline{y}}(e^{j\Omega})$  is even and the imaginary part of  $S_{\underline{x}\underline{y}}(e^{j\Omega})$  is odd.

It should be noticed that in the WSS case,  $\overline{\mathcal{P}_{xx}} = E[|\underline{x}[n]|^2]$ ,  $\overline{\mathcal{P}_{xy}} = E[\underline{x}^*[n]\underline{y}[n]]$ ,  $S_{\underline{x}\underline{x}}(e^{j\Omega}) = \mathcal{F}[R_{\underline{x}\underline{x}}[k]]$ , and  $S_{\underline{x}\underline{y}}(e^{j\Omega}) = \mathcal{F}[R_{\underline{x}\underline{y}}[k]]$ .

#### 1.04.4.14 White and colored noise

One usually refers to a disturbing signal  $d(t)$  ( $d[n]$ ) as noise. Since noise signals are typically unpredictable, they are preferably modeled as realizations of some noise random process  $\underline{d}(t)$  (sequence  $\underline{d}[n]$ ).

A very special case is the so-called **white noise** (by analogy with white light), which is a uniform combination of all frequencies.

Continuous-time white noise  $w(t)$  is sampled from a random process  $\underline{w}(t)$  characterized by the following properties:

- zero mean:  $\overline{\underline{w}}(t) = 0$ ;
- non-correlation between distinct time instants:  $R_{\underline{w}\underline{w}}(t, t + \tau) = 0, \tau \neq 0$ ;
- constant power spectral density:  $S_{\underline{w}\underline{w}}(j\omega) = S_{\underline{w}\underline{w}} \forall \omega$ ;
- infinite overall mean power:  $\overline{\mathcal{P}_{xx}} = \infty$ .

From the last property, continuous-time white noise is not physically realizable. Furthermore, WSS continuous-time white noise has  $R_{\underline{w}\underline{w}}(\tau) = S_{\underline{w}\underline{w}}\delta(\tau)$ .

Discrete-time white noise  $w[n]$  is sampled from a random sequence  $\underline{w}[n]$  characterized by the following properties:

- zero mean:  $\overline{\underline{w}}[n] = 0$ ;
- non-correlation between distinct time instants:  $R_{\underline{w}\underline{w}}[n, n + k] = 0, k \neq 0$ ;
- constant power spectral density:  $S_{\underline{w}\underline{w}}(e^{j\Omega}) = A[\sigma_{\underline{w}}^2[n]]$ ;
- overall mean power  $\overline{\mathcal{P}_{xx}} = A[\sigma_{\underline{w}}^2[n]]$ .

For WSS discrete-time white noise,  $S_{\underline{w}\underline{w}}(e^{j\Omega}) = \sigma_{\underline{w}}^2$ ,  $R_{\underline{w}\underline{w}}[k] = \sigma_{\underline{w}}^2\delta[k]$ , and  $\overline{\mathcal{P}_{xx}} = \sigma_{\underline{w}}^2$ .

Unless differently stated, white noise is implicitly assumed to be generated by a WSS random process (sequence). Notice, however, that the sequence  $d[n] = w(n) \cos(\Omega_0 n)$ , where  $0 < \Omega_0 < \pi$  rad and  $\underline{w}(n)$  is WSS white noise with unit variance, for example, satisfies all conditions to be called white noise, even if  $R_{\underline{d}\underline{d}}[n, n + k] = \delta[k] \cos(\Omega_0 n)$ .

A common (more stringent) model of white noise imposes that values at different time instants of the underlying process (sequence) be statistically i.i.d.

Any random noise whose associated power spectral density is not constant is said to be **colored noise**. One can find in the literature several identified colored noises (pink, grey, etc.), each one with a pre-specified spectral behavior. It should also be noticed that any band-limited approximation of white noise destroys its non-correlation property. Consider  $d(t)$  generated by a WSS random process  $\underline{d}(t)$  such that

$$S_{\underline{d}\underline{d}}(j\omega) = \begin{cases} \frac{P\pi}{W}, & -W < \omega < W; \\ 0, & \text{otherwise.} \end{cases} \quad (4.189)$$

It is common practice to call  $d(t)$  “white noise” of bandwidth  $W$  and overall mean power  $P$ . Since its auto-correlation is

$$R_{\underline{d}\underline{d}}(\tau) = \frac{P \sin(W\tau)}{W\tau}, \quad (4.190)$$

strictly speaking one cannot say  $d(t)$  is white noise.

#### 1.04.4.15 Applications: modulation, “Bandpass” and band-limited processes, and sampling

An interesting application of the spectral description of random processes is modeling of AM (amplitude modulation). Assuming a carrier signal  $c(t) = A_0 \cos(\omega_0 t)$  modulated by a real random signal  $m(t)$  sampled from a process  $\underline{m}(t)$ , the resulting modulated random process  $\underline{x}(t) = \underline{m}(t)A_0 \cos(\omega_0 t)$  has auto-correlation

$$R_{\underline{x}\underline{x}}(t, t + \tau) = \frac{A_0^2}{2} R_{\underline{m}\underline{m}}(t, t + \tau) [\cos(\omega_0 \tau) + \cos(2\omega_0 t + \omega_0 \tau)]. \quad (4.191)$$

If  $\underline{m}(t)$  is WSS, then

$$A[R_{\underline{x}\underline{x}}(t, t + \tau)] = \frac{A_0^2}{2} R_{\underline{m}\underline{m}}(\tau) \cos(\omega_0 \tau), \quad (4.192)$$

and the corresponding power spectral density is

$$S_{\underline{x}\underline{x}}(j\omega) = \frac{A_0^2}{4} [S_{\underline{m}\underline{m}}(j(\omega - \omega_0)) + S_{\underline{m}\underline{m}}(j(\omega + \omega_0))]. \quad (4.193)$$

We conclude that the AM constitution of  $\underline{x}(t)$  carries through its auto-correlation, which provides a simple statistical model for AM.

Quite often we find ourselves dealing with **band-limited** random signals. In the AM discussion above, typically  $\underline{m}(t)$  has bandwidth  $W \ll \omega_0$ . For a random process  $\underline{x}(t)$  whose spectrum is at least concentrated around  $\omega = 0$  (**baseband** process), we can attribute it an **RMS** (root-mean-squared) **bandwidth**  $W_{\text{RMS}}$  such that

$$W_{\text{RMS}}^2 = \frac{\int_{-\infty}^{\infty} \omega^2 S_{\underline{x}\underline{x}}(j\omega) d\omega}{\int_{-\infty}^{\infty} S_{\underline{x}\underline{x}}(j\omega) d\omega}. \quad (4.194)$$

If the spectrum is concentrated around a centroid

$$\bar{\omega}_0 = \frac{\int_0^{\infty} \omega S_{\underline{x}\underline{x}}(j\omega) d\omega}{\int_0^{\infty} S_{\underline{x}\underline{x}}(j\omega) d\omega}, \quad (4.195)$$

$W_{\text{RMS}}$  is given by

$$\left(\frac{W_{\text{RMS}}}{2}\right)^2 = \frac{\int_0^{\infty} (\omega - \bar{\omega}_0)^2 S_{\underline{x}\underline{x}}(j\omega) d\omega}{\int_0^{\infty} S_{\underline{x}\underline{x}}(j\omega) d\omega}. \quad (4.196)$$

If the process bandwidth excludes  $\omega = 0$ , it is called<sup>18</sup> a “**bandpass**” process.

It can be shown that if a band-limited baseband WSS random process  $\underline{x}(t)$  with bandwidth  $W$ , i.e., such that  $S_{\underline{x}\underline{x}}(j\omega) = 0$  for  $|\omega| > W$ , is sampled at rate  $\omega_s > 2W$  to generate the random sequence

$$\underline{x}[n] = \underline{x}\left(n \frac{2\pi}{\omega_s}\right), \quad (4.197)$$

then  $\underline{x}(t)$  can be recovered from  $\underline{x}[n]$  with zero mean-squared-error. This is the stochastic version of the **Nyquist criterion** for lossless sampling.

---

<sup>18</sup>With considerable freedom of nomenclature.

#### 1.04.4.16 Processing of random processes and sequences

Statistical signal modeling is often employed in the context of signal processing, and thus the interaction between random signals and processing systems calls for a systematic approach. In this chapter, we will restrict ourselves to **linear time-invariant** (LTI) systems.

A system defined by the operation  $y = L[x]$  between input  $x$  and output  $y$  is called **linear** if any linear combination of  $m$  inputs produce as output the same linear combination of their  $m$  corresponding outputs:

- for a continuous-time system,  $L\left[\sum_{m=1}^M \alpha_m x_m(t)\right] = \sum_{m=1}^M \alpha_m L[x_m(t)], \alpha_m \in \mathcal{C}$ ,
- for a discrete-time system,  $L\left[\sum_{m=1}^M \alpha_m x_m[n]\right] = \sum_{m=1}^M \alpha_m L[x_m[n]], \alpha_m \in \mathcal{C}$ .

For a linear system, one can define an **impulse response**  $h$  as the system output to a unit impulse  $\delta$  applied to the system input at a given time instant:

- for a continuous-time system, a unit impulse  $\delta(\cdot)$  applied at instant  $\tau$ , produces an impulse response  $h_\tau(t) = L[\delta(t - \tau)]$ ,
- for a discrete-time system, a unit impulse<sup>19</sup>  $\delta[\cdot]$  applied at instant  $k$ , produces an impulse response  $h_k[n] = L[\delta[n - k]]$ .

A system is called **time-invariant** if a given input  $x$  applied at different time instants produces the same output  $y$  accordingly time-shifted:

- for a continuous-time system, if  $L[x(t)] = y(t)$ , then  $L[x(t - \tau)] = y(t - \tau) \forall \tau$ ; thus,  $h_\tau(t) = h_0(t - \tau) \triangleq h(t - \tau)$ ,
- for a discrete-time system, if  $L[x[n]] = y[n]$ , then  $L[x[n - k]] = y[n - k] \forall k$ ; thus,  $h_\tau[n] = h_0[n - k] \triangleq h[n - k]$ .

The output of an LTI system to any input  $x$  is the **convolution**  $x * h$  between the input and the impulse response  $h$  of the system:

- for a continuous-time system,  $L[x(t)] = \int_{-\infty}^{\infty} x(\tau)h(t - \tau)d\tau \triangleq (x * h)(t)$ ,
- for a discrete-time system,  $L[x[n]] = \sum_{k=-\infty}^{\infty} x[k]h[n - k] \triangleq (x * h)[n]$ .

In the frequency domain, the output  $Y$  is related to the input  $X$  by the system **frequency response**  $H$ :

- for a continuous-time system,  $Y(j\omega) = X(j\omega)H(j\omega), H(j\omega) = \mathcal{F}[h(t)]$ ,
- for a discrete-time system,  $Y(e^{j\Omega}) = X(e^{j\Omega})H(e^{j\Omega}), H(e^{j\Omega}) = \mathcal{F}[h[n]]$ .

The product  $XH$  brings the concept of **filtering**:  $H$  defines how much of each frequency component of input  $X$  passes to the output  $Y$ . From now on, when referring to the processing of a random process (sequence) by a system we imply that each process realization is filtered by that system.

The filtering of a random process  $\underline{x}(t)$  by an LTI system with impulse response  $h(t)$  results in another random process  $\underline{y}(t)$  such that  $\underline{y}(t) = (\underline{x} * h)(t)$ . Assuming  $\underline{x}(t)$  WSS and possibly complex, so as  $h(t)$ , then  $\underline{y}(t)$  will be also WSS and<sup>20</sup>:

- $\underline{\bar{y}} = \underline{\bar{x}}H(j0)$ ;

---

<sup>19</sup>Unit impulse function, or Kronecker delta: For  $x \in \mathcal{Z}$ ,  $\delta[x] = 0 \forall x \neq 0$ , and  $\delta[0] = 1$ .

<sup>20</sup>Where notation  $f_{-}(t) \triangleq f(-t)$  was used.

- $R_{\underline{xy}}(\tau) = R_{\underline{yx}}^*(-\tau) = (R_{\underline{xx}} * h)(\tau);$
- $R_{\underline{yy}}(\tau) = (R_{\underline{xy}} * h_-^*)(\tau) = (R_{\underline{xx}} * h * h_-^*)(\tau);$
- $S_{\underline{xy}}(j\omega) = S_{\underline{yx}}^*(j\omega) = S_{\underline{xx}}(j\omega)H(j\omega);$
- $S_{\underline{yy}}(j\omega) = S_{\underline{xy}}(j\omega)H^*(j\omega) = S_{\underline{xx}}(j\omega)|H(j\omega)|^2.$

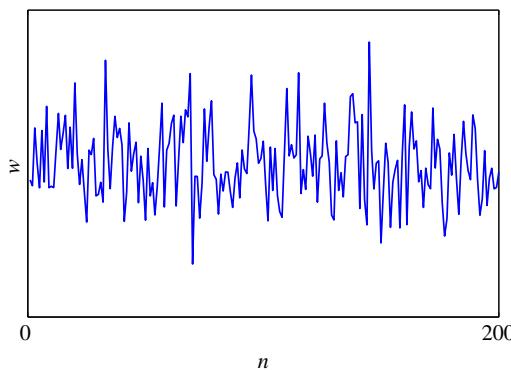

The processing of a random sequence  $\underline{x}[n]$  by an LTI system with impulse response  $h[n]$  results in another random sequence  $\underline{y}[n]$  such that  $\underline{y}[n] = (\underline{x} * h)[n]$ . Assuming  $\underline{x}[n]$  WSS and possibly complex, so as  $h[n]$ , then  $\underline{y}[n]$  will be also WSS and<sup>21</sup>:

- $\bar{\underline{y}} = \bar{\underline{x}}H(e^{j0});$
- $R_{\underline{xy}}[k] = R_{\underline{yx}}^*[-k] = (R_{\underline{xx}} * h)[k];$
- $R_{\underline{yy}}[k] = (R_{\underline{xy}} * h_-^*)[k] = (R_{\underline{xx}} * h * h_-^*)[k];$
- $S_{\underline{xy}}(e^{j\Omega}) = S_{\underline{yx}}^*(e^{j\Omega}) = S_{\underline{xx}}(e^{j\Omega})H(e^{j\Omega});$
- $S_{\underline{yy}}(e^{j\Omega}) = S_{\underline{xy}}(e^{j\Omega})H^*(e^{j\Omega}) = S_{\underline{xx}}(e^{j\Omega})|H(e^{j\Omega})|^2.$

Among the above results, one of the most important is the effect of filtering on the power spectral density  $S_{\underline{xx}}$  of the input WSS random process (sequence): it is multiplied by the squared magnitude  $|H|^2$  of the frequency response of the LTI system to produce the power spectral density  $S_{\underline{yy}}$  of the output WSS random process (sequence). As a direct consequence, any WSS random process (sequence) with known power spectral density  $S$  can be modeled by the output of an LTI system with squared magnitude response  $|H|^2 \propto S$  whose input is white noise.

In order to qualitatively illustrate this filtering effect:

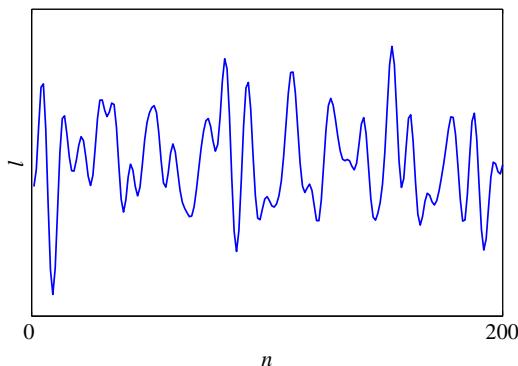

- Figure 4.13 shows 200 samples of white noise  $w[n]$ ;

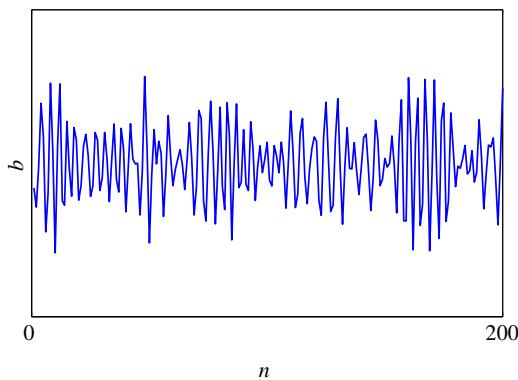

**FIGURE 4.13**

White noise.

<sup>21</sup>Where notation  $f_-[-n] \triangleq f[-n]$  was used.

**FIGURE 4.14**

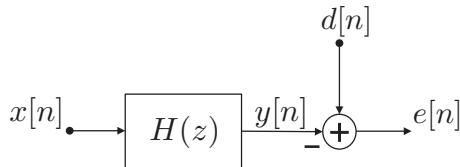

Realization of a “low-pass” sequence.

**FIGURE 4.15**

Realization of a “band-pass” sequence.

- Figure 4.14 shows 200 samples of  $l[n]$ , a slowly evolving signal obtained by low-pass filtering of  $w[n]$  to 20% of its original bandwidth;
- Figure 4.15 shows 200 samples of  $b[n]$ , an almost sinusoidal signal obtained by band-pass filtering of  $w[n]$  to the central 4% of its original bandwidth.

From the area of **optimum filtering**, whose overall goal is finding the best filter to perform a defined task, we can bring an important application of the concepts presented in this section. The general discrete **Wiener filter  $H$** , illustrated in Figure 4.16, is the linear time-invariant filter which minimizes the mean quadratic value  $E[e^2[n]]$  of the error  $e[n] = d[n] - y[n]$  between the desired signal  $d[n]$  and the filtered version  $y[n]$  of the input signal  $x[n]$ . Assuming that  $x[n]$  and  $d[n]$  are realizations of two jointly WSS random sequences  $\underline{x}[n]$  and  $\underline{d}[n]$ , if the optimum filter is not constrained to be causal, one finds that it

**FIGURE 4.16**

General discrete Wiener filter.

must satisfy the equation

$$(h * R_{\underline{xx}})[k] = R_{\underline{xd}}[k], \quad (4.198)$$

i.e., its frequency response is

$$H(e^{j\Omega}) = \frac{S_{\underline{xd}}(e^{j\Omega})}{S_{\underline{xx}}(e^{j\Omega})}. \quad (4.199)$$

If one needs a causal FIR solution, a different but equally simple solution can be found for  $h[n]$ .

We can solve a very simple example where we compute an optimum zero-order predictor for a given signal of which a noisy version is available. In this case,  $H(e^{j\Omega}) = c$  (a simple gain to be determined), the input  $x[n] = s[n] + v[n]$  (signal  $s[n]$  additively corrupted by noise  $v[n]$ ) and  $d[n] = x[n+1]$ . The solution is

$$c = \frac{R_{\underline{xx}}[1]}{R_{\underline{xx}}[0] + R_{\underline{vv}}[0]}, \quad (4.200)$$

which yields the minimum mean quadratic error

$$\mathbb{E}[e^2[n]] = \frac{R_{\underline{xx}}^2[0] + R_{\underline{xx}}[0]R_{\underline{vv}}[0] - R_{\underline{xx}}^2[1]}{R_{\underline{xx}}[0] + R_{\underline{vv}}[0]}. \quad (4.201)$$

Notice that if no noise is present,

$$c = \frac{R_{\underline{xx}}[1]}{R_{\underline{xx}}[0]} \quad (4.202)$$

and

$$\mathbb{E}[e^2[n]] = \frac{R_{\underline{xx}}^2[0] - R_{\underline{xx}}^2[1]}{R_{\underline{xx}}[0] + R_{\underline{vv}}[0]}. \quad (4.203)$$

The reader should be aware that this example studies a theoretical probabilistic model, which may therefore depend on several parameters which probably would not be available in practice and should rather be estimated. In fact, it points out the solution a practical system should pursue.

The Wiener filter is a kind of benchmark for adaptive filters [7], which optimize themselves recursively.

#### 1.04.4.17 Characterization of LTI systems and WSS random processes

A direct way to find the impulse response  $h(t)$  of an LTI system is to apply white noise  $\underline{w}(t)$  with power spectral density  $S_{\underline{w}\underline{w}}(\omega) = S_{\underline{w}\underline{w}}$   $\forall \omega$  to the system input, which yields  $R_{\underline{x}\underline{y}}(\tau) = S_{\underline{w}\underline{w}}h(\tau)$ . From an estimate  $\widehat{R}_{\underline{x}\underline{y}}(t)$  of the cross-correlation, one can obtain an estimate of the desired impulse response:  $\hat{h}(t) \approx \widehat{R}_{\underline{x}\underline{y}}(t)$ . In practice, assuming ergodicity, the following approximations are employed:

- $x(t) \approx \delta(t)$ ;
- $\widehat{R}_{\underline{x}\underline{y}}(\tau) = \widehat{\mathcal{R}_{xy}}(\tau) = \frac{1}{2T} \int_{-T}^T x(t)y(t + \tau)dt$  for sufficiently long  $T$ .

Furthermore, the operations are often performed in the discrete-time domain.

The effective bandwidth of an LTI system with frequency response  $H(j\omega)$  can be estimated by its **noise bandwidth**  $W_w$ . For a low-pass system, one looks for an equivalent ideal low-pass filter with bandwidth  $\pm W_w$  around  $\omega = 0$  with bandpass gain  $H(0)$ ;  $W_w$  is computed to guarantee that both systems deliver the same mean output power when the same white noise is applied to their both inputs. A straightforward algebraic development yields

$$W_w = \frac{\int_0^\infty |H(j\omega)|^2 d\omega}{|H(0)|^2}. \quad (4.204)$$

For a band-pass system with magnitude response centered about  $\omega_0$ , one looks for an ideal band-pass filter equivalent with bandwidth  $W_w$  around  $\pm\omega_0$  with bandpass gain  $H(j\omega_0)$ ;  $W_w$  is computed to guarantee that both systems deliver the same mean output power when the same equal white noise is applied to their both inputs. For this case,

$$W_w = \frac{\int_0^\infty |H(j\omega)|^2 d\omega}{|H(\omega_0)|^2}. \quad (4.205)$$

A real “bandpass” random process (see Section 1.04.4.15) about center frequency  $\omega_0$  can be expressed as  $\underline{n}(t) = \underline{m}(t) \cos[\omega_0 t + \underline{\theta}(t)]$ , where the envelope  $\underline{m}(t)$  and the phase  $\underline{\theta}(t)$  are both baseband random processes. We can write

$$\underline{n}(t) = \underline{n}_x(t) \cos(\omega_0 t) - \underline{n}_y(t) \sin(\omega_0 t), \quad (4.206)$$

where  $\underline{n}_x(t) = \underline{n} \cos(\underline{\theta}(t))$  and  $\underline{n}_y(t) = \underline{n} \sin(\underline{\theta}(t))$  are the quadrature components of  $\underline{n}(t)$ . In the typical situation where  $\underline{n}(t)$  is a zero-mean WSS random process with auto-correlation  $R_{nn}(\tau)$ , we can explicitly find the first and second-order moments of the quadrature components that validate the model. First define the **Hilbert transform** of a given signal  $n(t)$  as  $\hat{n}(t) = (n * h)(t)$ , where

$$H(j\omega) = \mathcal{F}[h(t)] = \begin{cases} -j, & \omega > 0; \\ j, & \omega < 0. \end{cases} \quad (4.207)$$

From  $R_{nn}(\tau)$ , we can find  $R_{\hat{n}\hat{n}}(\tau)$  and proceed to write:

- $\overline{\underline{n}_x} = \overline{\underline{n}_y} = 0$ ;
- $R_{\underline{n}_x \underline{n}_x}(\tau) = R_{\underline{n}_y \underline{n}_y}(\tau) = R_{nn}(\tau) \cos(\omega_0 \tau) + R_{\hat{n}\hat{n}}(\tau) \sin(\omega_0 \tau)$ ;
- $R_{\underline{n}_x \underline{n}_y}(\tau) = -R_{\underline{n}_y \underline{n}_x}(\tau) = R_{nn}(\tau) \sin(\omega_0 \tau) - R_{\hat{n}\hat{n}}(\tau) \cos(\omega_0 \tau)$ .

In the frequency domain, if we define

$$S_{\underline{n}\underline{n}}^+(\omega) \triangleq \begin{cases} S_{nn}(\omega), & \omega > 0 \\ 0, & \omega \leq 0, \end{cases} \quad (4.208)$$

then

- $S_{\underline{n}_x\underline{n}_x}(\omega) = S_{\underline{n}_y\underline{n}_y}(\omega) = S_{nn}^+(\omega + \omega_0) + S_{nn}^+(\omega - \omega + \omega_0);$
- $S_{\underline{n}_x\underline{n}_y}(\omega) = -S_{\underline{n}_y\underline{n}_x}(\omega) = j[S_{nn}^+(\omega + \omega_0) - S_{nn}^+(\omega - \omega + \omega_0)].$

In the particular case where  $\underline{n}(t)$  is Gaussian, it can be shown that  $\underline{n}_x(t)$  and  $\underline{n}_y(t)$  are Gaussian, and thus completely defined by their first- and second-order moments above.

#### 1.04.4.18 Statistical modeling of signals: random sequence as the output of an LTI system

A discrete-time signal  $x[n]$  with spectrum  $X(e^{j\Omega})$  can be modeled as the output of a linear time-invariant system whose frequency response is equal to  $X(e^{j\Omega})$  when excited by a unit impulse  $\delta[n]$ . In this case, the impulse response of the system is expected to be  $h[n] = x[n]$ .

In the context of statistic models, an analogous model can be built: now, we look for a linear time-invariant system which produces at its output the WSS random sequence  $\underline{x}[n]$  with power spectral density  $S_{\underline{x}\underline{x}}(e^{j\Omega})$ , when excited by a unit-variance random sequence  $\underline{w}[n]$  of white noise. As before, the frequency response of the system alone is expected to shape the output spectrum, yet this time in the mean power sense, i.e., the system must be such that  $S_{\underline{x}\underline{x}}(e^{j\Omega}) = |H(e^{j\Omega})|^2$ .

Assume the overall modeling system is described by the difference equation

$$x[n] = \sum_{k=1}^p a_p[k]x[n-k] + \sum_{k=0}^q b_q[k]w[n-k], \quad (4.209)$$

where  $w[n]$  is white noise with  $S_{ww}(e^{j\Omega}) = 1$ . The corresponding transfer function is

$$H(z) = \frac{B_q(z)}{A_p(z)} = \frac{\sum_{k=0}^q b_q[k]z^{-k}}{1 + \sum_{k=1}^p a_p[k]z^{-k}}. \quad (4.210)$$

The output  $\underline{x}[n]$  of this general system model with  $\underline{w}[n]$  at its input is called **ARMA (auto-regressive moving-average<sup>22</sup>) process** of order  $(p, q)$ . It can be described by the following difference equation in terms of its auto-correlation:

$$R_{\underline{x}\underline{x}}[k] = \sum_{l=1}^p a_p[l]R_{\underline{x}\underline{x}}[k-l] = \begin{cases} \sum_{l=0}^{q-k} b_k[l+k]h^*[l], & 0 \leq k \leq q; \\ 0, & k > q. \end{cases} \quad (4.211)$$

---

<sup>22</sup>Auto-regressive for its output feedback, moving average for its weighted sum of past input samples.

The values of  $R_{xx}[k]$  for  $k < 0$  can be easily found by symmetry.

If one restricts the system to be FIR (i.e., to have a finite-duration impulse response), then  $p = 0$ , i.e.,  $a_p[k] = 0$  for  $1 \leq k \leq p$ , and

$$H(z) = \sum_{k=0}^q b_q[k]z^{-k}. \quad (4.212)$$

The output of this “all-zero”<sup>23</sup> system model with  $\underline{w}[n]$  at its input is called an **MA (moving-average) process** of order  $q$ . Its auto-correlation can be found to be

$$R_{xx}[k] = \sum_{l=0}^{q-|k|} b_k[l + |k|]b_q^*[l]. \quad (4.213)$$

In this case,  $R_{xx}[k] = 0$  for  $k < -q$  or  $k > q$ . This model is more suited for modeling notches in the random sequence power spectrum.

If one restricts the system to be “all-pole,”<sup>24</sup> then  $q = 0$ , i.e.,  $b_q[k] = 0$  for  $1 \leq k \leq p$ , and

$$H(z) = \frac{b[0]}{1 + \sum_{k=1}^p a_p[k]z^{-k}}. \quad (4.214)$$

The output of this system model with  $\underline{w}[n]$  at its input is called an **AR (auto-regressive) process** of order  $p$ . Its auto-correlation follows the difference equation below:

$$R_{xx}[k] = \sum_{l=1}^p a_p[l]R_{xx}[k-l] = |b[0]|^2\delta[k]. \quad (4.215)$$

Again, the values of  $R_{xx}[k]$  for  $k < 0$  can be easily found by symmetry. This model is more suited for modeling peaks in the random sequence power spectrum, which is typical of quasi-periodic signals (as audio signals, for example). It should be noticed that, differently from the ARMA and MA cases, the equation for the AR process auto-correlation is linear in the system coefficients, which makes their estimation easier. If  $R_{xx}[k]$  is known for  $0 \leq k \leq p$ , and recalling that  $R_{xx}[-k] = R_{xx}^*[k]$ , one can:

- solve the  $p$ th-order linear equation system obtained by substituting  $k = 1, 2, \dots, p$  in Eq. (4.215) to find  $a_p[k]$ ,  $1 \leq k \leq p$ ;
- compute  $|b[0]|$  from Eq. (4.215) with  $k = 0$ .

All-pole modeling of audio signals is extensively used in restoration systems [8].

---

<sup>23</sup>This is a misname, since the poles of the system are at the origin. In fact, the zeros are the only responsible for shaping the frequency response of the system.

<sup>24</sup>This is another misname, since the zeros of the system are at the origin. In fact, the poles are the only responsible for shaping the frequency response of the system.

## 1.05.1 Introduction

The shift from analog signal processing (ASP) to digital signal processing (DSP) lies behind the tremendous development of information processing systems that are used today in practically all areas one can think of. For example, DSP has enabled the fast growth of mobile communication systems and has opened up for new sophisticated medical aids, just to mention a couple of important applications. The foremost advantages of DSP over ASP are its robustness and that it can perform functions with arbitrary precision. This is because arithmetic operations in the digital domain can be done with as small numerical errors as desired by simply increasing the resolution, i.e., by allocating more bits for the operands. This can always be done as the resolution in DSP systems is independent of physical variations, like temperature changes and processing inaccuracies etc., and is in contrast to ASP systems which are highly dependent on such variations. The trend during the past decades has therefore been to use as little ASP as possible and to replace analog functions with the corresponding digital functions. This trend has been sped up by the fast development of integrated circuit techniques and progress in the implementation of digital systems. Specifically, the introduction of cost-efficient signal processors and so called application-specific integrated circuits (ASICs) has enabled low-cost implementation and manufacturing of digital systems. The real world is however analog by nature which means that the need for ASP cannot be eliminated completely. In particular, it will always be necessary to use analog-to-digital converters (abbreviated A/D converters or ADCs) and digital-to-analog converters (abbreviated D/A converters or DACs) for interfacing the two realms.

Evidently, ADCs and DACs are crucial components in virtually all practical applications today. The fundamental signal processing operations in these components are sampling and quantization (in ADCs), and signal reconstruction (in DACs). This chapter considers the basic principles of these operations as detailed below.

### 1.05.1.1 Scope and prerequisites

The theory of sampling has a long history [1–4], and the literature is abundant, see for example [5–7] and references therein. In this chapter, we are only able to cover some parts of this field. The emphasis is on basic principles and analysis methods for uniform sampling and quantization which are the most common sampling and quantization schemes used in conventional ADCs and DACs. Further, we will

only consider linear models of the sampling and quantization processes. Practical ADCs and DACs exhibit (small) nonlinearities which also need to be analyzed in practice, but it is beyond the scope of this chapter to cover also this part. In other words, this chapter concentrates on the underlying principles of uniform sampling and quantization rather than fine implementation details. For such details, we refer to books on ADCs and DACs [8]. Furthermore, we take an “engineering approach” in that we concentrate on explaining the concepts that are sufficient for understanding and analyzing practical signals and systems. Some of the fine mathematical details are therefore sometimes left out.

It is assumed that the reader has a basic knowledge of continuous-time and discrete-time signals and systems as well as the Fourier, Laplace, and  $z$ -transforms. Some of the basics regarding signals and systems are however briefly recapitulated in Section 1.05.2. Further, Section 1.05.4 assumes that the reader is familiar with stochastic processes. Most of the material in the other sections can however be understood without reading Section 1.05.4.

### 1.05.1.2 Chapter outline

After this introductory section, Section 1.05.2 gives some basic concepts. Then, Section 1.05.3 discusses the basics of uniform sampling and reconstruction of deterministic signals. The content of this section is typically also found in introductory books in signal processing [9,10]. Section 1.05.4 considers the extension to sampling and reconstruction of stochastic processes (also called random processes). In introductory books in signal processing, this is typically treated very briefly or not at all.

Section 1.05.5 considers an application referred to as time-interleaved ADCs, which is a scheme that has been introduced for high-speed A/D conversion [11]. The section discusses the principles and signal reconstruction methods which are required in this scheme due to analog channel mismatches. Without correction, this scheme corresponds to nonuniform sampling (or generalizations), but the overall goal, with correction, is to achieve uniform sampling.

Section 1.05.6, covers the principles of quantization, both in ADCs and internally in digital systems, as they are closely related. In Section 1.05.7, oversampled ADCs and DACs are briefly discussed. Oversampling techniques are used in practice to, e.g., increase the performance and relax the requirements of the analog components. Finally, Section 1.05.8 presents a method for discrete-time modeling of mixed-signal systems. This is useful in systems with feedback, like so called  $\Sigma\Delta$ -modulator-based ADCs. Such converters can reach a very high resolution using oversampling together with noise shaping [12,13].

Finally, it is pointed out that, throughout the chapter, real-valued signals are used in the examples. However, the basic principles to be presented are valid for complex signals as well.

### 1.05.1.3 Current trends

The research and development of data converters have been quite intensive for several decades, both in academia and industry. This interest is foreseen to continue for many years to come as the requirements on the signal processing systems and thus the converters continuously increase. To exemplify, it was envisaged in [14] that an ADC capable of bandwidths of more than 100 MS/s and 17 bits resolution is required in fourth-generation communication systems. This is beyond the state-of-the art ADCs which can manage only some 13–14 effective bits of resolution at such sampling rates [15–17]. At the same time, it is also desirable to decrease the size and power consumption of the converters. To enable the

high-performance applications of tomorrow, it is therefore vital to continue to conduct research on new principles of data conversions as well their practical implementations.

There are different paths one can take to increase the performance. One way is to make use of parallel converters like time-interleaved ADCs [11] (to be discussed in Section 1.05.5) and/or parallel  $\Sigma\Delta$  ADCs [18]. Such converters have great potentials but due to analog channel mismatches they also introduce errors that must be compensated for. A recent trend here is “digitally assisted analog circuits,” where digital circuitry is added to correct for analog errors [19]. With the increasing computational capacity of digital systems, one can expect that this trend will continue. The digital parts may however be computationally excessive, and it is therefore vital to devise new algorithms to reduce the complexity.

Another trend is that of sub-Nyquist sampling covering so called sparse sampling and compressed sampling (also called compressed sensing) [20–22]. This is different from the traditional Nyquist-sampled systems in that additional knowledge of the input signal is taken into account. Specifically, if the signal is sparse in some sense, one can reduce the sampling rate and thereby relax the requirements on the converters. One scenario is for applications where the signals are locally narrow-band (in time) but globally wide-band. Conventionally, high-speed converters are then needed. Utilizing the sparse or compressed sampling paradigm, the sampling rate can be reduced substantially. However, at this point, mainly the concepts have been presented and analyzed for some specific cases and classes of signals. It is an open question how well such principles will work in practical implementations.

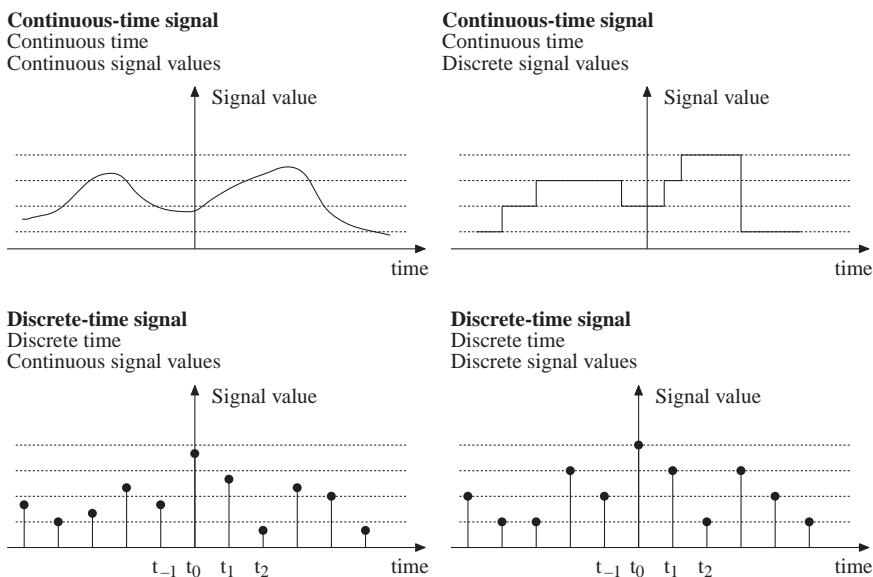

## 1.05.2 Preliminaries

### 1.05.2.1 Classification of signals

We communicate by conveying information (messages), like speech and images. In some contexts, one wishes to transmit information from one place to another, like in telephone systems. In other cases, it may be desired to store the information for later use, e.g., music stored on CDs.

Information can be transmitted using information bearing signals. A signal is a quantity that varies with time or other independent variables. Usually, the information must be converted to a desired signal type. For example, when we speak in a microphone, the generated sound is converted to an electrical voltage that varies with time. The sound can then be recovered by connecting the voltage to a loudspeaker. (In this context, however, we usually do not consider the sound as being recovered since it, in principal, is reconstructed at the same time as it is generated.) The same information can be represented in many different ways. Different types of signals can in other words contain exactly the same information. For example, speech and music can be represented in analog form on LPs and in digital form on CDs. The corresponding signals are then analog and digital, respectively.

In mathematical form, a signal is represented as a function (or sequence) of one or several independent variables. The signal is a one-dimensional signal if it is a function of one variable and a multi-dimensional signal if it is a function of several variables. This chapter considers one-dimensional signals only. An example of such signals is a speech signal. It is customary to let the independent variable represent time although it may represent whatever we wish, like temperature, pressure, etc. The time variable in the representation of a signal can be either continuous or discrete (quantized). The signal is a continuous-time signal if the variable is continuous and a discrete-time signal if the variable is discrete. A continuous-time signal is thus defined for all time instances (except possibly at discontinuities) whereas a

**FIGURE 5.1**

Different types of signals.

discrete-time signal is defined only at discrete time instances. We also differ between signals that can take on continuous signal values and those that only can take on discrete signal values. Consequently, signals can be divided into four different categories according to Figure 5.1.

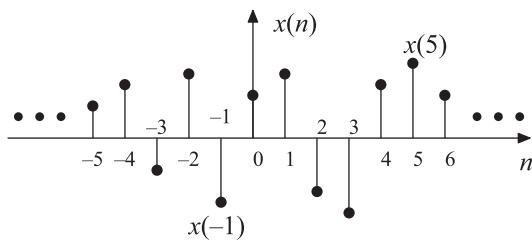

In the literature, a continuous-time signal with continuous signal values is often referred to as an analog signal, whereas a discrete-time signal with discrete signal values is called a digital signal. However, in some (earlier) literature, “analog” and “digital” are only related to the signal values, i.e., the signals to the left in Figure 5.1 are then analog whereas the signals to the right in the same figure are digital. In this book, we assume hereafter that analog signals are continuous-time signals whereas digital signals are discrete-time signals.

### 1.05.2.2 Discrete-time signals—sequences

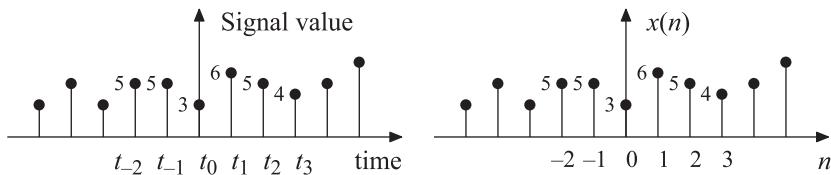

A continuous-time signal can mathematically be represented by a continuous function  $x(t)$  where  $t$  is a continuous variable. A discrete-time signal cannot be represented in this way since it is only defined at discrete instances. To handle discrete-time signals mathematically, one therefore makes use of sequences of numbers.

As one can see from Figure 5.1, the signal values of a discrete-time signal constitute a sequence of numbers. In mathematical form, a sequence of numbers can be written as

$$\{x(n)\}, \quad n = \dots, -2, -1, 0, 1, 2, \dots, \quad (5.1)$$

**FIGURE 5.2**

Graphical representation of a sequence  $x(n)$ .

**FIGURE 5.3**

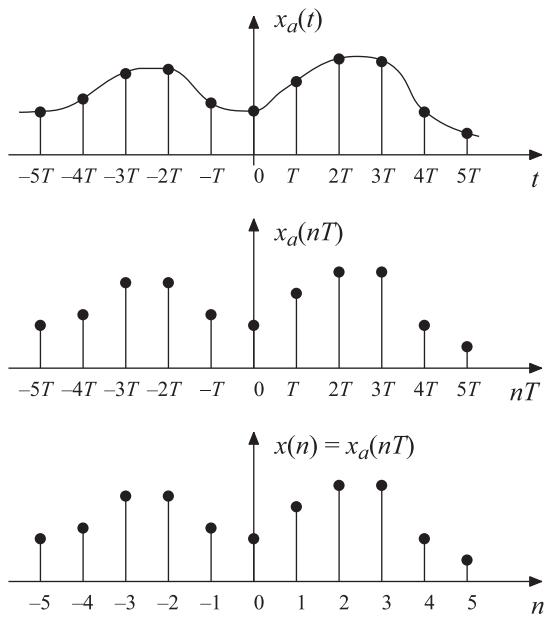

A discrete-time signal and its representation in the form of a sequence  $x(n)$ .

where  $\{x(n)\}$  denotes the sequence whereas  $x(n)$  denotes value number  $n$  in the sequence. The values  $x(n)$  are usually called samples because they are often generated through sampling of continuous-time signals, see the subsequent subsection. The notation of the sequence is thus  $\{x(n)\}$ , but when no misunderstandings can occur we write “the sequence  $x(n)$ ” for the sake of simplicity. A sequence can be represented graphically as illustrated in Figure 5.2. The horizontal axis is drawn as a continuous line but it is important to remember that the sequence is only defined for discrete values.

When a sequence represents a discrete-time signal, the samples  $x(n)$  equal the signal values of the signal at the time instances  $t = t_n$ , as illustrated in Figure 5.3. Since sequences often represent discrete-time signals, we frequently write “the discrete-time signal  $x(n)$ ” instead of “the sequence  $x(n)$ .” This is in accordance with the continuous-time case where one often writes “the continuous-time signal  $x(t)$ ” instead of “the function  $x(t)$ .”

### 1.05.2.3 Sampling of continuous-time signals

Discrete-time signals are often generated through sampling (measurement) of continuous-time signals. It is common to use the same time interval  $T$  between the sampling instances. The sampling then takes place at the time instances  $t = nT$ , as illustrated in Figure 5.4. The time interval is called the sampling period whereas  $f_s = 1/T$  is referred to as the sampling frequency, which thus denotes the number of sampling instances per second. This type of sampling is called uniform sampling. If  $x_d(t)$  denotes the

**FIGURE 5.4**

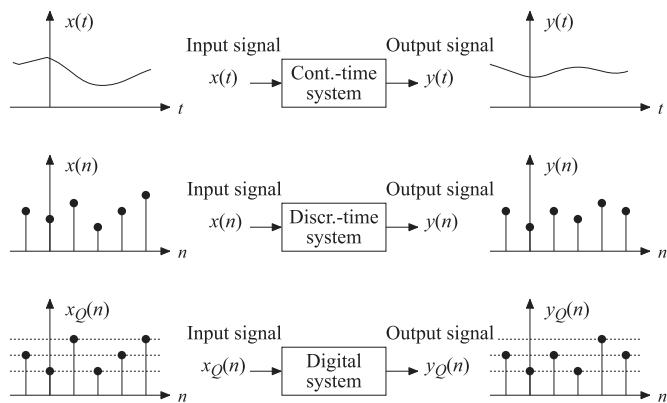

Sampling of a continuous-time signal.

continuous-time signal,<sup>1</sup> the corresponding discrete-time signal  $x(n)$  becomes  $x(n) = x_a(nT)$ . Instead of using the notation  $x(n)$  one may thus use  $x_a(nT)$  to stress that the signal values are obtained via uniform sampling of a continuous-time signal. Throughout this chapter, we mainly use  $x(n)$  for the sake of simplicity.

#### 1.05.2.4 Classification of systems

Systems can be classified in accordance with their input and output signal types. As we saw in the previous section, we can divide signals into four different categories. Hence, one may also divide systems into four basic classes as seen in Figure 5.5. A continuous-time system is a system whose input and output signals are continuous-time signals, whereas a discrete-time system is a system whose input and output signals are discrete-time signals. Mathematically, the role of a discrete-time system is thus to generate an output sequence given an input sequence. Therefore, instead of the terms “input signal” and “output signal,” we often use the terms “input sequence” and “output sequence.” A digital system is a discrete-time system in which the samples only can take on discrete values. Today, signal processing systems usually contain both continuous-time and discrete-time parts.

<sup>1</sup>The subscript “a” in  $x_a(t)$  stands for analog. We use the notation  $x_a(t)$  instead of  $x_c(t)$ , which would be natural when we deal with continuous-time signals. This is to avoid confusion with frequency edges  $\Omega_c$  etc., where “c” stands for cutoff.

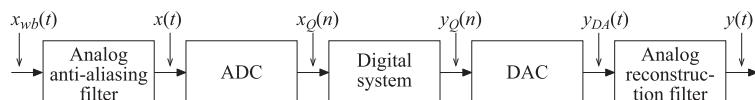

**FIGURE 5.5**

Three different types of systems.

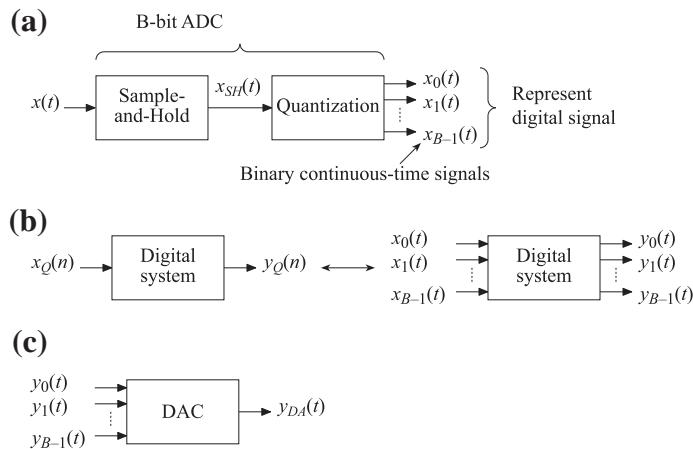

### 1.05.2.5 Digital signal processing of analog signals

The principle of digital signal processing of analog signals is illustrated in Figures 5.6–5.8. The first step is to convert the signal from analog into digital form. This is done by an ADC which takes care of both sampling and quantization. The so obtained digital signal can then be processed by a digital system which takes as input a sequence of samples,  $x_Q(n)$ , and generates an output sequence,  $y_Q(n)$  [ $Q$  indicates quantized signal values]. Finally, reconstruction takes place in order to go back to a continuous-time representation. This is performed by a DAC followed by an analog so called reconstruction filter.

To be able to perform A/D and D/A conversion without errors, the original signal must be bandlimited. Before the A/D conversion, the signal is therefore bandlimited with the aid of an analog so called anti-aliasing filter ( $wb$  in  $x_{wb}(t)$  in Figure 5.6 stands for wide-band). A/D conversion is done by first sampling and then quantizing the signal, see Figure 5.7a. In practice, the sampling is performed by a sample-and-hold-circuit (S/H circuit). An S/H circuit samples an analog signal at the time instances  $t = nT$  and holds this sample value until the next sampling instance. The output signal from an ideal S/H circuit is a new analog signal that ideally is piece-wise constant. The function of the S/H circuit can be seen in Figure 5.8a and b. The next step in the A/D conversion is to quantize the sample values using a quantizer. The input signal of the quantizer is thus the output signal from the S/H circuit. The input to

**FIGURE 5.6**

Digital signal processing of analog signals.

**FIGURE 5.7**

ADC, digital system, and DAC.

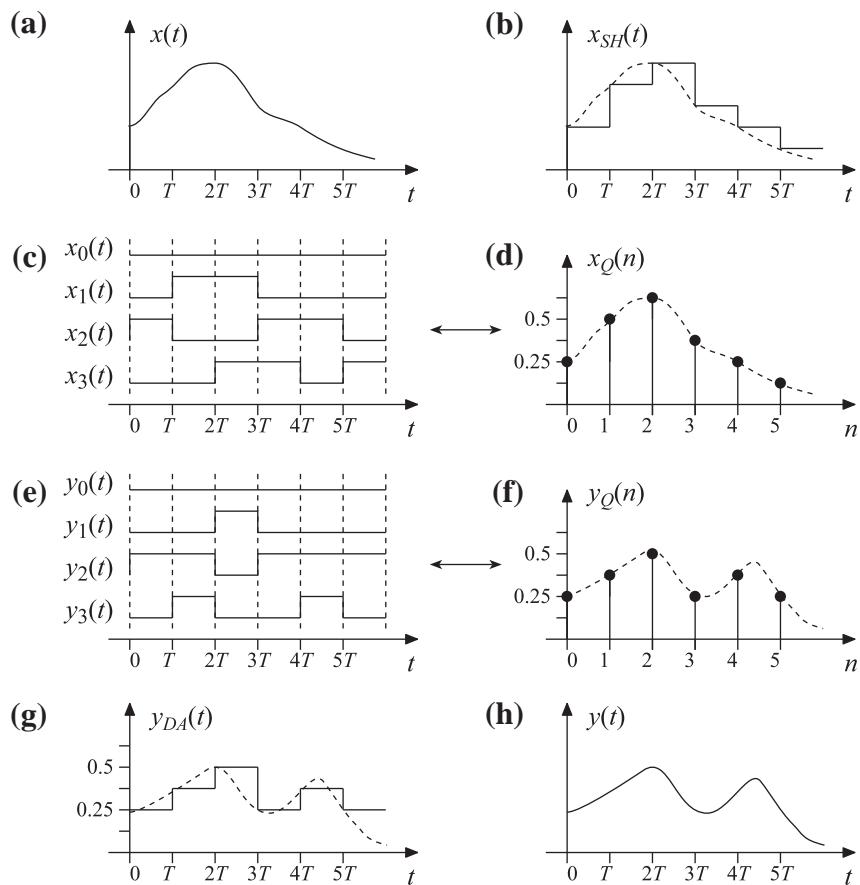

the quantizer needs to be kept constant long enough for the quantizer to produce a correct result which is why an S/H circuit is needed.

Quantization amounts to representing each sample in a binary form with a finite wordlength. There exist many different types of binary representations. One commonly used binary form is the two's-complement representation. A number  $x$ , which for the sake of simplicity is assumed here to lie between  $-1$  and  $1$ , is then represented as

$$x = -x_0 + \sum_{i=1}^{B-1} 2^{-i} x_i, \quad (5.2)$$

where  $x_i, i = 0, 1, \dots, B-1$ , can take on the values zero and one. The number of bits is thus  $B$ . The bits from a quantizer can be delivered in serial or parallel. In the latter case, the output signal from a  $B$ -bit quantizer consists in practice of  $B$  continuous-time signals which together represent the different sample values. In the ideal case, these continuous-time signals are binary. That is, they can only take on two different values, usually zero and one. The principle can be seen in Figure 5.8c and d. In practice, the signals must hold the values zero or one long enough so one can store them in registers, etc. Furthermore, it takes a certain time to perform the quantizations which means that a certain amount of delay will be introduced. The output signal from the quantizer is the desired digital signal that can be processed by a digital system. In a practical implementation, the sample values are represented in the same form as the quantizer output. The output signal from a digital system is thus represented in the same form as its input signal, see Figure 5.8e and f.

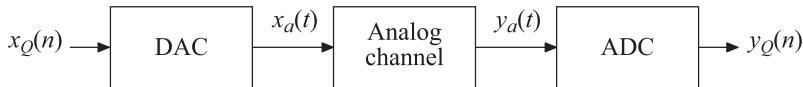

A digital signal can be converted to an analog signal using a DAC followed by an analog reconstruction filter. The input signal to the DAC is a digital signal represented in the same form as the output signal from the ADC, i.e., the output from the quantizer. The output signal from the DAC is a continuous-time signal that is piece-wise constant with a limited number of levels, see Figure 5.8(g). In other words, it

**FIGURE 5.8**

Typical signals in digital signal processing of analog signals.

is of the same type as the output signal from the S/H circuit with the difference that the DAC output signal takes on discrete signal values whereas the S/H circuit output signal takes on continuous signal values. Finally, to obtain the desired analog signal, the output signal from the DAC must be filtered. The role of this filter is to “smooth out” the piece-wise-constant signal from the DAC so as to obtain the desired signal.

As evident from above, sampling and reconstruction as well as quantization play fundamental roles in digital signal processing. The following sections treat the basic principles of these operations. We will only deal with relations between continuous-time signals and the discrete-time counterparts. Mathematically, this amounts to study relations between functions  $x_a(t)$  and the corresponding sequences  $x(n) = x_a(nT)$  as well as their transform-domain relations. We will not discuss the physical representation of the signals seen in Figures 5.7 and 5.8.

**FIGURE 5.9**

Simple model of a digital communication system.

### 1.05.2.6 Digital communication—analog signal processing of digital signals

In digital communication systems, the situation is opposite to that in the previous section in that analog signal processing is now used for processing digital signals. Figure 5.9 shows a simple model of a digital communication system. The original digital information is contained in  $x_Q(n)$ . This information is D/A converted before being transmitted over an analog channel. Finally, on the receiver side, the signal is A/D converted, generating  $y_Q(n)$ . It is desired to have  $y_Q(n) = x_Q(n)$  so as to receive the information sent. In practice, due to many different error sources in the communication channel, advanced digital signal processing methods are required to transmit information successfully. Regarding the sampling and reconstruction, one can make use of the same analysis methods here as for the system depicted earlier in Figure 5.6.

---

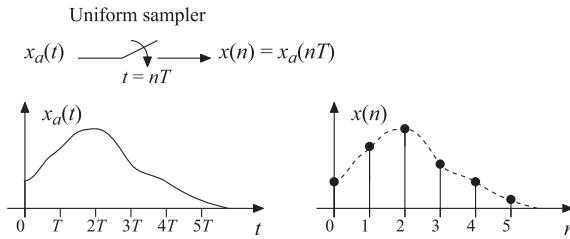

## 1.05.3 Sampling of deterministic signals

Discrete-time signals are often generated through sampling of continuous-time signals. It is therefore of interest to investigate the relations between the Fourier transform of a discrete-time signal and that of the underlying continuous-time signal. This relation is given by the so called Poisson's summation formula which leads us to the sampling theorem. This theorem states that a continuous-time signal can be sampled and perfectly reconstructed provided that the signal is bandlimited and the sampling frequency exceeds twice the bandwidth. If the theorem is fulfilled, the original signal can be retained via an ideal pulse amplitude modulator. This section treats basic concepts and theory on sampling and reconstruction. In practice, one can neither fulfill the sampling theorem nor perform the reconstruction perfectly because ideal pulse amplitude modulators cannot be implemented. Some of these practical aspects are included in the section. It is also noted that this section deals with deterministic signals. The extension to stochastic signals is treated in Section 1.05.4.

### 1.05.3.1 Uniform sampling

Discrete-time signals are typically generated through sampling (measurement) of continuous-time signals. Most signal processing applications are based on uniform sampling which means that the time interval between two consecutive sampling instances is constant. The sampling then takes place at the time instances  $t = nT$ ,  $n = \dots, -2, -1, 0, 1, 2, \dots$ , as illustrated in Figure 5.10. The time interval  $T$  is called the sampling period whereas  $f_s = 1/T$  is referred to as the sampling frequency, which thus denotes the number of sampling instances per second. If  $x_a(t)$  denotes the continuous-time signal, the corresponding discrete-time signal, represented by the sequence  $x(n)$ , becomes

$$x(n) = x_a(nT). \quad (5.3)$$

**FIGURE 5.10**

Uniform sampling.

### 1.05.3.2 Poisson's summation formula

This section derives a relation between the Fourier transforms of  $x(n)$  and  $x_a(t)$ . Assume that the continuous-time signal  $x_a(t)$  has the Fourier transform  $X_a(j\Omega)$ . We can then express  $x_a(t)$  in terms of its inverse Fourier transform according to

$$x_a(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} X_a(j\Omega) e^{j\Omega t} d\Omega. \quad (5.4)$$

In particular, we have for  $t = nT$ ,

$$x_a(nT) = \frac{1}{2\pi} \int_{-\infty}^{\infty} X_a(j\Omega) e^{j\Omega nT} d\Omega, \quad (5.5)$$

which can be rewritten as

$$\begin{aligned} x_a(nT) &= \dots + \frac{1}{2\pi} \int_{-3\pi/T}^{-\pi/T} X_a(j\Omega) e^{j\Omega nT} d\Omega + \frac{1}{2\pi} \int_{-\pi/T}^{\pi/T} X_a(j\Omega) e^{j\Omega nT} d\Omega \\ &\quad + \frac{1}{2\pi} \int_{\pi/T}^{3\pi/T} X_a(j\Omega) e^{j\Omega nT} d\Omega + \dots \end{aligned}$$

By making the variable substitutions  $\Omega \rightarrow \Omega - 2\pi k/T$ ,  $k$  integer, utilizing that  $e^{-j2\pi kn} = 1$ , and changing the order between summation and integration, we obtain

$$x_a(nT) = \sum_{k=-\infty}^{\infty} \frac{1}{2\pi} \int_{-\pi/T}^{\pi/T} X_a\left(j\Omega - j\frac{2\pi k}{T}\right) e^{j(\Omega - \frac{2\pi k}{T})nT} d\Omega, \quad (5.6)$$

$$= \frac{1}{2\pi} \int_{-\pi/T}^{\pi/T} \sum_{k=-\infty}^{\infty} X_a\left(j\Omega - j\frac{2\pi k}{T}\right) e^{j\Omega T n} d\Omega. \quad (5.7)$$

With  $\Omega T$  as integration variable we get

$$x_a(nT) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{1}{T} \sum_{k=-\infty}^{\infty} X_a\left(j\Omega - j\frac{2\pi k}{T}\right) e^{j\Omega T n} d(\Omega T). \quad (5.8)$$

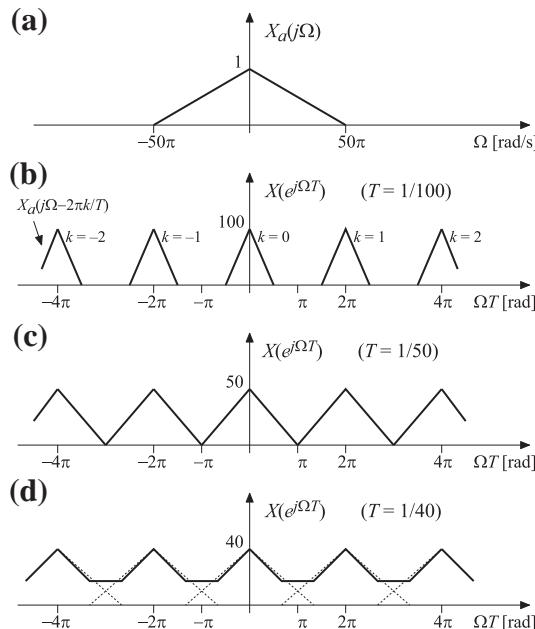

Further, we know that a discrete-time signal  $x(n)$  can be expressed in terms of its inverse Fourier transform according to

$$x(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} X(e^{j\Omega T}) e^{j\Omega T n} d(\Omega T). \quad (5.9)$$

Thus, if we let  $x(n) = x_a(nT)$ , and utilize the uniqueness of the Fourier transform, we obtain the following relation from (5.8) and (5.9):

$$X(e^{j\Omega T}) = \frac{1}{T} \sum_{k=-\infty}^{\infty} X_a \left( j\Omega - j\frac{2\pi k}{T} \right). \quad (5.10)$$

Equation (5.10) is referred to as Poisson's summation formula<sup>2</sup> which gives the relation between the Fourier transform of a continuous-time signal and the Fourier transform of the discrete-time signal that is generated by sampling the continuous-time signal uniformly with the sampling period  $T$  (sampling frequency  $f_s = 1/T$ ) [23]. Poisson's summation formula states that the spectrum of the discrete-time signal is obtained by summing the spectrum of the continuous-time signal and its shifted versions, weighted with  $1/T$ . This is illustrated in Figure 5.11 in the following example.

**FIGURE 5.11**

Spectra for a continuous-time signal and the corresponding sequences generated via sampling with three different sampling frequencies.

<sup>2</sup>If the sampled signal is discontinuous at a certain time instant, and if the signal is sampled at this instant, then the sample value must be chosen as the average of the left and right limits in order to make (5.10) valid.

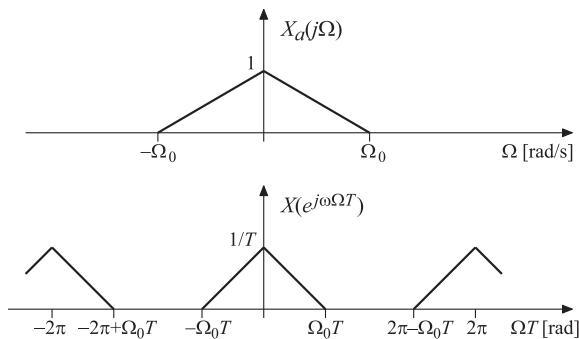

**FIGURE 5.12**

Illustration of the sampling theorem.

### 1.05.3.2.1 Example of Poisson's summations formula

Figure 5.11a shows the spectrum of a bandlimited continuous-time signal. Figure 5.11b–d show the spectra of three different discrete-time signals generated by sampling the continuous-time signal with the sampling frequencies 100 Hz, 50 Hz, and 40 Hz, respectively, i.e.,  $T = 1/100$  s,  $1/50$  s, and  $1/40$  s, respectively. Studying Figure 5.11, the following observations can be made. In the first two cases, the partial spectra do not overlap each other [Figure 5.11b, c]. This means that the shape of  $X_a(j\Omega)$  is preserved and it is thereby possible in principle to reconstruct  $x_a(t)$  from  $x(n)$ , as we shall see later. In the third case, the shape of  $X_a(j\Omega)$  is deteriorated since the partial spectra to some extent overlap each other [Figure 5.11d]. In this case, we can no longer perfectly reconstruct  $x_a(t)$  from  $x(n)$ . What distinguishes the three sequences is that they have been obtained using three different sampling frequencies. If the continuous-time signal is bandlimited, it can thus be sampled and reconstructed perfectly provided that the sampling frequency is sufficiently high. This is summarized below in the sampling theorem.

### 1.05.3.3 The sampling theorem

As illustrated above, a continuous-time signal can be sampled and reconstructed from the generated samples if the so called sampling theorem is fulfilled.

**Sampling theorem:** If a continuous-time signal  $x_a(t)$  is bandlimited to  $\Omega = \Omega_0$  ( $f = f_0$ ), i.e.,

$$X_a(j\Omega) = 0, \quad |\Omega| > \Omega_0 = 2\pi f_0, \quad (5.11)$$

then  $x_a(t)$  can be recovered from the samples  $x(n) = x_a(nT)$  provided that

$$f_s = \frac{1}{T} > 2f_0. \quad (5.12)$$

Thus, if (5.11) and (5.12) are satisfied, the continuous-time signal  $x_a(t)$  can be recovered from  $x(n) = x_a(nT)$ . One can understand this by studying Figure 5.12 (and also Figure 5.11). If the partial spectra in Poisson's summation formula do not overlap each other, the shape of  $X_a(j\Omega)$  is preserved

and it is thereby possible, in principle, to reconstruct  $x_a(t)$  from  $x(n)$ . From Figure 5.12, we see that overlap of spectra is avoided if

$$2\pi - \Omega_0 T > \Omega_0 T \Leftrightarrow \Omega_0 T < \pi. \quad (5.13)$$

Since  $\Omega = 2\pi f$  and  $f_s = 1/T$ , (5.13) is equivalent to

$$2\pi f_0 T < \pi \Leftrightarrow f_s = \frac{1}{T} > 2f_0, \quad (5.14)$$

which is the same as (5.12). The frequency  $f_s/2$  is called the Nyquist frequency whereas  $f_s$  is referred to as the Nyquist sampling frequency. Further, the frequency band  $\Omega \in [-\pi f_s, \pi f_s]$  (thus  $f \in [-f_s/2, f_s/2]$ ) is referred to as the first Nyquist band.

The sampling theorem says that the sampling frequency  $f_s$  must be strictly greater than  $2f_0$  in order to be able to recover the signal. It should be mentioned however that for some classes of signals, like energy signals, one may select  $f_s$  equal to  $2f_0$  and still reconstruct the signals (in a certain sense). For other classes of signals, like sinusoidal signals, it is necessary to fulfill  $f_s > 2f_0$ . This is because, for a sinusoidal signal with the frequency  $f_0$ , one may for example sample the zero-crossings. That is, if  $f_s$  equals  $2f_0$ , one may obtain a sequence with zero-valued samples which means that the continuous-time signal can not be reconstructed.

If  $f_s \leq 2f_0$ , the sampling theorem is not fulfilled in which case the signal is undersampled. This means that the partial spectra will overlap, as was discussed earlier and illustrated in Figure 5.11d. This in turn implies that the shape of the continuous-time signal's spectrum is not preserved, which means that the signal cannot be reconstructed exactly. The error that is then introduced is called aliasing distortion. The reason for this name is that frequency components above the Nyquist frequency are aliased to the baseband  $\Omega T \in [-\pi, \pi]$ , see Figure 5.11d. In practice, one often chooses a higher sampling frequency than that required to fulfill the sampling theorem, the reason being that one can thereby reduce the requirements on the analog components that are used in the A/D and D/A conversions. In such a case, the signal is oversampled. If  $f_s = M2f_0$ , one has  $M$  times oversampling. Oversampled A/D and D/A converters are discussed in Section 1.05.7.

#### 1.05.3.3.1 Example of aliasing

To further illustrate that the sampling theorem must be fulfilled in order to sample and reconstruct a signal, we consider stationary sinusoids. Let  $x_{a1}(t)$  and  $x_{a2}(t)$  be two stationary sinusoidal signals according to

$$x_{a1}(t) = \sin(\Omega_0 t) = \sin(2\pi f_0 t) \quad (5.15)$$

and

$$x_{a2}(t) = -\sin(3\Omega_0 t) = -\sin(6\pi f_0 t). \quad (5.16)$$

We now form the discrete-time signals  $x_1(n)$  and  $x_2(n)$  by sampling  $x_{a1}(t)$  and  $x_{a2}(t)$ , respectively, with a sampling frequency of  $f_s = 4f_0$ , i.e., a sampling period of  $T = 1/(4f_0)$ . This gives us

$$x_1(n) = x_{a1}(nT) = x_{a1}(0.25n/f_0) = \sin(0.5\pi n) \quad (5.17)$$

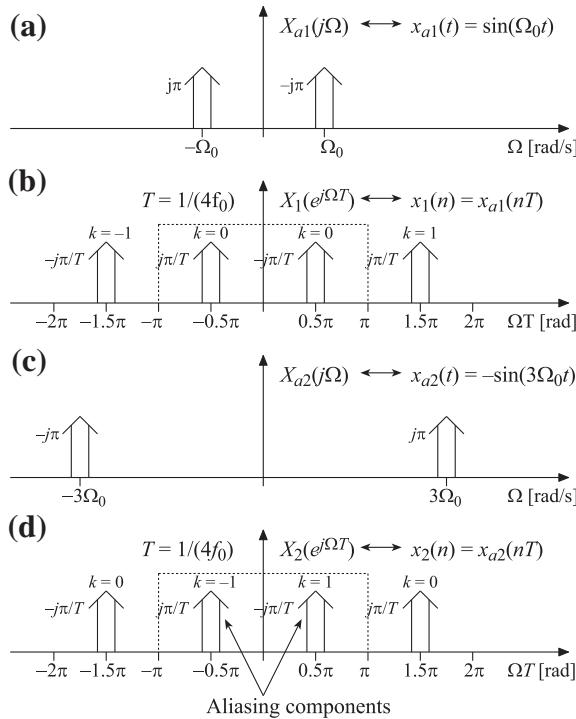

**FIGURE 5.13**

Illustration of aliasing in the example of Section 1.05.3.3.1.

and

$$x_2(n) = x_{a2}(nT) = x_{a2}(0.25n/f_0) = -\sin(1.5\pi n). \quad (5.18)$$

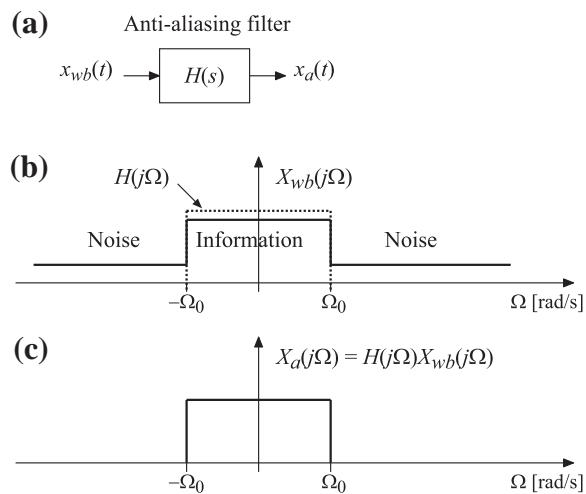

Since  $\sin(a) = \sin(a + 2\pi n)$  for all integers  $n$ , and  $\sin(a) = -\sin(-a)$ , we can rewrite  $x_2(n)$  as

$$\begin{aligned} x_2(n) &= -\sin(1.5\pi n) = -\sin(1.5\pi n - 2\pi n), \\ &= -\sin(-0.5\pi n) = \sin(0.5\pi n) = x_1(n). \end{aligned}$$

That is,  $x_2(n)$  equals  $x_1(n)$ . The reason for this is that the sampling theorem is not fulfilled for  $x_{a2}(t)$ . This means that the spectrum of  $x_{a2}(t)$  is aliased into the band  $\Omega T \in [-\pi, \pi]$ , as illustrated in Figure 5.13. If the sampling theorem is not met, we can thus obtain the same sequence through sampling of two different signals.

#### 1.05.3.4 Anti-aliasing filter

A condition for sampling and perfect reconstruction of a continuous-time signal is that it is strictly bandlimited. In practice, continuous-time signals are not strictly bandlimited which means that we will

**FIGURE 5.14**

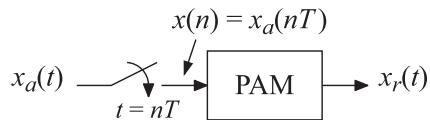

Band limitation using an anti-aliasing filter (wb stands for wide-band).

always have aliasing distortion since the partial spectra then overlap each other. This in turn implies that we can not reconstruct the signal perfectly, but instead we obtain a distorted signal. To obtain an acceptable level of distortion, one usually have to filter the signal before the sampling takes place, as seen in Figure 5.14a. In this context, the filter  $H(s)$  is called anti-aliasing filter because it is used to reduce the aliasing distortion.

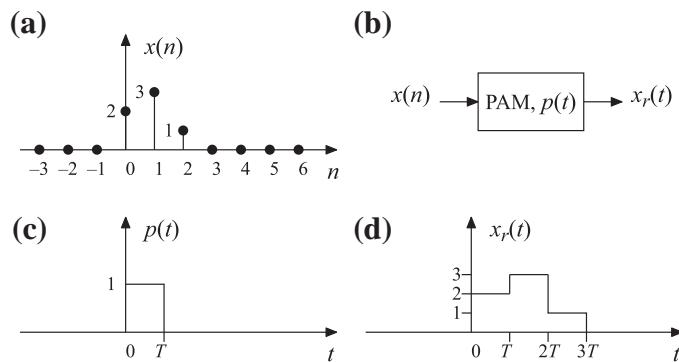

Apparently, the anti-aliasing filter affects the signal that is to be sampled. However, in many cases, the information in the signal lies in the low-frequency region whereas the high-frequency band only contains undesired frequency components like noise etc. If the anti-aliasing filter is an ideal lowpass filter, the information is unaffected whereas the undesired components are removed. This is illustrated in Figure 5.14b and c. In practice, one can not implement ideal filters which means that one always has to account for a certain amount of distortion. More about distortion is given in Section 1.05.3.6.

### 1.05.3.5 Reconstruction

Reconstruction refers to the process that forms a continuous-time signal from a discrete-time signal. The reconstruction can be done with the aid of pulse amplitude modulation. The system that performs the pulse amplitude modulation is called pulse amplitude modulator (PAM). The sampling and reconstruction can be represented as in Figure 5.15. We denote the reconstructed signal as  $x_r(t)$  to separate it from the original signal  $x_d(t)$ .

**FIGURE 5.15**

Sampling and reconstruction using a PAM.

**FIGURE 5.16**

Example of reconstruction (5.19).

The PAM forms the output signal  $x_r(t)$  through multiplication of the samples  $x(n)$  by the pulse (signal)  $p(t)$  and its shifted versions  $p(t - nT)$ . The output signal is given by

$$x_r(t) = \sum_{n=-\infty}^{\infty} x(n)p(t - nT). \quad (5.19)$$

Figure 5.16 shows an example of reconstruction according to (5.19).

#### 1.05.3.5.1 Ideal reconstruction

When the sampling theorem is fulfilled, it is in principle possible to obtain  $x_r(t) = x_a(t)$  by properly selecting  $p(t)$ . If the original signal  $x_a(t)$  is perfectly reconstructed from the samples  $x(n) = x_a(nT)$ , we have ideal reconstruction. As will be clear below, it is however not possible to perform ideal reconstruction in practice.

To see how to choose  $p(t)$  in order to obtain  $x_r(t) = x_a(t)$ , we proceed as follows. If we utilize the expression for the reconstructed signal  $x_r(t)$  in (5.19), its Fourier transform can be written as

$$\begin{aligned} X_r(j\Omega) &= \int_{-\infty}^{\infty} x_r(t) e^{-j\Omega t} dt = \int_{-\infty}^{\infty} \sum_{n=-\infty}^{\infty} x(n) p(t - nT) e^{-j\Omega t} dt \\ &= \sum_{n=-\infty}^{\infty} x(n) \int_{-\infty}^{\infty} p(t - nT) e^{-j\Omega t} dt \end{aligned} \quad (5.20)$$

assuming that integration and summation can be interchanged. The variable substitution  $v = t - nT$  in (5.20) yields

$$\begin{aligned} X_r(j\Omega) &= \sum_{n=-\infty}^{\infty} x(n) \int_{-\infty}^{\infty} p(v) e^{-j\Omega(v+nT)} dv \\ &= \left( \sum_{n=-\infty}^{\infty} x(n) e^{-j\Omega T n} \right) \left( \int_{-\infty}^{\infty} p(v) e^{-j\Omega v} dv \right) \\ &= X(e^{j\Omega T}) P(j\Omega). \end{aligned}$$

We also know that  $X(e^{j\Omega T})$  is related to  $X_a(j\Omega)$  via Poisson's summation formula. The Fourier transform of the reconstructed signal can therefore be related to the Fourier transform of the original signal according to

$$X_r(j\Omega) = P(j\Omega) X(e^{j\Omega T}) = P(j\Omega) \frac{1}{T} \sum_{k=-\infty}^{\infty} X_a \left( j\Omega - j \frac{2\pi k}{T} \right). \quad (5.21)$$

If the sampling theorem is fulfilled, the partial spectra  $X_a(j\Omega - j2\pi k/T)$  do not overlap each other as illustrated in Figure 5.17. We can therefore obtain  $X_r(j\Omega) = X_a(j\Omega)$  by letting  $P(j\Omega)$  be an ideal lowpass filter according to

$$P(j\Omega) = \begin{cases} T, & |\Omega| \leq \Omega_c < \pi/T, \\ 0, & |\Omega| > \Omega_c \end{cases} \quad (5.22)$$

with  $\Omega_0 < \Omega_c \leq \pi/T$  since  $P(j\Omega)$  then leaves  $X_a(j\Omega)$  unaffected and removes the remaining partial spectra. This is also illustrated in Figure 5.17. We then obtain (utilizing the uniqueness of the Fourier transform)

$$X_r(j\Omega) = X_a(j\Omega) \Leftrightarrow x_r(t) = x_a(t). \quad (5.23)$$

That is, the original signal  $x_a(t)$  is reconstructed from the samples  $x(n)$ .

The impulse  $p(t)$  is obtained by taking the inverse Fourier transform of  $P(j\Omega)$  in (5.22). For example, with  $\Omega_c = \pi/T$ , we get

$$p(t) = \frac{\sin(\pi t/T)}{\pi t/T}, \quad (5.24)$$

which is a two-sided function and thus not realizable in practice by causal systems.

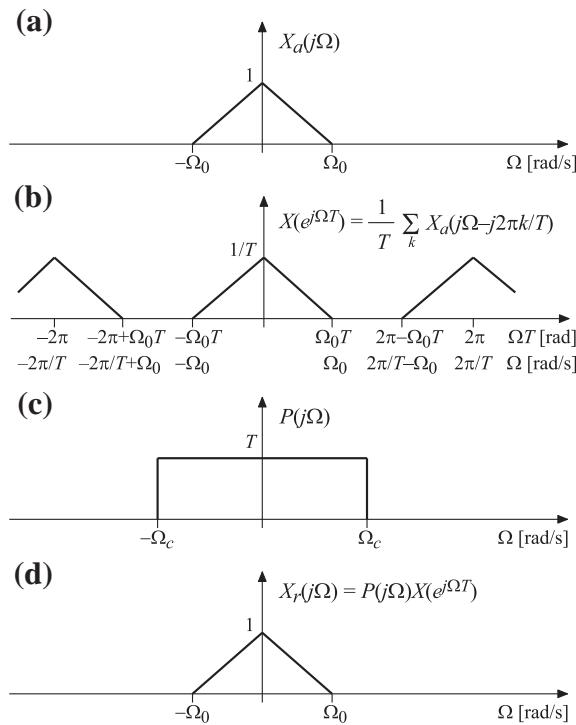

**FIGURE 5.17**

Illustration of ideal reconstruction.

### 1.05.3.5.2 Reconstruction using a D/A converter and an analog reconstruction filter

In practice, the reconstruction is performed using a D/A converter followed by an analog so called reconstruction filter as depicted in Figure 5.18. The D/A converter is in principle a PAM and can therefore be described with a pulse in accordance with the previous section. If we denote this pulse as  $q(t)$ , and let  $x_1(t)$  denote the output from the D/A converter, we get

$$X_1(j\Omega) = Q(j\Omega)X(e^{j\Omega T}). \quad (5.25)$$

Furthermore, we have

$$X_r(j\Omega) = H(j\Omega)X_1(j\Omega). \quad (5.26)$$

Combining (5.25) and (5.26) gives us

$$X_r(j\Omega) = Q(j\Omega)H(j\Omega)X(e^{j\Omega T}). \quad (5.27)$$

We can now write  $X_r(j\Omega)$  as

$$X_r(j\Omega) = P(j\Omega)X(e^{j\Omega T}), \quad (5.28)$$

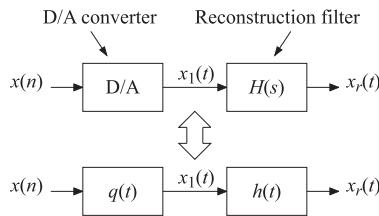

**FIGURE 5.18**

Illustration of ideal reconstruction.

where

$$P(j\Omega) = Q(j\Omega)H(j\Omega). \quad (5.29)$$

We know that, if  $P(j\Omega)$  is chosen as in (5.22), then  $x_r(t) = x_a(t)$ . Hence, also a scheme with a D/A converter followed by a reconstruction filter according to Figure 5.18 achieves ideal reconstruction provided that  $Q(j\Omega)H(j\Omega)$  satisfies

$$Q(j\Omega)H(j\Omega) = \begin{cases} T, & |\Omega| > \Omega_c < \pi/T, \\ 0, & |\Omega| > \Omega_c, \end{cases} \quad (5.30)$$

where  $\Omega_0 < \Omega_c \leq \pi/T$ . Dividing the reconstruction into two steps gives us more degrees of freedom. In particular, one can thereby let  $q(t)$  be a simple pulse since the only requirement is that the product  $Q(j\Omega)H(j\Omega)$  must meet the right-hand side of (5.30). In principle, the actual shape of the individual responses  $Q(j\Omega)$  and  $H(j\Omega)$  are therefore arbitrary. In practice, it is much easier to generate simple pulses, that subsequently are filtered through a conventional analog filter, instead of generating the more complicated pulses directly, like the sinc function in (5.24).

A common type of D/A converter is of the type zero-order hold. In this case,  $q(t)$  is a square pulse according to Figure 5.19d. This pulse can mathematically be expressed as

$$q(t) = \begin{cases} 1, & 0 < t < T, \\ 0, & t < 0, t > T. \end{cases} \quad (5.31)$$

Its Fourier transform is

$$Q(j\Omega) = e^{-j\Omega T/2} \frac{\sin(\Omega T/2)}{\Omega/2}. \quad (5.32)$$

Hence, the Fourier transform  $Q(j\Omega)$  is a sinc function with zero-crossings at  $\pm 2\pi k/T$ , for all integers  $k$ . We note that  $Q(j\Omega)H(j\Omega)$  satisfies (5.30) if the frequency response  $H(j\Omega)$  is selected as

$$H(j\Omega) = \begin{cases} T/Q(j\Omega), & |\Omega| \leq \Omega_c < \pi/T, \\ 0, & |\Omega| > \Omega_c. \end{cases} \quad (5.33)$$

For low frequencies,  $H(j\Omega)$  is thus

$$H(j\Omega) = e^{j\Omega T/2} \frac{\Omega/2}{\sin(\Omega T/2)}, \quad |\Omega| \leq \Omega_c < \pi/T. \quad (5.34)$$

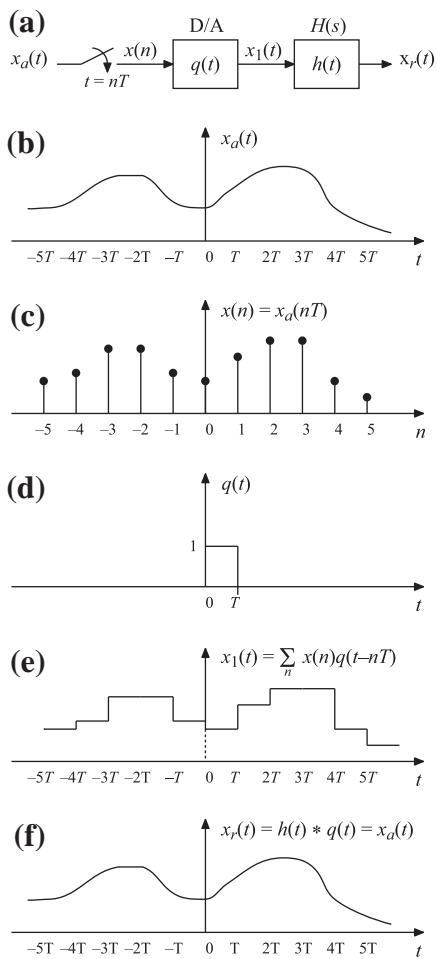

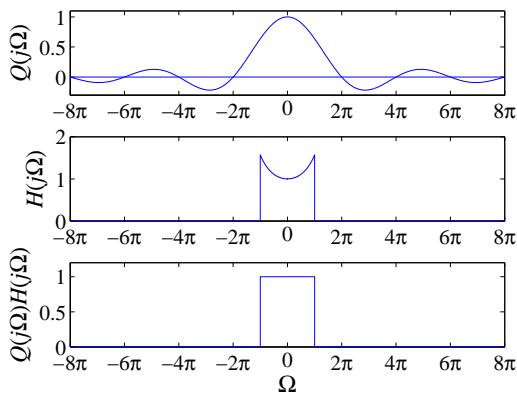

**FIGURE 5.19**

Illustration of reconstruction using a D/A converter and an analog filter.

When  $\Omega_c = \pi/T$ , the frequency response is as shown in Figure 5.20. The response of this filter is discontinuous at  $\Omega_c = \pi/T$  and it can therefore not be implemented in practice. Further, it would be very costly to approximate this function since a high filter order would be required in order to avoid a large distortion.

To get around these problems in practical implementations, one uses a certain amount of oversampling. This means that the sampling frequency is higher than the sampling theorem requires. One can thereby let the reconstruction filter have a transition band as shown in Figure 5.21. The higher is the sampling frequency, the wider can the transition band be. The filter requirements are thus relaxed when

**FIGURE 5.20**

Frequency responses in ideal reconstruction using a D/A converter followed by an analog reconstruction filter ( $T = 1$ ).

the sampling frequency is increased. Another advantage of using oversampling is that the quantization noise that is introduced in the A/D conversion thereby can be reduced. Oversampling will be discussed later in Section 1.05.7. An oversampled A/D converter generates more samples than is actually required to reconstruct the signal. To make sure that the subsequent digital system does not have to work at higher data rates than necessary, one reduces the data rate by using decimation [24]. This can be done without losing information since the signal has been oversampled. In other words, there is a redundancy in the corresponding discrete-time signal.

### 1.05.3.6 Distortion caused by undersampling

In practice, a signal is never strictly bandlimited which means that one will always undersample the signal and thereby obtain a certain amount of aliasing distortion. The sampling frequency must be high enough to ensure that the reconstructed signal does not differ too much from the original one. The following example illustrates how the choice of sampling frequency affects the reconstructed signal.

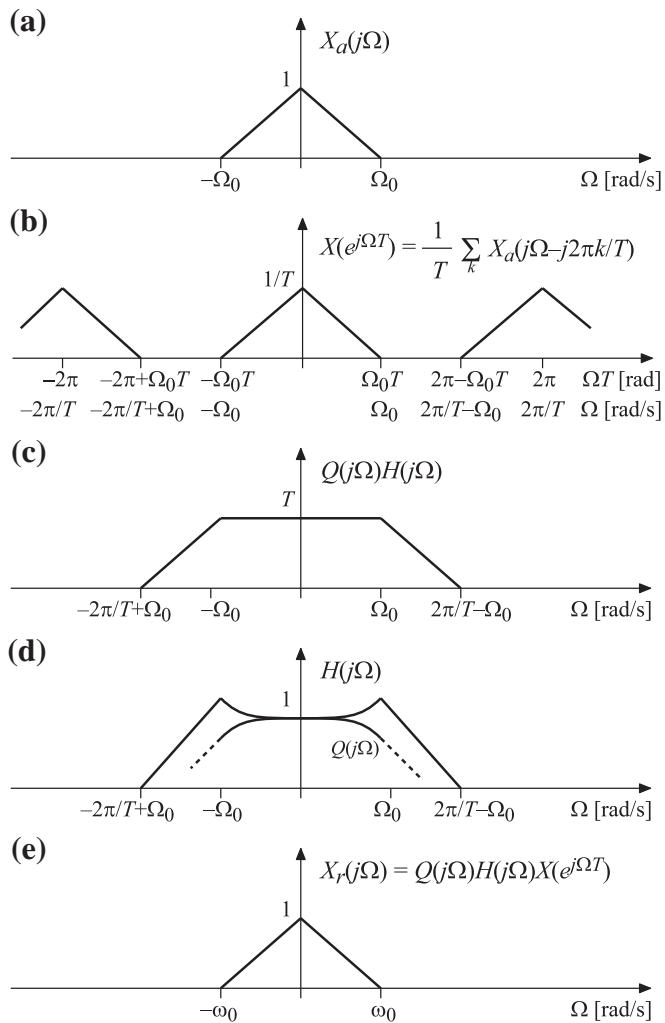

#### 1.05.3.6.1 Example of undersampling

Let  $x_a(t)$  be a continuous-time signal according to

$$x_a(t) = e^{-a|t|}, \quad a > 0. \quad (5.35)$$

This signal has a real Fourier transform given by

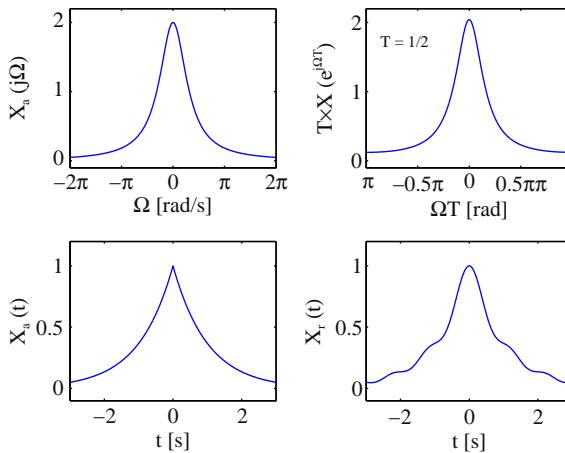

$$X_a(j\Omega) = \frac{2a}{\Omega^2 + a^2}. \quad (5.36)$$

**FIGURE 5.21**

Typical spectra using oversampling and reconstruction via a D/A converter followed by an analog reconstruction filter.

Apparently,  $X_a(j\Omega)$  is not bandlimited. We now sample  $x_a(t)$  with the sampling frequency  $f_s = 1/T$  which gives us the discrete-time signal  $x(n)$  according to

$$x(n) = x_a(nT) = e^{-a|nT|} = (e^{-aT})^{|n|}. \quad (5.37)$$

**FIGURE 5.22**

Spectra and signals in the example in Section 1.05.3.6.1 for  $T = 1/2$ .

The Fourier transform of  $x(n)$  is

$$X(e^{j\Omega T}) = \frac{1 - e^{-2aT}}{1 - 2e^{-aT} \cos(\Omega T) + e^{-2aT}}. \quad (5.38)$$

When  $X_a(j\Omega)$  is real, so is  $X(e^{j\Omega T})$  since the two transforms can be related to each other via Poisson's summation formula. Finally, we perform reconstruction using an ideal PAM where  $P(j\Omega)$  is given by

$$P(j\Omega) = \begin{cases} T, & |\Omega| \leq \pi/T, \\ 0, & |\Omega| > \pi/T. \end{cases} \quad (5.39)$$

This gives us the signal  $x_r(t)$  whose Fourier transform is

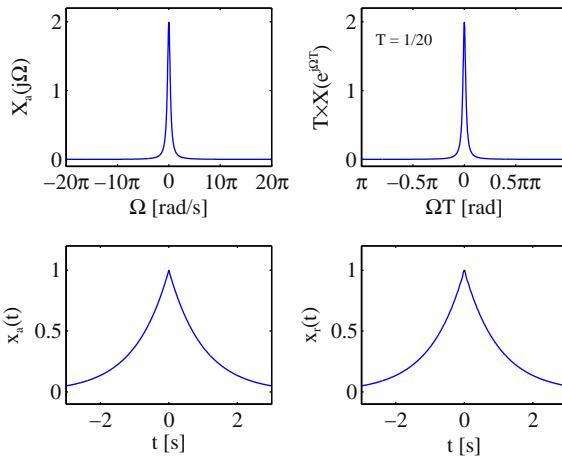

$$X_r(j\Omega) = \begin{cases} TX(e^{j\Omega T}), & |\Omega| \leq \pi/T, \\ 0, & |\Omega| > \pi/T, \end{cases} \quad (5.40)$$

where  $X(e^{j\Omega T})$  is given by (5.38). Figures 5.22 and 5.23 show the spectra  $X_a(j\Omega)$  and  $X(e^{j\Omega T})$  as well as the signals  $x_a(t)$  and  $x_r(t)$ . In Figure 5.22,  $T = 1/2$  whereas  $T = 1/20$  in Figure 5.23. In both cases,  $a = 1$ . For  $T = 1/2$ , the distortion is clearly visible, both in the time and frequency domains. If we instead choose  $T = 1/20$ , i.e., we increase the sampling frequency by a factor of ten, the distortion is no longer visually noticeable. An acceptable level of distortion can thus be obtained by selecting the sampling frequency high enough.

### 1.05.3.7 Distortion measure for energy signals

When the sampling theorem is not satisfied, the reconstructed signal  $x_r(t)$  will differ from the original signal  $x_a(t)$ . We thereby get an error  $e(t)$  according to

$$e(t) = x_r(t) - x_a(t). \quad (5.41)$$

**FIGURE 5.23**

Spectra and signals in the example in Section 1.05.3.6.1 for  $T = 1/20$ .

For energy signals, a common measure of the “size” of the distortion is the ratio between the error energy and the signal energy, whereby one computes  $E_e/E_x$  where  $E_x$  and  $E_e$  denote the energies of  $x_a(t)$  and  $e(t)$ , respectively. These energies are given by

$$E_x = \int_{-\infty}^{\infty} x_a^2(t) dt = \frac{1}{2\pi} \int_{-\infty}^{\infty} |X_a(j\Omega)|^2 d\Omega \quad (5.42)$$

and

$$E_e = \int_{-\infty}^{\infty} e^2(t) dt = \frac{1}{2\pi} \int_{-\infty}^{\infty} |E(j\Omega)|^2 d\Omega, \quad (5.43)$$

where we have utilized Parseval’s formula. If we now make use of (5.41) we can rewrite (5.43) as

$$E_e = \frac{1}{2\pi} \int_{-\infty}^{\infty} |X_r(j\Omega) - X_a(j\Omega)|^2 d\Omega. \quad (5.44)$$

When the reconstruction is done with an ideal PAM,  $X_r(j\Omega)$  is given by

$$X_r(j\Omega) = \begin{cases} TX(e^{j\Omega T}), & |\Omega| \leq \pi/T, \\ 0, & |\Omega| > \pi/T, \end{cases} \quad (5.45)$$

where

$$TX(e^{j\Omega T}) = \sum_{k=-\infty}^{\infty} X_a \left( j\Omega - j \frac{2\pi k}{T} \right). \quad (5.46)$$

The energy  $E_e$  can in this case be expressed as

$$E_e = \frac{1}{2\pi} \int_{-\pi/T}^{\pi/T} |TX(e^{j\Omega T}) - X_a(j\Omega)|^2 d\Omega + \frac{1}{2\pi} \int_{|\Omega| \geq \pi/T} |X_a(j\Omega)|^2 d\Omega \quad (5.47)$$

or, alternatively,

$$E_e = \frac{1}{2\pi} \int_{-\pi/T}^{\pi/T} \left| \sum_{k \neq 0} X_a \left( j\Omega - j \frac{2\pi k}{T} \right) \right|^2 d\Omega + \frac{1}{2\pi} \int_{|\Omega| \geq \pi/T} |X_a(j\Omega)|^2 d\Omega. \quad (5.48)$$

The energies  $E_x$  and  $E_e$  are often difficult to compute analytically. In such cases, one has to use numerical computations.

#### 1.05.3.7.1 Example of distortion measure

We consider the same signals as in the example of Section 1.05.3.6.1 with  $a = 1$ . The energies  $E_x$  and  $E_e$  can in this case be computed as

$$E_x = \frac{1}{2\pi} \int_{-\infty}^{\infty} \left( \frac{2}{\Omega^2 + 1} \right)^2 d\Omega \quad (5.49)$$

and

$$\begin{aligned} E_e &= \frac{1}{2\pi} \int_{-\pi/T}^{\pi/T} \left( \frac{1 - e^{-2aT}}{1 - 2e^{-aT} \cos(\Omega T) + e^{-2aT}} - \frac{2}{\Omega^2 + 1} \right)^2 d\Omega \\ &\quad + \frac{1}{2\pi} \int_{|\Omega| \geq \pi/T} \left( \frac{2}{\Omega^2 + 1} \right)^2 d\Omega, \end{aligned} \quad (5.50)$$

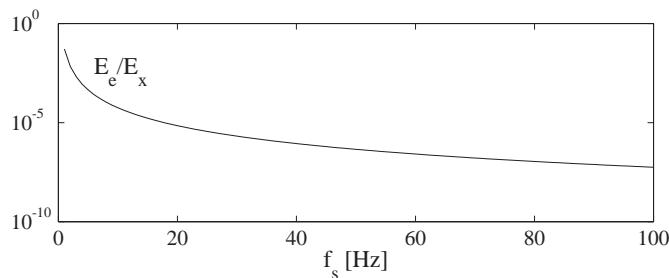

respectively. Since the integrands are symmetric here, we can alternatively express  $E_x$  and  $E_e$  according to

$$E_x = \frac{1}{\pi} \int_0^{\infty} \left( \frac{2}{\Omega^2 + 1} \right)^2 d\Omega \quad (5.51)$$

and

$$\begin{aligned} E_e &= \frac{1}{\pi} \int_0^{\pi/T} \left( \frac{1 - e^{-2aT}}{1 - 2e^{-aT} \cos(\Omega T) + e^{-2aT}} - \frac{2}{\Omega^2 + 1} \right)^2 d\Omega \\ &\quad + \frac{1}{\pi} \int_{\pi/T}^{\infty} \left( \frac{2}{\Omega^2 + 1} \right)^2 d\Omega \end{aligned} \quad (5.52)$$

respectively. The integral in (5.51), and the downmost one in (5.52), can easily be computed analytically whereby one obtains  $E_x = 1$ . For the uppermost integral in (5.52), it is more difficult to find a closed-form expression and we therefore compute it numerically. Figure 5.24 plots the ratio  $E_e/E_x$  for different sampling frequencies  $f_s = 1/T$ . (Here,  $E_e/E_x$  equals  $E_e$  since  $E_x = 1$ .) We see that the distortion as expected reduces when the sampling frequency is increased. The example in Section 1.05.3.6.1 considered the two cases  $f_s = 2$  and  $f_s = 20$ . In these cases, the distortion figures are about  $6.86 \times 10^{-3}$  and  $5.30 \times 10^{-6}$ , respectively.

**FIGURE 5.24**

Distortion as a function of the sampling frequency in the example of Section 1.05.3.7.1.

### 1.05.3.8 Bandpass sampling

We have so far considered lowpass signals meaning that the signal spectrum  $X_a(j\Omega)$  is contained in the low-frequency region  $\Omega \in [-\Omega_0, \Omega_0]$ . When the sampling frequency satisfy  $f_s > 2f_0 = \Omega_0/\pi$ , sampling and ideal reconstruction can theoretically be achieved. For a given sampling frequency,  $f_s = 1/T$ , the signal is in other words restricted to the frequency region  $\Omega \in [-\pi/T, \pi/T]$ . This frequency region is referred to as the first Nyquist band (or Nyquist zone). The theory can then be extended to bandpass signals for which the spectrum is contained in the band-pass frequency region  $\Omega \in [-N\pi/T, -(N-1)\pi/T] \cup [(N-1)\pi/T, N\pi/T]$  which is called the  $N$ th Nyquist band. Using again Poisson's summation formula (and following, e.g., the example in Section 1.05.3.2.1) it is then readily shown that the partial spectra do not overlap which means that the signal is not aliased and thus theoretically can be reconstructed without errors. In the reconstruction, the pulse  $p(t)$  must here correspond to a bandpass filter instead of a lowpass filter.

---

## 1.05.4 Sampling of stochastic processes

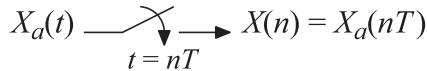

This section extends the sampling theory from deterministic signals to wide-sense stationary (WSS) stochastic processes.

### 1.05.4.1 Uniform sampling

Let  $X_a(t)$  be a continuous-time WSS stochastic process with mean  $m_{X_a}$ , autocorrelation function  $r_{X_a X_a}(\tau)$ , and power spectrum  $R_{X_a X_a}(j\Omega)$ . We now form  $X(n)$  by sampling  $X_a(t)$  uniformly according to

$$X(n) = X_a(nT). \quad (5.53)$$

Graphically, we represent uniform sampling of a stochastic process as in Figure 5.25.

**FIGURE 5.25**

Uniform sampling of a stochastic process.

As shown below,  $X(n)$  is also a WSS process whose mean  $m_X$ , autocorrelation sequence  $r_{XX}(k)$ , and power spectrum  $R_{XX}(e^{j\Omega T})$  are given by

$$m_X = m_{X_a}, \quad (5.54)$$

$$r_{XX}(k) = r_{X_a X_a}(kT), \quad (5.55)$$

and

$$R_{XX}(e^{j\Omega T}) = \frac{1}{T} \sum_{p=-\infty}^{\infty} R_{X_a X_a} \left( j\Omega - j \frac{2\pi p}{T} \right). \quad (5.56)$$

Equation (5.56) is the same relation as in Poisson's summation formula for deterministic signals. One can therefore understand that the following sampling theorem can be formulated for WSS processes.

*Sampling theorem for WSS processes:* If a continuous-time WSS process  $X_a(t)$  is bandlimited to  $\Omega = \Omega_0$  ( $f = f_0$ ), i.e., if

$$R_{X_a X_a}(j\Omega) = 0, \quad |\Omega| > \Omega_0 = 2\pi f_0, \quad (5.57)$$

then,  $X_a(t)$  can be recovered from the samples  $X(n) = X_a(nT)$  if

$$f_s = \frac{1}{T} > 2f_0. \quad (5.58)$$

Here, recovered means that we can form a new process  $X_r(t)$  from  $X(n)$ , such that  $X_r(t)$  equals  $X_a(t)$  in the sense that  $E\{[X_r(t) - X_a(t)]^2\} = 0$ , where  $E$  denotes expectation.

Equations (5.54) and (5.55) follow immediately from their definitions according to

$$m_X = E\{X(n)\} = E\{X_a(nT)\} = m_{X_a} \quad (5.59)$$

and

$$\begin{aligned} r_{XX}(k) &= E\{X(n)X(n-k)\} \\ &= E\{X_a(nT)X_a(nT - kT)\} = r_{X_a X_a}(kT), \end{aligned} \quad (5.60)$$

respectively. This shows that  $X(n)$  is a WSS process since both the mean and autocorrelation sequence are independent of  $n$ . As for (5.56), it is first noted that the autocorrelation function can be written in terms of its inverse Fourier transform according to

$$r_{X_a X_a}(\tau) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{X_a X_a}(j\Omega) e^{j\Omega\tau} d\Omega. \quad (5.61)$$

In particular, one obtains for  $\tau = kT$

$$r_{X_a X_a}(kT) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{X_a X_a}(j\Omega) e^{j\Omega T k} d\Omega. \quad (5.62)$$

By dividing the indefinite integral into an infinite number of definite integrals, in the same way as we did in Section 1.05.3.2 when deriving Poisson's summation formula, we obtain

$$r_{X_a X_a}(kT) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{1}{T} \sum_{p=-\infty}^{\infty} R_{X_a X_a}\left(j\Omega - j\frac{2\pi p}{T}\right) e^{j\Omega T k} d(\Omega T). \quad (5.63)$$

We also know that the autocorrelation sequence can be expressed in terms of its inverse Fourier transform according to

$$r_{XX}(k) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{XX}(e^{j\Omega T}) e^{j\Omega T k} d(\Omega T). \quad (5.64)$$

Since  $r_{XX}(k) = r_{X_a X_a}(kT)$ , and the Fourier transform is unique, the right-hand sides in the two equations above must be equal, which finally gives us (5.56).

### 1.05.4.2 Reconstruction of stochastic processes

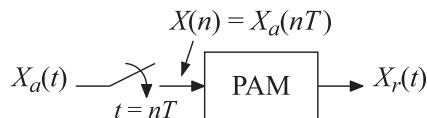

Reconstruction of stochastic processes can be performed with a PAM according to Figure 5.26. The reconstructed process  $X_r(t)$  is given by

$$X_r(t) = \sum_{n=-\infty}^{\infty} X(n) p(t - nT). \quad (5.65)$$

One can show that  $X_r(t)$  is equal to  $X_a(t)$  if the sampling theorem is fulfilled and  $p(t)$  is chosen as

$$p(t) = \frac{\sin(\pi t/T)}{\pi t/T} = \text{sinc}(t/T). \quad (5.66)$$

This is in analogy with ideal reconstruction of deterministic signals. Note again that equality holds in the sense that  $E[X_r(t) - X_a(t)]^2 = 0$ . However, in practice, one cannot have strictly bandlimited processes which introduces aliasing distortion in the sampling process. Further, errors are introduced in the reconstruction since only approximate sinc functions can be generated. The reconstructed process will therefore differ from the original process.

**FIGURE 5.26**

Sampling and reconstruction of a stochastic process using a PAM.

An additional problem here is that  $X_r(t)$  generally will not be a WSS process which complicates the analysis of distortion etc. To get around this dilemma, the sampling and reconstruction in (5.53) and (5.65) are replaced with

$$X(n) = X_a(nT + \Psi) \quad (5.67)$$

and

$$X_r(t) = \sum_{n=-\infty}^{\infty} X(n)p(t - nT - \Psi), \quad (5.68)$$

respectively, where  $\Psi$  is a stochastic variable that is uniformly distributed in the interval  $(0, T)$ . In practice, this means that each realization of the sampling and reconstruction process incorporates a stochastic delay  $\Psi$ . However, the sampling and reconstruction are still synchronized since they incorporate the same delay  $\Psi$ . The purpose of introducing the delay  $\Psi$  is that the reconstructed process  $X_r(t)$  then becomes WSS. The stochastic delay  $\Psi$  introduced in (5.67) does not have any implications as to stationarity and ensemble averages. That is,  $X(n)$  is still WSS and (5.54)–(5.56) still hold. Further, as shown below, the same stochastic delay  $\Psi$  introduced in (5.68) makes  $X_r(t)$  a WSS process with the following mean  $m_{X_r}$ , autocorrelation function  $r_{X_r X_r}(\tau)$ , and power spectrum  $R_{X_r X_r}(j\Omega)$ :

$$m_{X_r} = \frac{1}{T} m_X P(0), \quad (5.69)$$

$$r_{X_r X_r}(\tau) = \frac{1}{T} \sum_{k=-\infty}^{\infty} r_{XX}(k) \int_{-\infty}^{\infty} p(u)p(u - \tau + kT)du, \quad (5.70)$$

and

$$R_{X_r X_r}(j\Omega) = \frac{1}{T} |P(j\Omega)|^2 R_{XX}(e^{j\Omega T}). \quad (5.71)$$

Moreover, as is also shown below, the reconstruction error  $E\{[X_r(t) - X_a(t)]^2\}$  is given by

$$\begin{aligned} E\{[X_r(t) - X_a(t)]^2\} &= \frac{1}{2\pi T^2} \int_{-\infty}^{\infty} |P(j\Omega) - T|^2 R_{X_a X_a}(j\Omega) d\Omega \\ &\quad + \frac{1}{2\pi T^2} \int_{-\infty}^{\infty} \sum_{p \neq 0} |P(j\Omega)|^2 R_{X_a X_a}\left(j\Omega - j\frac{2\pi p}{T}\right) d\Omega. \end{aligned} \quad (5.72)$$

From this equation, we see that, if  $p(t)$  is ideal according to (5.66), in which case  $P(j\Omega)$  is an ideal lowpass filter with passband up to  $\pi/T$  and gain  $T$ , then the reconstruction error becomes

$$\begin{aligned} E\{[X_r(t) - X_a(t)]^2\} &= \frac{1}{2\pi} \int_{|\Omega| \geq \pi/T} R_{X_a X_a}(j\Omega) d\Omega \\ &\quad + \frac{1}{2\pi} \int_{-\pi/T}^{\pi/T} \sum_{p \neq 0} R_{X_a X_a}\left(j\Omega - j\frac{2\pi p}{T}\right) d\Omega, \end{aligned} \quad (5.73)$$

which can be rewritten as

$$E\{[X_r(t) - X_a(t)]^2\} = \frac{2}{\pi} \int_{\pi/T}^{\infty} R_{X_a X_a}(j\Omega) d\Omega. \quad (5.74)$$

If, in addition,  $X_a(t)$  is bandlimited to  $\pi/T$ , i.e.,  $R_{X_a X_a}(j\Omega) = 0$  for  $|\Omega| \geq \pi/T$ , it follows immediately from (5.74) that  $E[X_r(t) - X_a(t)]^2 = 0$  in which case perfect reconstruction is achieved.

We now show (5.69)–(5.71). The mean of  $X_r(t)$  becomes

$$\begin{aligned} m_{X_r} &= E\{X_r(t)\} = E\left\{\sum_{n=-\infty}^{\infty} X(n)p(t-nT-\Psi)\right\} \\ &= \sum_{n=-\infty}^{\infty} E\{X(n)p(t-nT-\Psi)\} \\ &= \sum_{n=-\infty}^{\infty} E\{X(n)\} E\{p(t-nT-\Psi)\}, \end{aligned} \quad (5.75)$$

where we have utilized that  $X(n)$  and  $p(t-nT-\Psi)$  are uncorrelated. Further, we have  $E\{X(n)\} = m_X$  and

$$E\{p(t-nT-\Psi)\} = \frac{1}{T} \int_0^T p(t-nT-\Psi)d\Psi = \frac{1}{T} \int_{t-nT-T}^{t-nT} p(v)dv \quad (5.76)$$

which gives us

$$m_{X_r} = \frac{1}{T} m_X \sum_{n=-\infty}^{\infty} \int_{t-nT-T}^{t-nT} p(v)dv = \frac{1}{T} m_X \int_{-\infty}^{\infty} p(v)dv = \frac{1}{T} m_X P(0). \quad (5.77)$$

We see that the mean is independent of  $t$ .

The autocorrelation function for  $X_r(t)$  becomes

$$\begin{aligned} r_{X_r X_r}(\tau) &= E\{X_r(t)X_r(t-\tau)\} \\ &= E\left\{\sum_{n=-\infty}^{\infty} X(n)p(t-nT-\Psi) \sum_{m=-\infty}^{\infty} X(m)p(t-\tau-mT-\Psi)\right\} \\ &= E\left\{\sum_{n=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} X(n)X(m)p(t-nT-\Psi)p(t-\tau-mT-\Psi)\right\} \\ &= \sum_{n=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} E\{X(n)X(m)\} \\ &\quad \times E\{p(t-nT-\Psi)p(t-\tau-mT-\Psi)\} \\ &= \sum_{n=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} r_{XX}(n-m) \\ &\quad \times \frac{1}{T} \int_0^T p(t-nT-\Psi)p(t-\tau-mT-\Psi)d\Psi. \end{aligned} \quad (5.78)$$

The variable substitutions  $k = n - m$  and  $u = t - nT - \Psi$  yield

$$\begin{aligned} r_{X_r X_r}(\tau) &= \sum_{n=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} r_{XX}(k) \frac{1}{T} \int_{t-nT-T}^{t-nT} p(u) p(u - \tau + kT) du \\ &= \frac{1}{T} \sum_{k=-\infty}^{\infty} r_{XX}(k) \int_{-\infty}^{\infty} p(u) p(u - \tau + kT) du. \end{aligned} \quad (5.79)$$

We see that also the autocorrelation function is independent of  $t$ . Hence,  $X_r(t)$  is a WSS process. The power spectrum of  $X_r(t)$  becomes

$$\begin{aligned} R_{X_r X_r}(\tau) &= \int_{-\infty}^{\infty} r_{X_r X_r}(\tau) e^{-j\Omega\tau} d\tau \\ &= \int_{-\infty}^{\infty} \left( \frac{1}{T} \sum_{k=-\infty}^{\infty} r_{XX}(k) \int_{-\infty}^{\infty} p(u) p(u - \tau + kT) du \right) e^{-j\Omega\tau} d\tau \\ &= \frac{1}{T} \sum_{k=-\infty}^{\infty} r_{XX}(k) \int_{-\infty}^{\infty} p(u) \int_{-\infty}^{\infty} p(u - \tau + kT) e^{-j\Omega\tau} d\tau du. \end{aligned} \quad (5.80)$$

The variable substitution  $v = u - \tau + kT$  gives us

$$\begin{aligned} R_{X_r X_r}(\tau) &= \frac{1}{T} \sum_{k=-\infty}^{\infty} r_{XX}(k) \int_{-\infty}^{\infty} p(u) \int_{-\infty}^{\infty} p(v) e^{-j\Omega(u-v+kT)} dv du \\ &= \frac{1}{T} \sum_{k=-\infty}^{\infty} r_{XX}(k) e^{-j\Omega Tk} \int_{-\infty}^{\infty} p(u) e^{-j\Omega u} du \int_{-\infty}^{\infty} p(v) e^{j\Omega v} dv du \\ &= \frac{1}{T} R_{XX}(e^{j\Omega T}) P(j\Omega) P^*(j\Omega) \\ &= \frac{1}{T} |P(j\Omega)|^2 R_{XX}(e^{j\Omega T}). \end{aligned} \quad (5.81)$$

The last two equalities hold when  $p(t)$  is a real function.

Next, (5.72) is shown. To this end, the reconstruction error is first expanded as

$$E \left\{ [X_r(t) - X_a(t)]^2 \right\} = E \left\{ X_r^2(t) \right\} + E \left\{ X_a^2(t) \right\} - 2E \{ X_r(t) X_a(t) \}. \quad (5.82)$$

The first term in (5.82) can be computed as

$$\begin{aligned} E \left\{ X_r^2(t) \right\} &= \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{X_r X_r}(j\Omega) d\Omega = \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{1}{T} |P(j\Omega)|^2 R_{XX}(e^{j\Omega T}) d\Omega \\ &= \frac{1}{2\pi T^2} \int_{-\infty}^{\infty} |P(j\Omega)|^2 \sum_{p=-\infty}^{\infty} R_{X_a X_a} \left( j\Omega - j \frac{2\pi p}{T} \right) d\Omega. \end{aligned} \quad (5.83)$$

The second term in (5.82) is simply

$$E \left\{ X_a^2(t) \right\} = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{X_a X_a}(j\Omega) d\Omega. \quad (5.84)$$

In the third term of (5.82) we have

$$\begin{aligned} E \{ X_r(t) X_a(t) \} &= E \left\{ \sum_{n=-\infty}^{\infty} X_a(nT + \Psi) p(t - nT - \Psi) X_a(t) \right\} \\ &= E \left\{ \sum_{n=-\infty}^{\infty} r_{X_a X_a}(t - nT - \Psi) p(t - nT - \Psi) \right\} \end{aligned} \quad (5.85)$$

assuming that  $X_a(t)$  and  $\Psi$  are uncorrelated. Since it is assumed that  $\Psi$  is uniformly distributed on  $[0, T]$ , it follows from (5.85) that

$$E \{ X_r(t) X_a(t) \} = \sum_{n=-\infty}^{\infty} \frac{1}{T} \int_0^T r_{X_a X_a}(t - nT - \Psi) p(t - nT - \Psi) d\Psi. \quad (5.86)$$

The variable substitution  $u = t - nT - \Psi$  now yields

$$\begin{aligned} E \{ X_r(t) X_a(t) \} &= \frac{1}{T} \sum_{n=-\infty}^{\infty} \int_{t-nT-T}^{t-nT} r_{X_a X_a}(u) p(u) du \\ &= \frac{1}{T} \int_{-\infty}^{\infty} r_{X_a X_a}(u) p(u) du. \end{aligned} \quad (5.87)$$

Using Parseval's relation

$$\int_{-\infty}^{\infty} x(t) y^*(t) dt = \frac{1}{2\pi} \int_{-\infty}^{\infty} X(j\Omega) Y^*(j\Omega) d\Omega, \quad (5.88)$$

together with the fact that  $p(u)$  is real, i.e.,  $p(u) = p^*(u)$ , (5.87) can equivalently be written as

$$E \{ X_r(t) X_a(t) \} = \frac{1}{2\pi T} \int_{-\infty}^{\infty} R_{X_a X_a}(j\Omega) P^*(j\Omega) d\Omega. \quad (5.89)$$

Making use of the facts that  $R_{X_a X_a}(j\Omega) = R_{X_a X_a}(-j\Omega)$  and  $P^*(j\Omega) = P(-j\Omega)$ , (5.89) can equivalently be written as

$$E \{ X_r(t) X_a(t) \} = \frac{1}{2\pi T} \int_{-\infty}^{\infty} R_{X_a X_a}(j\Omega) P(j\Omega) d\Omega. \quad (5.90)$$

Inserting (5.83), (5.84), (5.89), and (5.90) into (5.82), we finally obtain

$$\begin{aligned}
 E[X_r(t) - X_a(t)]^2 &= \frac{1}{2\pi T^2} \int_{-\infty}^{\infty} |P(j\Omega)|^2 \sum_{p=-\infty}^{\infty} R_{X_a X_a} \left( j\Omega - j\frac{2\pi p}{T} \right) d\Omega \\
 &\quad + \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{X_a X_a}(j\Omega) d\Omega \\
 &\quad - \frac{1}{2\pi T} \int_{-\infty}^{\infty} R_{X_a X_a}(j\Omega) P^*(j\Omega) d\Omega \\
 &\quad - \frac{1}{2\pi T} \int_{-\infty}^{\infty} R_{X_a X_a}(j\Omega) P(j\Omega) d\Omega \\
 &= \frac{1}{2\pi T^2} \int_{-\infty}^{\infty} |P(j\Omega) - T|^2 R_{X_a X_a}(j\Omega) d\Omega \\
 &\quad + \frac{1}{2\pi T^2} \int_{-\infty}^{\infty} \sum_{p \neq 0} |P(j\Omega)|^2 R_{X_a X_a} \left( j\Omega - j\frac{2\pi p}{T} \right) d\Omega. \tag{5.91}
 \end{aligned}$$

#### 1.05.4.2.1 Example of reconstruction error power

Let  $X_a(t)$  be the output from an analog filter  $H(s)$  with the input  $X_{wb}(t)$ . Assume that  $X_{wb}(t)$  is white noise with zero mean and power spectrum  $\sigma_{X_{wb}}^2$ , and that  $H(s)$  is a first-order lowpass filter according to

$$H(s) = \frac{\Omega_0}{s + \Omega_0}. \tag{5.92}$$

We now form  $X(n)$  and  $X_r(t)$  through uniform sampling of  $X_a(t)$  and reconstruction with a PAM according to (5.67) and (5.68), respectively. We assume that  $P(j\Omega)$  is ideal and given by (5.66). We now wish to compute the average powers of  $X_a(t)$ ,  $X(n)$ , and  $X_r(t)$ . These quantities are obtained by integrating the corresponding power spectra.

The power spectrum of  $X_a(t)$  is

$$R_{X_a X_a}(j\Omega) = |H(j\Omega)|^2 R_{X_{wb} X_{wb}}(j\Omega), \tag{5.93}$$

where

$$R_{X_{wb} X_{wb}}(j\Omega) = \sigma_{X_{wb}}^2 \tag{5.94}$$

and

$$|H(j\Omega)|^2 = \frac{\Omega_0^2}{\Omega^2 + \Omega_0^2}. \tag{5.95}$$

The power of  $X_a(t)$  therefore becomes

$$\begin{aligned}
 E \left\{ X_a^2(t) \right\} &= \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{X_a X_a}(j\Omega) d\Omega = \frac{1}{2\pi} \int_{-\infty}^{\infty} |H(j\Omega)|^2 R_{X_{wb} X_{wb}}(j\Omega) d\Omega \\
 &= \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{\Omega_0^2}{\Omega^2 + \Omega_0^2} \sigma_{X_{wb}}^2 d\Omega = \frac{\Omega_0 \sigma_{X_{wb}}^2}{2\pi} [\arctan(\Omega/\Omega_0)]_{-\infty}^{\infty} \\
 &= \frac{\Omega_0 \sigma_{X_{wb}}^2}{2}.
 \end{aligned} \tag{5.96}$$

The power of  $X(n)$  is the same as that of  $X_a(t)$  because

$$E \left\{ X^2(n) \right\} = r_{XX}(0) = r_{X_a X_a}(0) = E \left\{ X_a^2(t) \right\}. \tag{5.97}$$

The power spectrum of  $X_r(t)$  is

$$R_{X_r X_r}(j\Omega) = \frac{1}{T} |P(j\Omega)|^2 R_{XX}(e^{j\Omega T}), \tag{5.98}$$

where

$$R_{XX}(e^{j\Omega T}) = \frac{1}{T} \sum_{p=-\infty}^{\infty} R_{X_a X_a} \left( j\Omega - j\frac{2\pi p}{T} \right). \tag{5.99}$$

When  $p(t)$  is given by (5.66), one obtains

$$P(j\Omega) = \begin{cases} T, & |\Omega| \leq \pi/T, \\ 0, & |\Omega| > \pi/T. \end{cases} \tag{5.100}$$

The power of  $X_r(t)$  thus becomes

$$\begin{aligned}
 E \left\{ X_r^2(t) \right\} &= \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{X_r X_r}(j\Omega) d\Omega = \frac{1}{2\pi} \int_{-\pi/T}^{\pi/T} T R_{XX}(e^{j\Omega T}) d\Omega \\
 &= \frac{1}{2\pi} \int_{-\pi/T}^{\pi/T} \sum_{p=-\infty}^{\infty} R_{X_a X_a} \left( j\Omega - j\frac{2\pi p}{T} \right) d\Omega \\
 &= \frac{1}{2\pi} \sum_{p=-\infty}^{\infty} \int_{-\pi/T}^{\pi/T} R_{X_a X_a} \left( j\Omega - j\frac{2\pi p}{T} \right) d\Omega.
 \end{aligned} \tag{5.101}$$

The variable substitutions  $j\Omega - j2\pi p/T \rightarrow j\Omega$  finally give us

$$\begin{aligned}
 E \left\{ X_r^2(t) \right\} &= \frac{1}{2\pi} \sum_{p=-\infty}^{\infty} \int_{-\pi/T-j2\pi p/T}^{\pi/T-j2\pi p/T} R_{X_a X_a}(j\Omega) d\Omega \\
 &= \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{X_a X_a}(j\Omega) d\Omega = E \left\{ X_a^2(t) \right\}.
 \end{aligned} \tag{5.102}$$

That is, also the power of  $X_r(t)$  is the same as that of  $X_a(t)$ . We thus have

$$E \{ X_a^2(t) \} = E \{ X^2(n) \} = E \{ X_r^2(t) \}. \quad (5.103)$$

Finally, it is observed that the reconstruction error is

$$\begin{aligned} E \{ [X_r(t) - X_a(t)]^2 \} &= \frac{2}{\pi} \int_{\pi/T}^{\infty} R_{X_a X_a}(j\Omega) d\Omega \\ &= \frac{2}{\pi} \int_{\pi/T}^{\infty} |H(j\Omega)|^2 R_{X_{wb} X_{wb}}(j\Omega) d\Omega \\ &= \frac{2}{\pi} \int_{\pi/T}^{\infty} \frac{\Omega_0^2}{\Omega^2 + \Omega_0^2} \sigma_{X_{wb}}^2 d\Omega \\ &= \frac{2\Omega_0 \sigma_{X_{wb}}^2}{\pi} [\arctan(\Omega/\Omega_0)]_{\pi/T}^{\infty} \\ &= \frac{2\Omega_0 \sigma_{X_{wb}}^2}{\pi} (\pi/2 - \arctan[\pi/(\Omega_0 T)]). \end{aligned} \quad (5.104)$$

We see that, with a fixed  $\Omega_0$ ,  $E \{ [X_r(t) - X_a(t)]^2 \} \rightarrow 0$  when  $T \rightarrow 0$ , i.e., we can make the reconstruction error as small as desired by a proper selection of the sampling period  $T$  (sampling frequency  $f_s = 1/T$ ).

## 1.05.5 Nonuniform sampling and generalizations

This section considers the extension to nonuniform sampling [25] and generalizations. This appears in many different forms and contexts and it is beyond the scope of this section to present a comprehensive survey. Instead, we will concentrate on one particular application, namely  $M$ -channel time-interleaved A/D converters which in the simplest case corresponds to an  $M$ -periodic nonuniform sampling grid [26–28]. In this application, the sampling grid is close to a uniform grid and, thus, the obtained nonuniform-sequence is close to the desired uniform-sampling sequence. Nevertheless, reconstruction is required to recover the uniform-sampling sequence from the nonuniform-sampling sequence. The generalized case is an extension in the sense that the  $M$  channels experience different and general frequency responses.

### 1.05.5.1 Time-interleaved ADCs

Time interleaving of multiple parallel ADCs is a technique to increase the effective sampling rate of the overall converter. Using an  $M$ -channel time-interleaved ADC, the effective sampling rate is increased by a factor of  $M$ . Unfortunately, the effective resolution of the individual channel converters is not maintained in the overall converter because of channel mismatch errors. It is therefore necessary to compensate for these errors in order to restore the resolution [29,30]. The errors can broadly be divided into linear and nonlinear mismatch errors [30,31]. This section only deals with linear mismatch errors

in which case the channels are modeled as linear systems, thus having specific frequency responses. There are also static offset mismatch errors present but they are signal independent and straightforward to compensate for, and therefore not explicitly included in the formulas to be presented in this section. However, as noted later in Section 1.05.5.1, one can make use of the same frequency domain expression as that used for relating the input and output signals.

Up to a certain resolution, one can assume that the channel frequency responses have frequency-independent magnitude and phase delay responses, which corresponds to static gain and linear-phase (time-skew) mismatch errors. Without gain errors, this case corresponds to nonuniform sampling and the problem is then to recover the uniform-sampling sequence from the nonuniform-sampling sequence. Numerous papers have addressed this problem over the last decades, see for example [29, 32–37] and references therein. However, to reach a very high resolution for high-speed conversion, one needs to extend the channel model to general frequency responses, thus with frequency dependent magnitude and phase delay responses [30, 38]. In this case, one has to compensate for these frequency-response mismatch errors, not only static gain and linear-phase parts which correspond to approximations of the true responses. Recent papers have considered the more general problem [38–48] which corresponds to the “generalizations” mentioned above.

Before proceeding, it is also noted that calibration of time-interleaved ADCs requires estimation of and compensation for the channel frequency response mismatches. This section only discusses the compensation which requires that accurate models of the channel frequency responses are available. However, the estimation benefits from efficient compensation techniques, for example when the calibration is done through simultaneous estimation and compensation by minimizing an appropriate cost measure [42]. The compensation techniques to be discussed here can thus be used either after the channel frequency responses have been estimated or as a part of a calibration technique.

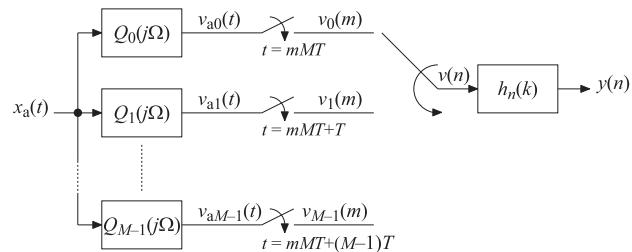

### 1.05.5.2 Problem formulation

The point of departure is that we have a continuous-time signal  $x_a(t)$  bandlimited to  $\Omega_0 < \pi/T$  which means that the Nyquist criterion for uniform sampling with a sampling frequency of  $1/T$  without aliasing is fulfilled. That is, sampling according to  $x(n) = x_a(nT)$  does not introduce aliasing and we have in the frequency domain

$$X(e^{j\Omega T}) = \frac{1}{T} X_a(j\Omega), \quad \Omega T \in [-\pi, \pi], \quad (5.105)$$

where  $X(e^{j\Omega T})$  and  $X_a(j\Omega)$  denote the Fourier transforms of the sequence  $x(n)$  and continuous-time signal  $x_a(t)$ , respectively. This means that  $x_a(t)$  can be recovered from  $x(n)$ . It is generally advisable to make  $\Omega_0$  correspond to some 80–90% of the overall Nyquist band as the computational complexity of the compensation system becomes prohibitive when it approaches 100%, as exemplified later in Section 1.05.5.6. However, normally this does not impose additional band limitations as a certain amount of oversampling is required anyhow to get reasonable requirements on the analog anti-aliasing filter that precedes the ADC, in accordance with Figure 5.39 seen later in Section 1.05.7.1, which depicts a typical system for conversion of an analog signal into its digital representation.

In an  $M$ -channel time-interleaved ADC, without correction, we do not obtain the desired uniform sequence  $x(n)$  but instead another sequence, say  $v(n)$ , through interleaving of  $M$  subsequences, as seen

**FIGURE 5.27**

$M$ -channel time-interleaved ADC with different channel frequency responses  $Q_n(j\Omega)$ ,  $n = 0, 1, \dots, M - 1$ , and an  $M$ -periodic time-varying compensation system with impulse response  $h_n(k) = h_{n+M}(k)$ .

in Figure 5.27. This can equivalently be viewed as if  $v(n)$  is obtained by applying  $x_a(t)$  to a time-varying continuous-time system and then sampling the output at  $t = nT$ .

Utilizing (5.105), the sequence  $v(n)$  can then be expressed via the inverse Fourier transform as

$$v(n) = \frac{1}{2\pi} \int_{-\Omega_0 T}^{\Omega_0 T} Q_n(j\Omega) X(e^{j\Omega T}) e^{j\Omega T n} d(\Omega T), \quad (5.106)$$

where  $Q_n(j\Omega) = Q_{n+M}(j\Omega)$  is an  $M$ -periodic time-varying system frequency response and  $Q_n(j\Omega)$ ,  $n = 0, 1, \dots, M - 1$ , constitute the  $M$  ADC channel frequency responses. For example, with static gain constants,  $g_n$ , and static time skews,  $d_n$  (given in percent of the sampling period  $T = 1/f_s$ ), the channel frequency responses are modeled as  $Q_n(j\Omega) = g_n e^{j\Omega T d_n}$ . With  $g_n = 1$ , this corresponds to  $v(n) = x_a(nT + d_n T)$  and thus a nonuniform sampling and reconstruction problem. It is also noted that the model above holds also in the more general case when  $M \rightarrow \infty$ , thus also for single-channel ADCs with a time-varying frequency response.

The problem to be solved can now be formulated as follows: Given the sequence  $v(n)$  in (5.106), form a new sequence  $y(n)$  that is to approximate the sequence  $x(n) = x_a(nT)$  as closely as desired. This problem is considered in Section 1.05.5.4.

### 1.05.5.2.1 Relaxed problem

The overall output  $y(n)$  should ideally approximate the sequence  $x(n) = x_a(nT)$ . This requires that all channel frequency responses  $Q_n(j\Omega)$  are known. In practice, it is customary to determine the ratio between the channel frequency responses and then match the channels. Typically, one chooses the first channel as a reference and then matches all other channels to this reference channel. In the reconstruction, this means that we set  $Q_0(j\Omega) = 1$  and divide the remaining  $Q_n(j\Omega)$  by the actual  $Q_0(j\Omega)$ . In the estimation, the frequency response ratios are obtained directly so we will never have available  $Q_n(j\Omega)$  but only an estimation of  $Q_n(j\Omega)/Q_0(j\Omega)$ . After the compensation, the overall ADC will then experience a linear distortion,  $Q_0(j\Omega)$ , because we then have  $Y(e^{j\Omega T}) = Q_0(j\Omega)X(e^{j\Omega T})$ . In other words, the linear distortion after compensation is determined by the frequency response of the reference ADC. In the compensation, this also means that the samples from the reference channel are taken as they are and only the other channels' samples are corrected. Finally, it is noted that, in the

overall system where the A/D converter is to be used, the linear distortion needs to be equalized but this problem exists for all types of A/D converters. In a larger composite system, like a communication system, a single equalizer can be used to equalize all linear distortion at the same time, emanating from the filters, A/D converters, communication channel, etc.

### 1.05.5.3 Reconstruction

Regardless whether the sequence  $x(n)$  has been obtained through uniform sampling of  $x_a(t)$  or through nonuniform sampling and/or its generalization (like in time-interleaved ADCs considered here), it is often desired to reconstruct  $x_a(t)$  from the generated sequence of samples  $x(n)$ . Thus, in the generalized case, it is desired to recover  $x_a(t)$  from the sequence  $v(n)$ . This can, in principle, be done in two different ways. The first way is to reconstruct  $x_a(t)$  directly from  $v(n)$  through analog reconstruction functions. Although it is known how to do this in principle (see e.g., [5, 25, 49, 50]), problems arise when it comes to practical implementations. In particular, it is very difficult to practically implement analog functions with high precision. It is therefore desired to use the second way which is to perform the reconstruction in the digital domain, i.e., to first recover  $x(n) = x_a(nT)$ . One then needs only one conventional digital-to-analog converter (DAC) and analog filter to obtain  $x_a(t)$ . Such components are much easier to implement than components that are to approximate complicated analog functions. Recovery of  $x(n)$  is also of interest even if  $x_a(t)$  is not to be reconstructed. For example, in receivers in digital communication systems,  $x(n)$  is the desired result. The subsequent two sections discusses two reconstruction methods for recovering  $x(n)$  from  $v(n)$  in time-interleaved ADCs.

### 1.05.5.4 Reconstruction using a time-varying FIR system

A time-interleaved ADC corresponds to a time-varying system, and the compensation thus corresponds to inverting such a system. For an  $M$ -channel system, this amounts to determining an  $M$ -periodic time-varying discrete-time system characterized by an  $M$ -periodic impulse response, say  $h_n(k) = h_{n+M}(k)$ , or, equivalently,  $M$  time-invariant impulse responses  $h_n(k)$ ,  $n = 0, 1, \dots, M - 1$ .

Using an  $N$ th-order  $M$ -periodic time-varying finite-length impulse response (FIR) system, the reconstructed output sequence,  $y(n)$ , is given by the convolution sum as

$$y(n) = \sum_{k=-N/2}^{N/2} v(n-k)h_n(k), \quad (5.107)$$

where  $h_n(k) = h_{n+M}(k)$  denotes the  $M$ -periodic impulse response. Thus, to correct each output sample, one needs to compute  $N + 1$  multiplications and  $N$  additions. It is convenient here to make use of a noncausal system, which means that the impulse response is assumed to be centered around  $k = 0$  which corresponds to zero delay. A causal system is then obtained by introducing a delay of  $N/2$  samples into the system. It is noted that we have assumed here that the order  $N$  of the system is even, to keep the notation simple. Odd-order systems can be used as well after some minor appropriate modifications.

To determine the impulse response coefficients, it is convenient to express the output  $y(n)$  in the time-frequency domain [27], instead of the time-domain given in (5.107). This will be done here in terms of an  $M$ -periodic time-frequency function  $A_n(j\Omega) = A_{n+M}(j\Omega)$ , or, equivalently,  $M$  frequency

functions  $A_n(j\Omega)$ ,  $n = 0, 1, \dots, M - 1$ . To this end, we insert (5.106) into (5.107), and interchange the summation and integration, and obtain

$$y(n) = \frac{1}{2\pi} \int_{-\Omega_0 T}^{\Omega_0 T} A_n(j\Omega) X(e^{j\Omega T}) e^{j\Omega T n} d(\Omega T), \quad (5.108)$$

where

$$A_n(j\Omega) = \sum_{k=-N/2}^{N/2} h_n(k) Q_{n-k}(j\Omega) e^{-j\Omega T k}. \quad (5.109)$$

Further, we can write the desired sequence  $x(n)$  in terms of the inverse Fourier transform according to

$$x(n) = \frac{1}{2\pi} \int_{-\Omega_0 T}^{\Omega_0 T} X(e^{j\Omega T}) e^{j\Omega T n} d(\Omega T). \quad (5.110)$$

Comparing (5.108) and (5.110), it is seen that perfect reconstruction (PR) is obtained if

$$A_n(j\Omega) = 1, \quad \Omega \in [-\Omega_0, \Omega_0] \quad (5.111)$$

for  $n = 0, 1, \dots, M - 1$ , because, then,  $y(n) = x(n)$  for all  $n$  as  $A_n(j\Omega)$  is  $M$ -periodic. Thus, if all  $A_n(j\Omega) = 1$ , we get the desired result  $x(n) = x_a(nT)$ . The problem is thus to determine the  $M$  impulse responses  $h_n(k)$ ,  $n = 0, 1, \dots, M - 1$ , so that  $A_n(j\Omega)$  approximate unity. If the channel frequency responses  $Q_n(j\Omega)$  are known, this can be done optimally in e.g., least-squares or minimax senses. In practice, one does not explicitly estimate  $Q_n(j\Omega)$  but instead  $Q_n(j\Omega)/Q_0(j\Omega)$  if  $Q_0(j\Omega)$  is the reference channel, in accordance with the discussion earlier in Section 1.05.5.2.1. The ratios  $Q_n(j\Omega)/Q_0(j\Omega)$  are then used in the design which corresponds to selecting  $h_0(k) = \delta(k)$  (unit impulse). It thus suffices to determine the  $M - 1$  impulse responses  $h_n(k)$  for  $n = 1, 2, \dots, M - 1$ , so that the corresponding  $A_n(j\Omega)$  approximate unity. After compensation with these filters, the overall ADC will experience the actual linear distortion  $Q_0(j\Omega)$ .

### 1.05.5.5 Error metrics

A common metric of ADCs is the signal-to-noise ratio (SNR). In this case, the aim is to minimize  $A_n(j\Omega) - 1$  in the least-squares sense which means that the quantities  $P_n$  given by

$$P_n = \frac{1}{2\pi} \int_{-\Omega_0 T}^{\Omega_0 T} |A_n(j\Omega) - 1|^2 d(\Omega T) \quad (5.112)$$

are minimized, either separately or simultaneously (in which case e.g., the mean of  $P_n$  is minimized). The minimization of  $P_n$  corresponds to the minimization of the expected error  $E\{[y(n) - x(n)]^2\}$  when the input signal is a stochastic process with a constant power spectrum in the region  $[-\Omega_0, \Omega_0]$  [27].

Another common metric of ADCs is the spurious-free dynamic range (SFDR). In this case, it is appropriate to write the input-output relation in the frequency domain in terms of a distortion function  $V_0(e^{j\Omega T})$  and  $M - 1$  aliasing functions  $V_m(e^{j\Omega T})$ ,  $m = 1, 2, \dots, M - 1$ . This is similar to frequency-domain input-output relations for multirate filter banks [24]. One can then write the output Fourier transform as

$$Y(e^{j\Omega T}) = V_0(e^{j\Omega T})X(e^{j\Omega T}) + \sum_{m=1}^{M-1} V_m(e^{j\Omega T})X(e^{j(\Omega T - 2\pi m/M)}), \quad (5.113)$$

where

$$V_0(e^{j\Omega T}) = \frac{1}{M} \sum_{n=0}^{M-1} B_n(e^{j\Omega T}) \quad (5.114)$$

and

$$V_m(e^{j\Omega T}) = \frac{1}{M} \sum_{n=0}^{M-1} e^{-j2\pi mn/M} B_n(e^{j(\Omega T - 2\pi m/M)}), \quad (5.115)$$

with  $B_n(e^{j\Omega T})$  being the  $2\pi$ -periodic extensions of  $A_n(j\Omega)$  in (5.109). That is,  $B_n(e^{j\Omega T}) = A_n(j\Omega)$  for  $-\pi \leq \Omega T \leq \pi$ . The distortion function corresponds to a regular frequency response seen from the input to the output, whereas the aliasing functions give the size of the aliased (frequency shifted) versions of the input. Specifically, a frequency component at  $\Omega = \Omega_0$  is affected by the modulus and phase of the distortion frequency response  $V_0(e^{j\Omega_0 T})$ , and we also get aliased versions at the “digital frequencies”  $\Omega_m T = \Omega_0 T + 2\pi m/M$ ,  $m = 1, 2, \dots, M - 1$ , with amplitudes determined by  $V_m(e^{j(\Omega_0 T + 2\pi m/M)})$ . Note also that, for real signals which always have frequency components at  $\Omega_0 T$  and  $-\Omega_0 T$  simultaneously, aliased versions also appear at  $-\Omega_0 T + 2\pi m/M$ ,  $m = 1, 2, \dots, M - 1$ .

Ideally, the distortion function should equal unity whereas the aliasing functions should be zero, in which case we have PR, because then we obtain  $Y(e^{j\Omega T}) = X(e^{j\Omega T})$  and thus  $y(n) = x(n)$ . In practice, we can only approximate PR. Typically, one then aims at minimizing two tolerances, say  $\delta_d$  and  $\delta_a$ , between unity and zero, respectively. One can then solve the problem in several slightly different ways. One typical way is to minimize  $\delta$  subject to the constraints

$$|V_0(e^{j\Omega T}) - 1| \leq \delta \quad \Omega T \in [-\Omega_0 T, \Omega_0 T] \quad (5.116)$$

and

$$|V_m(e^{j\Omega T})| \leq \delta (\delta_a / \delta_d), \quad \Omega T \in \Omega_m T, \quad (5.117)$$

for  $m = 1, 2, \dots, M - 1$ , where

$$\Omega_m T = \left[ -\Omega_0 T + \frac{2\pi m}{M}, \Omega_0 T + \frac{2\pi m}{M} \right]. \quad (5.118)$$

Clearly,  $|V_0(e^{j\Omega T})| \leq \delta_d$  and  $|V_m(e^{j\Omega T})| \leq \delta_a$  if  $\delta \leq \delta_d$ . It is noted that  $\delta_d$  and  $\delta_a$  are related through

$$|\delta_d| \leq (M - 1)|\delta_a| + |A_n(j\Omega) - 1|_{\min}, \quad (5.119)$$

which means that it is usually sufficient to ensure that the aliasing is suppressed as this implies a small distortion as well. Specifically, for the relaxed problem, (5.119) reduces to  $|\delta_d| \leq (M - 1)|\delta_a|$ , provided  $|V_0(e^{j\Omega T}) - 1|$  in (5.116) is replaced with  $|V_0(e^{j\Omega T}) - B_q(e^{j\Omega T})|$ ,  $q$  denoting the reference channel. The relation above is a consequence of the following equation which can be derived from (5.115):

$$\sum_{m=0}^{M-1} e^{j2\pi mq/M} V_m(e^{j(\Omega T + 2\pi m/M)}) = B_q(e^{j\Omega T}). \quad (5.120)$$

In a practical system, we cannot minimize  $\delta$  directly though as we do not have access to the distortion and aliasing functions. Instead,  $\delta$  is reduced indirectly to an acceptable level through some estimation and correction scheme.

#### 1.05.5.1 DC offset

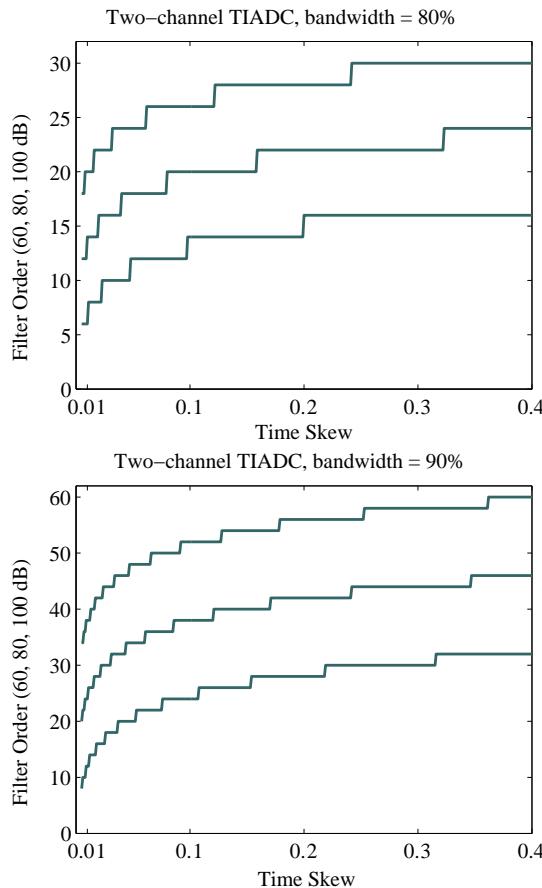

It is finally noted in this section that the representation in (5.113) can be used for DC offset mismatch as well, if we let  $X$  represent a DC signal, because it can be seen as a DC input that is time-interleaved and amplified differently in the different channels. In accordance with the discussion on aliasing above, it is seen that offset mismatches give rise to tones at  $\Omega_m T = 2\pi m/M, m = 0, 1, \dots, M - 1$ , with amplitudes determined by frequency independent  $V_m$ , as  $B_n$  in this case are frequency independent constants equaling the channel offset values. Specifically, with all  $B_n$  being equal, say,  $B_n = c$ , we obtain from (5.115) that  $V_0 = c$  and  $V_m = 0$  for  $m = 1, 2, \dots, M - 1$ , as we in this case have a regular DC offset.

#### 1.05.5.6 Oversampling

A good approximation can generally only be achieved if the input signal is bandlimited in accordance with the Nyquist theorem. It is generally advisable to use at least 10% oversampling as the complexity of the reconstructor otherwise may become prohibitive. However, if low complexity is not crucial, the amount of oversampling can be reduced. The increase of complexity with decreasing oversampling is illustrated in Figures 5.28 and 5.29 which plot the system (filter) order versus time skew in a two-channel time-interleaved ADCs for an reconstruction error [ $P_1$  in (5.112)] of  $-60$ ,  $-80$ , and  $-100$  dB. It is seen that the order is roughly doubled when the don't-care band between the upper band edge and the Nyquist frequency  $f_s/2$  is halved, (which occurs when we go from 80% to 90%, etc.). However, it is also seen that for small time skews and moderate reconstruction errors, one may increase the bandwidth as the order in such cases is relatively low. Recall that, for a reconstruction system of order  $N$ , in accordance with the convolution sum in (5.107), one needs to compute  $N + 1$  multiplications and  $N$  additions to correct each output sample.

#### 1.05.5.7 Reconstruction based on least-squares design

From the previous section, we see that the overall compensation system can be designed by minimizing the quantities  $P_n, n = 0, 1, \dots, M - 1$ , in (5.112). The quantities  $P_n$  can be minimized separately or

**FIGURE 5.28**

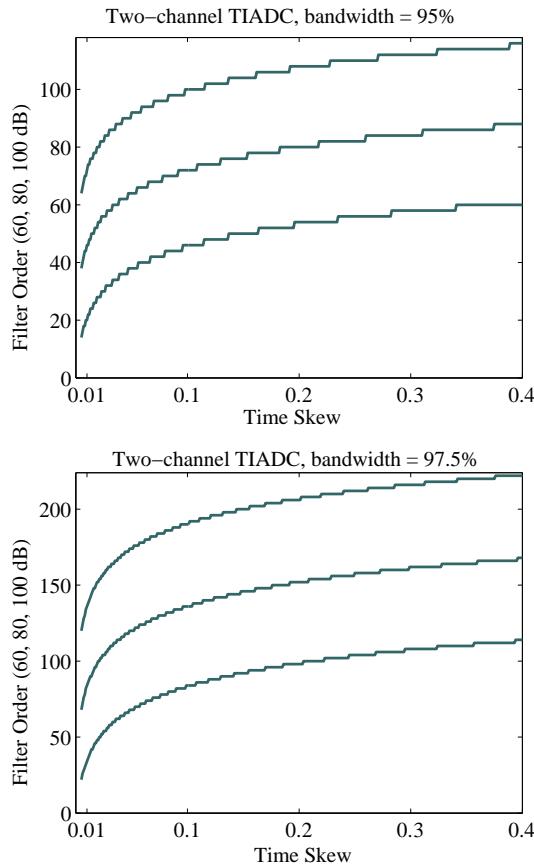

System (filter) order versus time skew in percent of the sampling period  $T = 1/f_s$  in a two-channel time-interleaved ADC for 80% and 90% of the Nyquist band.

simultaneously. In the former case, the corresponding  $M$  impulse responses  $h_n(k)$ ,  $n = 0, 1, \dots, M-1$ , can be computed separately as [45]

$$\mathbf{h}_n = -0.5\mathbf{S}_n^{-1}\mathbf{c}_n, \quad (5.121)$$

with  $c_{n,k}$ ,  $k = -N, -N+1, \dots, N$ , being

$$\begin{aligned} c_{n,k} &= -\frac{1}{\pi} \int_{-\Omega_0 T}^{\Omega_0 T} |Q_{n-k}(j\Omega)| \\ &\quad \times \cos(\Omega T k - \arg\{Q_{n-k}(j\Omega)\}) d(\Omega T), \end{aligned} \quad (5.122)$$

**FIGURE 5.29**

System (filter) order versus time skew in percent of the sampling period  $T = 1/f_s$  in a two-channel time-interleaved ADC for 95% and 97.5% of the Nyquist band.

$S_n$  being  $(N + 1) \times (N + 1)$  symmetric and positive definite matrices with entries  $s_{n,kp}$ ,  $k, p = -N/2, -N/2 + 1, \dots, N/2$  given by

$$s_{n,kp} = \frac{1}{2\pi} \int_{-\Omega_0 T}^{\Omega_0 T} |Q_{n-k}(j\Omega)| |Q_{n-p}(j\Omega)| \times \cos(\Omega T(p - k) + \arg\{Q_{n-k}(j\Omega)\} - \arg\{Q_{n-p}(j\Omega)\}) d(\Omega T) \quad (5.123)$$

and the constant  $C$  being  $C = \Omega_0 T / \pi$ . In order to compute  $h_n$  in (5.121), it is necessary to compute the integrals in (5.122) and (5.123), which generally have to be computed numerically.

Above, the overall compensation system is designed by determining the  $M$  filter impulse responses  $h_n(k)$  through  $M$  separate matrix inversions ( $M - 1$  in the practical relaxed case), where the size of

the matrices is  $(N + 1) \times (N + 1)$ , where  $N + 1$  is the filter impulse response length [45,47]. In the alternative case, corresponding to simultaneous design, the impulse responses  $h_n(k)$  are designed simultaneously. This was done in [39], which poses the design problem in terms of  $M$  synthesis filters that are designed simultaneously by inverting one matrix of size  $M(N + 1) \times M(N + 1)$ . Whereas the separate-design technique yields optimum filters with respect to the reconstruction error in the band of interest, the technique in [39] may give somewhat better results as to distortion and aliasing, because it includes those quantities in the overall error cost measure. The main advantage of the separate-design approach is that the design problem comprises  $M$  smaller subproblems instead of one large problem. It may therefore be more numerically robust and simpler to design and implement.

In addition to the above mentioned design techniques, [39,45,47], there are a few other related techniques [38,40,41,47]. In [38], separately designed synthesis filters were obtained through windowing techniques, which, however, are known to result in suboptimum filters. A somewhat different compensation technique, that also utilizes separately designed filters, was proposed in [40,41], but that technique needs additional cosine and sine modulators which increases the implementation cost of the compensation system. Finally, it is noted that one may alternatively use numerical optimization in accordance with [27], but this is costly and therefore less suitable for on-line design applications.

For all methods described above, new values of the impulse responses  $h_n(k)$  must be computed whenever the frequency responses  $Q_n(j\Omega)$  are changed, which occur in a practical time-interleaved ADC due to temperature variations etc. This requires recomputation of the filter coefficients using windowing techniques (including inverse Fourier transforms), matrix inversions, or numerical optimization. This may be acceptable for off-line design which can be adopted in, e.g., spectrum analysis applications. In real-time low-power applications, on the other hand, these on-line redesign procedures can become too costly and time consuming to implement. The next section discusses a compensation structure for which on-line design is not needed. This structure was introduced in [46]. A similar structure has been reported in [48].

### 1.05.5.8 Reconstruction using a polynomial based approach

As discussed in the previous section, the reconstruction can in principle be done through the time varying system  $h_n(k)$ . For an  $N$ th-order reconstructor, each system  $h_n(k)$  has then  $N + 1$  free parameters (multipliers) that must be estimated and implemented, and thus  $(M - 1)(N + 1)$  in total for a practical  $M$ -channel system (in the relaxed case). This becomes difficult from the estimation point of view and expensive to implement except for small values of  $M$ .

Depending on the behavior of the channel responses  $Q_n(j\Omega)$ , the number of free parameters may be reduced by modeling them as  $P$ th-order polynomials in  $j\Omega$  according to

$$Q_n(j\Omega) = \varepsilon_n^{(0)} \left[ 1 + \sum_{p=1}^P \varepsilon_n^{(p)} (j\Omega T)^p \right], \quad (5.124)$$

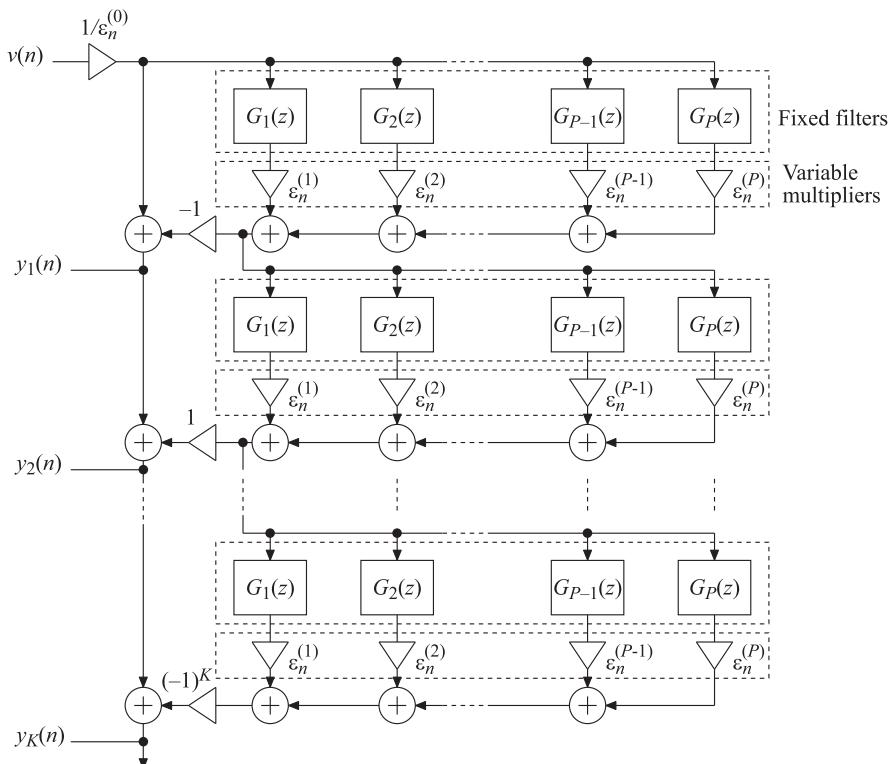

where  $\varepsilon_n^{(0)}$  is a gain constant (ideally equal to unity) and the remaining  $\varepsilon_n^{(p)}$  are constants (ideally equal to zero) used for modeling the frequency dependency. This does not impose a fundamental restriction as it is known that any frequency response can be approximated as closely as desired by a properly chosen polynomial and polynomial order. For example, when the system has frequency independent

time skews,  $d_n T$ ,  $Q_n(j\Omega)$  can be written as

$$Q_n(j\Omega) = \varepsilon_n^{(0)} e^{j\Omega T d_n} \approx \varepsilon_n^{(0)} [1 + \sum_{p=1}^P d_n^p (j\Omega T)^p / p!], \quad (5.125)$$

from which we obtain  $\varepsilon_n^{(p)} = d_n^p / p!$ . In this case it suffices to estimate two parameters per channel (three, including offset errors).

A general structure for the reconstruction based on the model in (5.124) is seen in Figure 5.30. This structure makes use of  $K$  sets of fixed subfilters  $G_p(z)$ ,  $p = 1, 2, \dots, P$ , that approximate the  $p$ th-order differentiators in (5.124). Figure 5.30 shows a noncausal filter structure for convenience. The corresponding causal structure is obtained by propagating  $D$  delay elements into each vertical branch and replacing  $\varepsilon_n^{(p)}$  with  $\varepsilon_{n-D}^{(p)}$ , where  $D$  is the (possibly approximate) delay of the subfilters, which can be either linear-phase finite-length impulse response (FIR) subfilters, or approximately linear-phase FIR or infinite-length impulse response (IIR) subfilters. Using  $N$ th-order linear-phase FIR subfilters,

**FIGURE 5.30**

Reconstruction based on the model in (5.124).

$D = N/2$ . The remaining errors in the output  $y_K(n)$  of the  $K$ -stage structure in Figure 5.30 are of orders  $(\Omega_0 T \varepsilon_n^{(p)})^{K+1}$ . This means that one can reach any desired error level by increasing the number of stages, provided  $|\Omega_0 T \varepsilon_n^{(p)}|$  is small which is the case in practical time-interleaved ADCs. The error will in practice decrease with  $K$  to a level that is determined by the channel model accuracy, i.e., by the distances between  $Q_n(j\Omega)$  and the actual frequency responses.

### 1.05.5.9 Performance discussion

The performance of the overall compensated ADC is naturally bounded by the performance of the individual converters. In this section, we only consider the compensation of the linear mismatch errors. Ultimately, the overall ADC's performance is therefore determined by the nonlinear distortion of the individual converters. In practice, the compensation structure presented above has virtually no effect on the nonlinear distortion. That is, the undesired frequency components caused by nonlinear distortion pass the compensation structure more or less unaffected. This is because the nonlinear distortion components, which are small themselves, passes a time-varying system that approximates a pure delay, provided  $\varepsilon_n^{(p)}$ ,  $p = 1, 2, \dots, P$ , are small which is the case in practice. This will be illustrated below in an example. It should be noted though that the time interleaving introduces nonlinear-distortion frequency components that are not present in the individual converters, but the total nonlinear-distortion power is virtually the same [30,31].

#### 1.05.5.9.1 Example of frequency response mismatch correction

To illustrate the theory above, an example is provided. It is assumed here that the number of channels is  $M = 4$ , the bandwidth is  $\Omega_0 T = 0.9\pi$ , and the four channel frequency responses  $Q_n(j\Omega)$ ,  $n = 0, 1, 2, 3$ , are modeled as

$$Q_n(j\Omega) = \frac{e^{j\Omega T d_n}}{1 + j\frac{\Omega}{\Omega_c}(1 + \Delta_n)} = \frac{e^{j\Omega T d_n}}{1 + j\Omega T \frac{f_s}{2\pi f_c}(1 + \Delta_n)}, \quad (5.126)$$

where  $f_s = 1/T$  denotes the sampling frequency whereas  $f_c$  and  $\Omega_c$  denote the 3-dB cutoff frequency and angular frequency, respectively, and  $d_n$  and  $\Delta_n$  correspond to analog matching errors. Here, we have chosen  $f_s/f_c = 1/2$ , which corresponds to a bandwidth of about two times the overall Nyquist band or, equivalently, eight times the individual channel ADC Nyquist band. Further, we have set  $d_0 = -0.02$ ,  $d_1 = 0.02$ ,  $d_2 = -0.01$ ,  $d_3 = 0.01$ ,  $\Delta_0 = -0.005$ ,  $\Delta_1 = 0.005$ ,  $\Delta_2 = -0.004$ , and  $\Delta_3 = 0.004$ . The term in the numerator in (5.126) models static aperture delay mismatches whereas the denominator models the sample-and-hold circuit [30,31,38]. The values for these parameters correspond to time and bandwidth mismatch spurs of some  $-30$  dB and  $-60$  dB, respectively, which is realistic at least for well-matched ADCs operating in their lower Nyquist bands. Hence, for a 10-bit resolution, one may ignore the bandwidth mismatch.

We assume that the zeroth channel is the reference channel. Consequently, we need to find the polynomial models of the rational functions  $Q_n(j\Omega)/Q_0(j\Omega)$ ,  $n = 0, 1, 2, 3$ . Including terms up to third order, we obtain from (5.126)

$$\frac{Q_n(j\Omega)}{Q_0(j\Omega)} = 1 + j\Omega T \varepsilon_n^{(1)} + (j\Omega T)^2 \varepsilon_n^{(2)} + \dots + (j\Omega T)^3 \varepsilon_n^{(3)}, \quad (5.127)$$

where

$$\varepsilon_n^{(1)} = d_n - d_0 + \Delta_0 - \Delta_n, \quad (5.128)$$

$$\varepsilon_n^{(2)} = \frac{(d_n - d_0)^2}{2} - \Delta_n(\Delta_0 - \Delta_n) - (d_n - d_0)(\Delta_0 - \Delta_n) \quad (5.129)$$

and

$$\varepsilon_n^{(3)} = \frac{(d_n - d_0)^3}{6} + \Delta_n^2(\Delta_0 - \Delta_n) - (d_n - d_0)\Delta_n(\Delta_0 - \Delta_n) + \frac{(d_n - d_0)^2}{2}(\Delta_0 - \Delta_n). \quad (5.130)$$

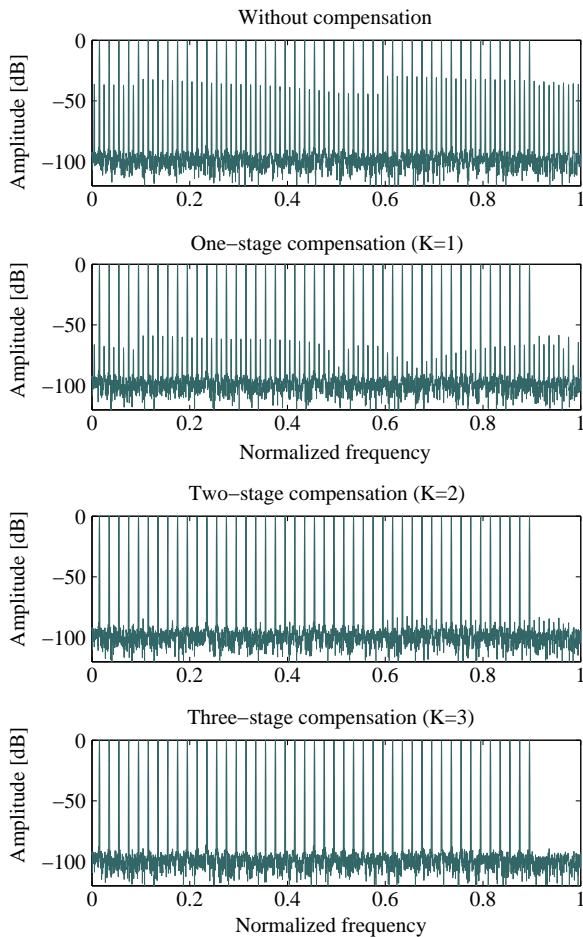

Here, we can compute the different parameters  $\varepsilon_n^{(p)}$  needed for the compensation, as we have assumed that we know the channel frequency responses. In practice, these parameters are obtained through some estimation technique for this purpose. It is noted that  $\varepsilon_0^{(1)} = \varepsilon_0^{(2)} = \varepsilon_0^{(3)} = 0$  as we have assumed that the zeroth channel is the reference, i.e., the samples from this channel are taken directly without compensation.

We have applied a 16-bit multi-sine input to this four-channel system. Without compensation, the output spectrum becomes as seen in Figure 5.31 which reveals large spurs. Figure 5.31 also plots the output spectra after compensation using one, two, and three stages, respectively. It is seen that, after three stages, the errors have been reduced to a level that corresponds to some 16 bits. This reveals that any desired error level can be reached in the frequency band  $\Omega \in [-\Omega_0, \Omega_0]$  by increasing the number of stages, provided the model order is high enough. In this example, the third-order model in (5.127) is required to reach 16 bits. Using instead a second-order model, we end up with spurs of some  $-80$  dB for  $K \geq 2$ , which corresponds to 13–14 bits. Hence, the approximation of (5.126) by a numerator polynomial of a certain order imposes a performance bound that cannot be surpassed by increasing  $K$  alone. In other words, to reach the desired result, one must select both the model order and number of stages appropriately. It is also noted that one stage suffices to reach some  $-60$  dB, thus about 10 bits.

Finally, to illustrate that the compensation has virtually no effect on nonlinear distortion, as discussed previously, we have also applied a two-tone input including the distortion term  $0.0001x^2(n)$  and plotted the output spectra in Figure 5.32 for the uncompensated system and compensated system with  $K = 3$ . From the figure, it is seen that the two large unwanted spurs (of some  $-40$  dB) caused by the interleaving have been suppressed whereas the smaller nonlinear-distortion spurs (of some  $-90$  dB to  $-85$  dB) are practically unaffected by the compensation.

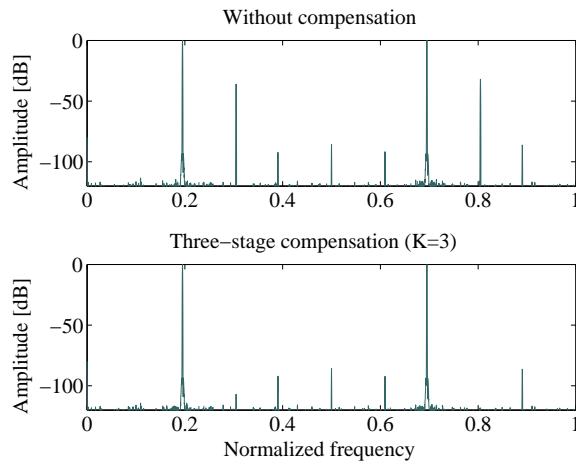

## 1.05.6 Quantization

In ideal linear systems, all signal values are represented with real numbers and all computations are done with infinite precision. In a practical implementation, one can however only use finite precision both for the input and output signal values and the internal signal values. Hence, instead of the ideal system in Figure 5.33a, we will in practice implement the one shown in Figure 5.33b. The boxes  $Q$  (with additional indices) represent quantizers. The function of a quantizer  $Q$  depends on the

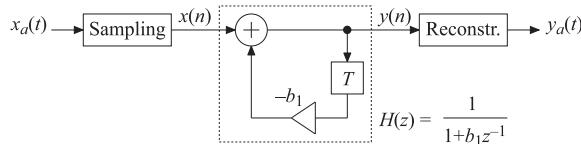

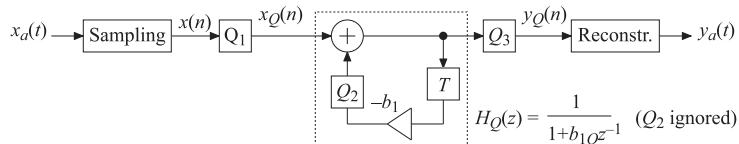

**FIGURE 5.31**

Spectra in the example of frequency response mismatch correction.

type of arithmetic that is to be used in the implementation. In general-purpose computers, one uses floating-point arithmetic. However, for many fixed functions (like filters), the large number range provided by floating-point arithmetic is not needed and thus becomes unnecessarily expensive to implement. In very-large-scale integration (VLSI) implementations, one therefore usually employs fixed-point arithmetic in order to minimize the implementation cost. We henceforth understand that fixed-point arithmetic is used. One may further choose between several different formats like sign and magnitude, one's complement, and two's complement, etc. Here, we consider two's complement format which is commonly used in VLSI implementations.

**FIGURE 5.32**

Spectra in the example of frequency response mismatch correction with the presence of a nonlinear distortion term  $0.0001x^2(n)$ .

**(a) Ideal linear system****(b) Actual nonlinear system****FIGURE 5.33**

(a) Ideal linear system. (b) Actual nonlinear system in a practical implementation.

Using two's complement arithmetic, a quantized number  $x_Q$ , within the number range  $-X_m \leq x_Q \leq X_m(1 - Q)$ , is represented with the  $B$ -bit fractional binary number  $x_B$  given by

$$x_B = -x_0 + \sum_{i=1}^{B-1} 2^{-i} x_i, \quad (5.131)$$

where  $x_i, i = 0, 1, \dots, B - 1$ , are either zero or one and where  $x_B$  is related to  $x_Q$  according to

$$x_Q = X_m x_B. \quad (5.132)$$

The quantity  $x_0$  is referred to as the sign bit which is zero for positive numbers (including zero) and one for negative numbers. Further, it is seen that  $-1 \leq x_B \leq 1 - Q$ . Hence, the quantity  $X_m$  is a scaling constant that is used for relating numbers within the range  $-1 \leq x_B \leq 1 - Q$  to numbers within the range  $-X_m \leq x_Q \leq X_m(1 - Q)$ . For example, in the context of A/D conversion, we can view  $X_m$  as the full-scale amplitude of the A/D converter. Another role of  $X_m$  is to enable representation of numbers larger than one in magnitude. In this case,  $X_m = 2^P$ , for some integer  $P$ , which can be interpreted as if the binary point has been moved to the right. Often, this scaling constant is not explicitly implemented but instead implicit.

The quantizers that inevitably are present introduce a number of errors that need to be analyzed when designing and implementing digital systems. The errors can be divided into four broad categories as discussed below. It is beyond the scope of this section to discuss all of these issues in detail. The subsequent subsections concentrate on quantization errors in the A/D conversion process and the related round-off errors in digital systems. For a comprehensive treatment of quantization effects, we refer in particular to the digital filter literature [51–53].

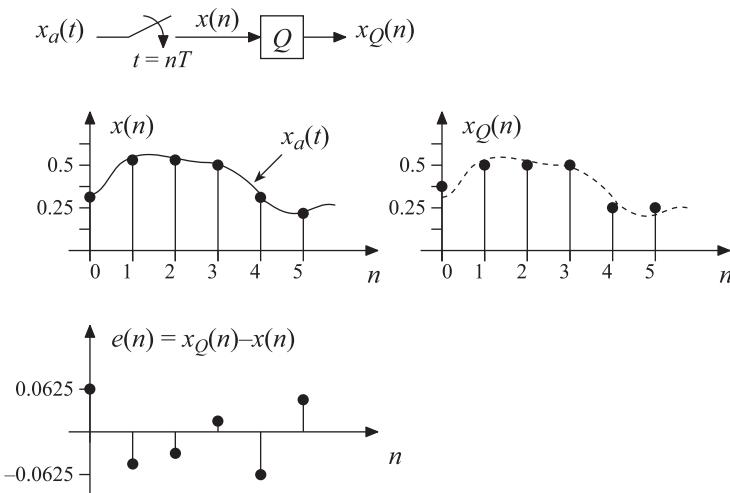

- Quantization errors in the A/D conversion—A/D conversion consists of sampling followed by quantization of the sample values. Thereby, a quantization error is introduced in the sampled signal.
- Overflow errors—Overflow errors occur when the available number range is exceeded. This may give rise to large sustaining errors referred to as parasitic large-scale oscillations. Digital system must be designed so that such errors are suppressed once the disturbance that incurred them vanishes. This is done by scaling the signal levels appropriately, not only at inputs and outputs but also inside the systems.
- Round-off errors—in digital systems, the results of arithmetic operations normally need be rounded (truncated). This gives rise to round-off errors at the output of the systems.
- Coefficient errors—the coefficients of a digital system must be represented with finite precision. This give rise to a static error in the corresponding transfer function, frequency response, etc.

### 1.05.6.1 Quantization errors in A/D conversion

A/D conversion consists of sampling followed by quantization according to Figure 5.34. In the sampling process, the samples  $x(n)$  are obtained as  $x(n) = x_a(nT)$ . Quantization means that each sample is represented in binary form with finite wordlength. This gives rise to a quantization error, i.e., an error in the representation of  $x_a(nT)$ , according to

$$e(n) = x_Q(n) - x(n). \quad (5.133)$$

This is also illustrated in Figure 5.34. The size of the quantization error depends on the types of binary representation and quantizer that are used. It is common to use fixed-point two's complement representation and uniform quantization in which case  $x(n)$  is rounded to the nearest number in the number representation.

**FIGURE 5.34**

A/D conversion—sampling and quantization.

If we assume that two's complement representation is used, and that the number range for the quantizer is  $-X_m \leq x_Q \leq X_m(1 - Q)$ , where  $Q$  is the quantization step,  $x_Q(n)$  can for a  $B$ -bit quantizer be written as

$$x_Q(n) = X_m x_B(n) \quad (5.134)$$

with

$$x_B(n) = -x_0(n) + \sum_{i=1}^{B-1} 2^{-i} x_i(n), \quad (5.135)$$

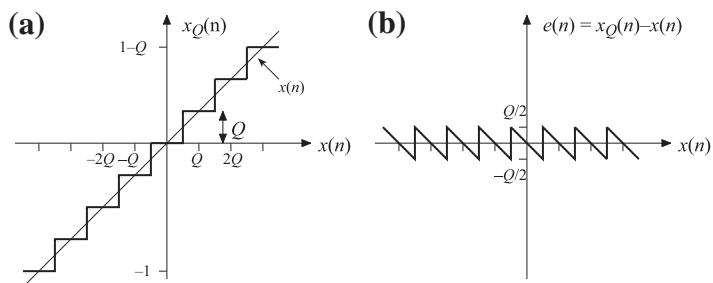

where  $x_i(n)$ ,  $i = 0, 1, \dots, B-1$ , are either zero or one. When the samples  $x_Q(n)$  are represented with  $B$  bits, they can take on  $2^B$  different values, as illustrated in Figure 5.35 for a uniform quantizer, assuming for simplicity that  $X_m = 1$ . The quantization step  $Q$  is given by

$$Q = X_m 2^{-(B-1)}. \quad (5.136)$$

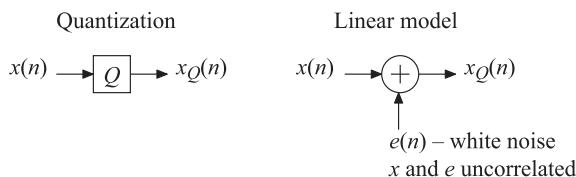

Quantization is a nonlinear operation which in general is much more difficult to analyze than a linear operation. To analyze the effects of the quantization errors, one therefore makes use of a linear model of the quantization according to Figure 5.36. In the linear model,  $x_Q(n)$  is obtained by adding  $x(n)$  and an error sequence  $e(n)$  according to

$$x_Q(n) = x(n) + e(n), \quad (5.137)$$

where it is assumed that  $x(n)$  and  $e(n)$  are uncorrelated. Further,  $e(n)$  is assumed to be uniformly distributed white noise. That is, one understands that the samples  $e(n)$  are uncorrelated and the errors that  $e(n)$  can take on occur with equal probability. This model is appropriate when  $x_a(t)$  varies irregularly since the quantization errors then vary more or less randomly and independently of previous errors.

**FIGURE 5.35**

(a) Uniform quantization with \$X\_m = 1\$ and \$B = 3\$ bits. (b) Quantization error.

**FIGURE 5.36**

Linear model of quantization.

Using uniform quantization, we have

$$|e(n)| \leq Q/2, \quad (5.138)$$

where \$Q\$ is the quantization step according to (5.136). Each sample \$e(n)\$ is therefore assumed to have the probability density function

$$f(e) = \begin{cases} 1/Q, & |e| \leq Q/2, \\ 0, & |e| > Q/2. \end{cases} \quad (5.139)$$

The mean value and variance of \$e(n)\$ become

$$m_e = 0 \quad (5.140)$$

and

$$\sigma_e^2 = \frac{Q^2}{12} = X_m^2 \frac{2^{-2(B-1)}}{12}, \quad (5.141)$$

respectively.

A measure that is commonly used for comparing the (useful) signal power and noise power is the SNR which is defined as

$$\text{SNR} = 10 \times \log_{10} \left( \frac{\text{Signal power}}{\text{Noise power}} \right). \quad (5.142)$$

Since the noise power is here the variance of  $e(n)$  [due to  $m_e = 0$ ], i.e.,  $\sigma_e^2$  in (5.141), we can write the SNR as

$$\text{SNR} = 10 \times \log_{10} (\text{Signal power}) - 10 \times \log_{10} \left( X_m^2 \frac{2^{-2(B-1)}}{12} \right), \quad (5.143)$$

which alternatively can be written as

$$\text{SNR} = 10 \times \log_{10} (\text{Signal power}) + 4.77 + 6.02B - 20 \times \log_{10} (X_m). \quad (5.144)$$

We note that the SNR increases by 6 dB for each bit that we add. For a full-scale sinusoidal signal with the amplitude  $X_m$ , the signal power is  $X_m^2/2$  which corresponds to  $20 \times \log_{10} (X_m) - 3.01$  dB. In this case, the SNR is

$$\text{SNR} = 1.76 + 6.02B. \quad (5.145)$$

In for example a CD player,  $B = 16$  bits. The SNR becomes in this case 98.1 dB.

### 1.05.6.2 Round-off errors

This section considers round-off errors (or round-off noise) in digital systems. The round-off noise is computed under the assumption that the quantization errors can be modeled as white noise, which is appropriate in many practical situations. It is further assumed that the digital system operate under normal conditions which means that overflows or other abnormal disturbances do not occur. In other words, we assume a linear model of the system incorporating one input signal and one or several noise sources. The problem is then to determine the round-off noise power and SNR at the output of the system. To this end, one makes use of the theory of linear systems excited with white stochastic processes. We will explain the principle by means of examples, where we assume  $X_m = 1$  for simplicity, but without loss of generality.

#### 1.05.6.2.1 Quantization and round-off noise example 1

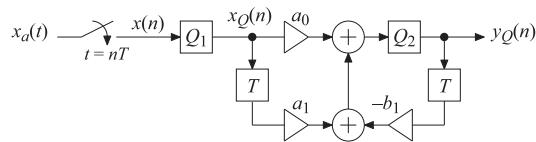

Consider a system represented by the structure in Figure 5.37a. First, sampling and quantization take place, with the quantization step  $Q_1$ , i.e., A/D conversion with  $B_1$  bits where  $Q_1 = 2^{-(B_1-1)}$ . The output from the quantization is  $x_Q(n)$  which subsequently is filtered. The filter is realized by a first-order direct form recursive IIR filter structure. In an implementation of this filter, the result of the arithmetic operations must at some point(s) inside the filter be rounded or truncated. Otherwise, the wordlength would increase in each iteration of the filter algorithm since it is recursive. Here, only one quantizer with the quantization step  $Q_2 = 2^{-(B_2-1)}$  is used and it is placed after the upper-most addition<sup>3</sup>.

We now wish to analyze the effects at the output of the filter caused by quantization errors. To be able to separate the origins of the errors we distinguish between the errors emanating from the A/D conversion, here referred to as quantization noise, and the errors coming from the quantizations of the

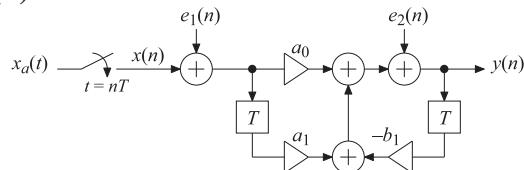

---

<sup>3</sup>The results of the remaining operations must thereby in this case be represented with more bits but this is only one option. For example, one may instead introduce quantizers after each operation. This will increase the noise at the output of the filter but, on the other hand, one may then use a shorter wordlength inside the filter. It is generally not obvious which alternative one should use in order to arrive at the cheapest implementation. It has to be investigated in each specific case.

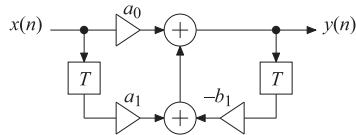

(a) Sampling, quantization, and filtering

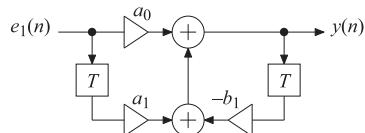

(b) Linear model

(d) Contribution from noise source #1

(e) Contribution from noise source #2

**FIGURE 5.37**

Signal-flow graphs used for computation of the round-off noise.

arithmetic operations inside the filter, usually referred to as round-off noise. To be able to analyze the different errors, we make use of a linear model of the quantizations which results in the structure shown in Figure 5.37b. The error sequences  $e_1(n)$  and  $e_2(n)$  are assumed to be white noise with zero mean and variances  $\sigma_{e1}^2$  and  $\sigma_{e2}^2$ , respectively<sup>4</sup>. These error sequences are often called noise sources.

<sup>4</sup>When quantizing already quantized numbers, as is the case at the output of  $Q_2$ , one should actually use a discrete rectangular probability function. The difference is however negligible except when only a few bits are discarded.

Since we use linear models, we can regard the input and noise sources one at a time according to Figure 5.37c–e. The total output round-off noise variance is then computed as the sum

$$\sigma_y^2 = \sigma_{y1}^2 + \sigma_{y2}^2, \quad (5.146)$$

where

$$\sigma_{y1}^2 = \sigma_{e1}^2 \sum_{n=-\infty}^{\infty} h_1^2(n) \quad (5.147)$$

is the output quantization noise variance and

$$\sigma_{y2}^2 = \sigma_{e2}^2 \sum_{n=-\infty}^{\infty} h_2^2(n) \quad (5.148)$$

is the output round-off noise variance. Here,  $h_1(n)$  and  $h_2(n)$  are the impulse responses as seen from the respective noise source to the output. They can be obtained through inverse transformation of the corresponding transfer functions  $H_1(z)$  and  $H_2(z)$ .

Here, the transfer function from  $e_1(n)$  to  $y(n)$  is the same as that from  $x(n)$  to  $y(n)$  and given by

$$H_1(z) = \frac{a_0 + a_1 z^{-1}}{1 + b_1 z^{-1}}, \quad (5.149)$$

whereas the transfer function from  $e_2(n)$  to  $y(n)$  is

$$H_2(z) = \frac{1}{1 + b_1 z^{-1}}. \quad (5.150)$$

In the causal-filter case, the region of convergence is  $|z| > b_1$  for both of these transfer functions. We then get

$$h_1(n) = a_0(-b_1)^n u(n) + a_1(-b_1)^{n-1} u(n-1) \quad (5.151)$$

and

$$h_2(n) = (-b_1)^n u(n), \quad (5.152)$$

respectively, where  $u(n)$  denotes the unit-step sequence. This gives us the corresponding noise gains

$$\sum_{n=-\infty}^{\infty} h_1^2(n) = a_0^2 + \left(a_0 - \frac{a_1}{b_1}\right)^2 \sum_{n=1}^{\infty} b_1^{2n} = \frac{a_0^2 + a_1^2 - 2a_0a_1b_1}{1 - b_1^2} \quad (5.153)$$

and

$$\sum_{n=-\infty}^{\infty} h_2^2(n) = \sum_{n=0}^{\infty} b_1^{2n} = \frac{1}{1 - b_1^2}, \quad (5.154)$$

respectively.

If the quantizations  $Q_1$  and  $Q_2$  correspond to  $B_1$  and  $B_2$  bits, respectively, the variances  $\sigma_{e1}^2$  and  $\sigma_{e2}^2$  become

$$\sigma_{e1}^2 = \frac{Q_1^2}{12}, \quad \sigma_{e2}^2 = \frac{Q_2^2}{12}. \quad (5.155)$$

This gives us the variances  $\sigma_{y1}^2$  and  $\sigma_{y2}^2$  according to

$$\sigma_{y1}^2 = \sigma_{e1}^2 \sum_{n=-\infty}^{\infty} h_1^2(n) = \frac{Q_1^2}{12} \frac{a_0^2 + a_1^2 - 2a_0a_1b_1}{1 - b_1^2} \quad (5.156)$$

and

$$\sigma_{y2}^2 = \sigma_{e2}^2 \sum_{n=-\infty}^{\infty} h_2^2(n) = \frac{Q_2^2}{12} \frac{1}{1 - b_1^2}, \quad (5.157)$$

respectively. Finally, we obtain

$$\sigma_y^2 = \sigma_{y1}^2 + \sigma_{y2}^2 = \frac{Q_1^2}{12} \frac{a_0^2 + a_1^2 - 2a_0a_1b_1}{1 - b_1^2} + \frac{Q_2^2}{12} \frac{1}{1 - b_1^2}, \quad (5.158)$$

which can be rewritten as

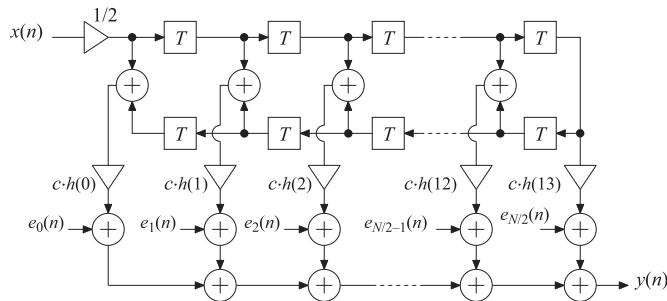

$$\sigma_y^2 = \frac{Q_1^2}{12} \frac{1}{1 - b_1^2} \left( a_0^2 + a_1^2 - 2a_0a_1b_1 + \frac{Q_2^2}{Q_1^2} \right). \quad (5.159)$$

From the equation above, we see that the contribution from the quantizer  $Q_2$  can be neglected if we choose  $Q_2$  sufficiently small as compared to  $Q_1$ . That is, by increasing the number of bits within the filter, the round-off noise can be made negligible compared to the quantization noise. This shows that digital systems can be implemented with as high resolution as desired. However, an increased internal wordlength also results in a more expensive implementation. One should therefore not use longer wordlengths than necessary to meet the specification at hand, typically given in terms of an SNR required. It should also be noted that the digital signal that in the end is to be D/A converted must be quantized to  $B_1$  bits if we want to use the same number of bits as that used in the A/D converter. This will give rise to additional round-off noise, equally large as that in the A/D conversion, which in turn degrades the resolution by half a bit. One can alleviate this problem by using oversampling techniques.

### 1.05.6.2.2 Quantization and round-off noise example 2

In this example, we compute the round-off noise at the output of a linear-phase direct-form FIR filter structure and the increase in SNR that is achieved by using so called  $L_2$ -norm scaling instead of safe scaling.

Assuming that quantization takes place after each multiplication, the linear model of the whole filter is as shown in Figure 5.38. Apparently, the errors pass directly to the output, i.e., the transfer function from each noise source to the filter's output is equal to unity. Assuming that the errors are uncorrelated white noise sources, the total output noise variance equals the sum of the individual variances. As

**FIGURE 5.38**

Linear model of a linear-phase FIR filter with quantizers.

a consequence, if all noise sources have the same variance, say  $\sigma_e^2$ , the total output variance for an  $N$ th-order filter,  $N$  being even, becomes

$$\sigma_y^2 = (N/2 + 1)\sigma_e^2. \quad (5.160)$$

With  $N = 26$ , as in this example, we thus have

$$\sigma_y^2 = 14\sigma_e^2. \quad (5.161)$$

This corresponds to a degradation of almost two bits as compared to the case where one quantizer is placed at the output. That is, the outputs of quantizers placed inside the filter need to be two bits longer than the output of a single quantizer located at the output, in order to achieve (roughly) the same round-off noise. On the other hand, this means that we can use adders with shorter wordlengths which reduces the implementation cost. The alternative of using one quantizer at the output requires the use of full-length adders inside the filter which increases the implementation cost.

Next, we consider the increase in SNR that is achieved by using so called  $L_2$ -norm scaling instead of safe scaling in the filter. Scaling of signal levels is used to avoid or reduce the probability of overflows, but it may also be used to increase the SNR. In the FIR filter in Figure 5.38, the only node that needs to be scaled (assuming a scaled input) is the output which is scaled by multiplying all impulse response values  $h(n)$  by the scaling coefficient  $c$ . In this filter, the output SNR is affected by the scaling because the output round-off noise variance is independent of the multiplier coefficient values whereas the output signal power is scaled with  $c^2$ . With safe scaling,  $c$  is chosen as

$$c = \frac{1}{\sum_{n=-\infty}^{\infty} |h(n)|}. \quad (5.162)$$

Using the convolution sum and the triangle inequality, one can show that  $c$  according to (5.162) guarantees no overflow. On the other hand, it also results in a lower SNR. The SNR can be increased by using a larger value of  $c$ , but this also comes with overflow with a certain probability. With  $L_2$ -norm scaling,  $c$  is chosen as

$$c = \frac{1}{\sqrt{\sum_{n=-\infty}^{\infty} |h(n)|^2}}. \quad (5.163)$$

Using  $L_2$ -norm scaling for white-noise Gaussian input signals, the probability of overflow at the output will be the same as the probability of overflow at the input.

There is thus a trade-off between high SNR and probability of overflow. In this example, we obtain  $c = 1.238477$  using safe scaling and  $c = 3.330192$  using  $L_2$ -norm scaling. The increase in SNR that is achieved by using  $L_2$ -norm scaling instead of safe scaling is therefore

$$20 \times \log_{10} (3.330192) - 20 \times \log_{10} (1.238477) \approx 8.59 \text{ [dB]} \quad (5.164)$$

which roughly corresponds to some 1.5 bits. That is, using  $L_2$ -norm scaling instead of safe scaling, we can implement the filter using 1.5 bits shorter data wordlength, which in practice means 1 bit or 2 bits shorter wordlength.

## 1.05.7 Oversampling techniques

This section discusses oversampling techniques which are used in A/D and D/A conversions for relaxing the requirements on the analog filters and quantizers.

### 1.05.7.1 Oversampled A/D converters

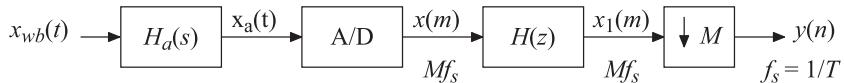

The principle of an oversampled A/D converter is shown in Figure 5.39. To elaborate on this principle, assume the typical spectra shown in Figure 5.40. Say that we have a signal  $x_{wb}(t)$  containing information in the baseband up to  $\pi/T$  and undesired frequency components above  $\pi/T$ , like wideband noise [Figure 5.40a]. The information can, in principle, be sampled and reconstructed without errors if the sampling frequency is  $f_s = 1/T$ . Due to the wideband noise, the sampling will however also introduce aliasing distortion. Theoretically, aliasing distortion can be avoided by band limiting the input signal using an ideal analog lowpass filter with passband up to  $\pi/T$ , but such a filter cannot be realized in practice. Hence, we must let the filter have a transition band. The wider this band is, the simpler it becomes to implement the filter. On the other hand, we must then increase the sampling frequency so as to avoid aliasing distortion.

Assume that we use  $M$  times oversampling, i.e., that we choose a sampling frequency  $f_{s1}$  according to

$$f_{s1} = Mf_s. \quad (5.165)$$

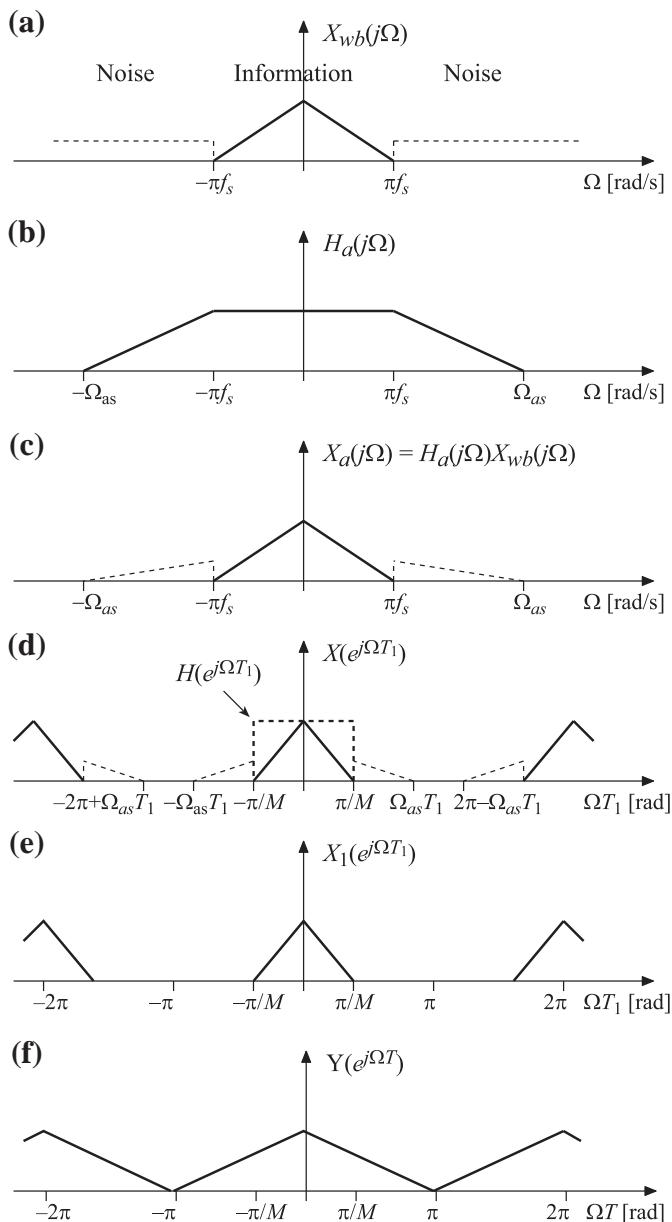

This corresponds to a sampling period  $T_1$  according to

$$T_1 = T/M. \quad (5.166)$$

**FIGURE 5.39**

Oversampled A/D converter.

**FIGURE 5.40**

Principle spectra in an oversampled A/D converter.

We can now avoid aliasing distortion by selecting the stopband edge of the anti-aliasing filter  $H_a(s)$  appropriately. It suffices to ensure that aliasing into the baseband is avoided since the information is then unaffected, see Figure 5.40c. Frequency components that are aliased into the remaining frequency region are allowed since they can be eliminated by the digital filter  $H(z)$  that succeeds the A/D converter, see Figure 5.40d. We see that the stopband edge of the analog filter must satisfy

$$2\pi - \Omega_{as} T_1 > \pi/M \iff \Omega_{as} < 2\pi M f_s - \pi f_s \quad (5.167)$$

in order to avoid aliasing distortion. In practice, the distortion is suppressed to a level determined by the attenuation of the analog anti-aliasing filter. To make sure that one can reduce the distortion to any desired level, (5.167) must be satisfied as the distortion then is determined by the filter's stopband attenuation.

In addition, one has to take into account that the digital filter has a transition band as well, which means that the overall design is somewhat more complicated than indicated above. Specifically, to avoid aliasing into the baseband, the information must therefore be limited to an angle frequency below  $\pi/T$ . If the information is limited to, say  $\Omega_c$ , then the transition band of the digital filter ranges from  $\Omega_c T_1$  to  $\pi/M$ .

We see that  $x_1(m)$  corresponds to the information oversampled by a factor of  $M$ . The A/D converter thus generates  $M$  times more samples per time unit than actually needed for reconstruction of the information. To make sure that the succeeding digital system does not have to work at a higher data rate than necessary, one therefore reduces the sampling rate through decimation (downsampling) by a factor of  $M$ . Since we have  $M$  times oversampling after  $H(z)$ , we can do this without loosing information. When  $M$  is an integer, the decimation is done by simply extracting only every  $M$ th sample in the output sequence of  $H(z)$  [24, 54, 55]. This is done by a downsample, represented by  $\downarrow M$ . (For a noninteger  $M$ , more elaborate schemes must be employed.) The result is the sequence  $y(n)$  corresponding to the information sampled with the frequency  $f_s = 1/T$ , see Figure 5.40f.

One motivation for using oversampling is, as mention earlier, that one in this way can relax the requirements on the analog anti-aliasing filter. Another reason is that oversampling enables the use of an A/D converter with lower resolution than the desired one, i.e., with fewer bits than the desired number of bits. The reason is that the digital filter removes a large part of the noise power whereas it, virtually, leaves the information unaffected. This means that the signal-to-noise ratio (SNR) of  $y(n)$  is higher than that of  $x(m)$ . To elaborate on this point, say that  $x(m)$  is quantized to  $B_1$  bits (and again assuming a maximum signal value of  $X_m = 1$  for simplicity). We then know that the noise variance is

$$\sigma_e^2 = \frac{2^{-2(B_1-1)}}{12}. \quad (5.168)$$

Further, we know that the noise variance at the output of the filter  $H(z)$ , say  $\sigma_h^2$ , is given by

$$\sigma_h^2 = \sigma_e^2 \frac{1}{2\pi} \int_{-\pi}^{\pi} |H(e^{j\Omega T})|^2 d(\Omega T). \quad (5.169)$$

If we now for the sake of simplicity assume that  $H(z)$  is an ideal unity-gain lowpass filter with passband up to  $\pi/M$ , we get

$$\sigma_h^2 = \sigma_e^2 \frac{1}{2\pi} \int_{-\pi}^{\pi} |H(e^{j\Omega T})|^2 d(\Omega T) = \frac{1}{2\pi} \int_{-\pi/M}^{\pi/M} |H(e^{j\Omega T})|^2 d(\Omega T) = \frac{\sigma_e^2}{M}. \quad (5.170)$$

Since  $H(z)$  leaves the information unaffected, the SNR is  $M$  times higher at the output of the filter than at the input of the filter, i.e., the output of the A/D converter. We can therefore obtain a desired resolution of  $B$  bits by using oversampling and an A/D converter with a lower resolution of  $B_1$  bits. From the equations above, we obtain

$$\frac{2^{-2(B_1-1)}}{12M} = \frac{2^{-2(B-1)}}{12}, \quad (5.171)$$

which gives us

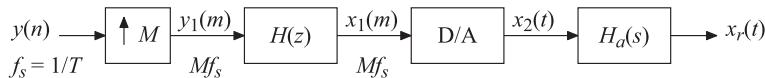

$$B_1 = B - 0.5 \log_2(M). \quad (5.172)$$

We see that for each doubling of the sampling frequency, we gain half a bit in resolution. By using oversampling techniques, one can thus use A/D converters with lower resolution than the desired one. In the extreme case, so called one-bit converters are employed. For such an A/D converter, one must however use a very high oversampling factor if a high resolution is desired. This causes problems in wideband applications since the sampling frequency then becomes too high to handle. By utilizing so called  $\Sigma\Delta$ -modulators, the oversampling factor required to achieve a certain resolution can be reduced [12]. The basic principle is to shape the noise so that most of its energy is located in the high-frequency region (for a lowpass converter). In this way, one gains more than a factor of  $M$  in noise reduction when using a lowpass filter with a passband width of  $\pi/M$ . It is beyond the scope of this chapter to discuss  $\Sigma\Delta$ -converters in detail. However, Section 1.05.8 deals with modeling of mixed-signal systems, which is useful in the analysis of such converters. That section will also provide an example of second-order  $\Sigma\Delta$ -modulators.

### 1.05.7.2 Oversampled D/A converters

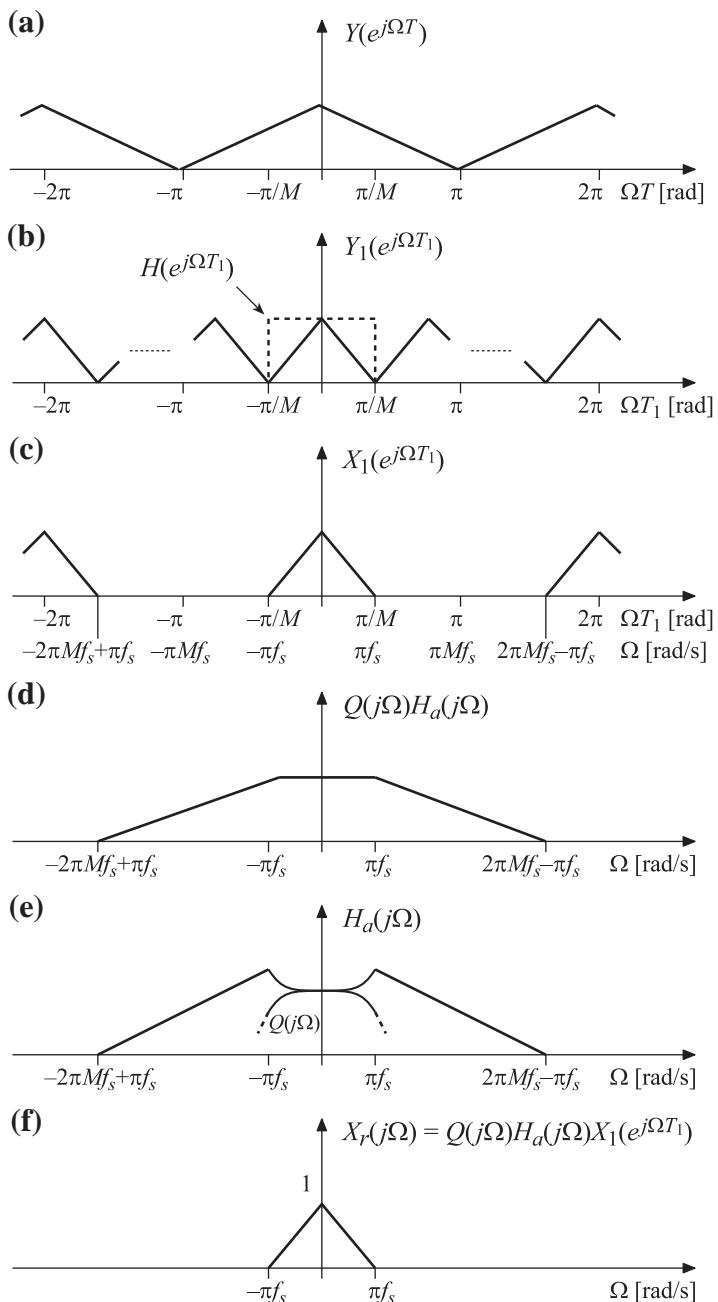

As discussed in the previous section, the requirements on the analog anti-aliasing filters can be relaxed by using oversampled A/D converters. The requirements on the analog reconstruction filter can likewise be relaxed by using oversampled D/A converters according to Figure 5.41.

We start with the sequence  $y(n)$  generated by the oversampled A/D converter in Figure 5.39. To illustrate the principle we use again the spectra in Figure 5.40. The spectrum of  $y(n)$  is then as shown in Figure 5.42a. The first step in an oversampled D/A converter is digital interpolation by a factor of  $M$ . This is done through an upsampler, represented by  $\uparrow M$ , followed by a filter  $H(z)$  [24,54,55]. The result is the sequence  $x_1(m)$  whose spectrum is shown in Figure 5.42c. We see that this sequence has the same spectrum as  $x_1(m)$  in the oversampled A/D converter, see Figures 5.39 and 5.40. In other words, it corresponds to the information oversampled by a factor of  $M$ . In the next step, reconstruction is performed through a D/A converter followed by a reconstruction filter. The D/A converter works at the higher sampling frequency  $Mf_s$ . As in Section 1.05.3.5.2, the D/A converter is here described by

**FIGURE 5.41**

Oversampled D/A converter.

**FIGURE 5.42**

Principle spectra in an oversampled D/A converter.

the pulse  $q(t)$  according to Figure 5.19d. Ideally,  $Q(j\Omega)H_a(j\Omega)$  and  $H_a(j\Omega)$  are then as shown in Figures 5.42d and e, respectively. We see that the stopband edge of the analog reconstruction filter must satisfy

$$\Omega_{as} < 2\pi M f_s - \pi f_s, \quad (5.173)$$

which is the same requirement as that of the anti-aliasing filter in an oversampled A/D converter. By increasing  $M$ , we thus relax the filter requirements since a wider transition band is then allowed.

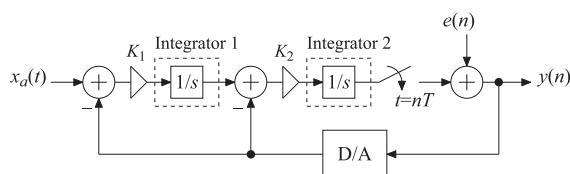

In practice, one can let the digital filter equalize the deviation of  $Q(j\Omega)$ , which is needed since  $Q(j\Omega)$  is not constant in the baseband. That is,  $H(z)$  is designed so that

$$|H(e^{j\Omega T_1})Q(j\Omega)| \approx \text{constant}, \quad \text{for } |\Omega| < \pi f_s. \quad (5.174)$$

As analog reconstruction filter, one can then use a conventional lowpass filter with (approximately) constant gain in both the passband and stopband. In that way, the requirements on this filter are further relaxed. Instead, the requirements on the digital filter has become more severe, but it is much easier to implement digital filters with stringent requirements than analog filters.

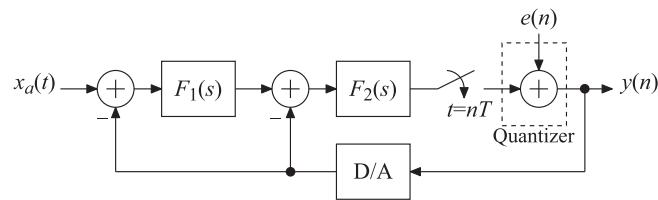

### 1.05.8 Discrete-time modeling of mixed-signal systems

Many systems today are mixed-signal systems conducting both continuous-time and discrete-time signal processing. From the analysis point of view, it is often advantageous to use a discrete-time model of the mixed-signal system. This section presents an analysis method for linear time-invariant systems containing sampling and reconstruction inside a feedback loop [56]. Using this method, the input/output stability as well as the frequency responses of such mixed systems can easily be analyzed. One application is ADCs realized with sigma-delta modulators ( $\Sigma\Delta$ -modulators) with continuous-time input signals. An example is seen in Figure 5.43 which is a linear model of a double feedback loop continuous-time-input  $\Sigma\Delta$ -modulator. Figure 5.44 shows a generalization where  $F_0(s)$  and  $F_1(s)$  are transfer functions of general loop filters. However, the analysis method that will be presented here is applicable to any linear and time-invariant system that can be represented by the general structure shown in Figure 5.45, where  $N$  is a two-input/one-output system and where the single output is uniformly sampled and reconstructed through pulse amplitude modulation before being fed back again to  $N$ . Apparently, the structures of Figures 5.43 and 5.44 belong to the class of all structures that can be represented by the general structure of Figure 5.45.

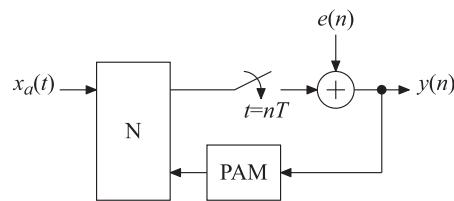

**FIGURE 5.43**

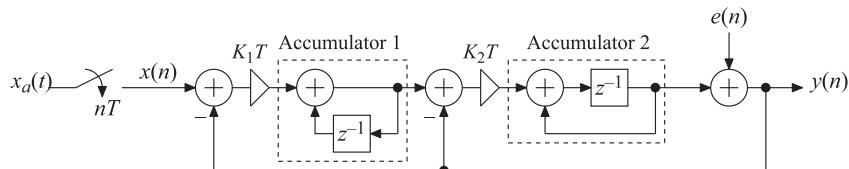

Linear model of a second-order double feedback loop continuous-time-input  $\Sigma\Delta$ -modulator.

**FIGURE 5.44**

Generalization of the scheme in Figure 5.44.

**FIGURE 5.45**

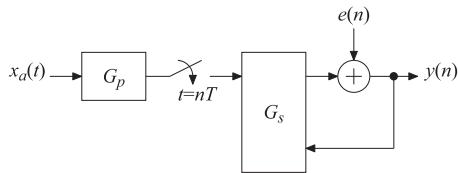

General hybrid continuous-time/discrete-time system setup with a feedback loop.

**FIGURE 5.46**

 Linear model of a second-order discrete-time-input  $\Sigma\Delta$ -modulator.

It is of practical interest to analyze systems such as that of Figure 5.43 with respect to stability as well as frequency responses as seen from  $x_a(t)$  and  $e(n)$  to the output  $y(n)$ . Here,  $e(n)$  models quantization errors that occur in the quantizer that follows the sampler. For continuous-time-input  $\Sigma\Delta$ -modulators, stability and frequency response analyses are often performed by using the so called “sampled-data equivalent” discrete-time-input  $\Sigma\Delta$ -modulator seen in Figure 5.46 [12,13,57], where integrators are replaced with accumulators. However, these “sampled-data equivalents” are only approximations of the actual behavior of the continuous-time-input  $\Sigma\Delta$ -modulator, as will be exemplified later in this section. That is, they do not correctly describe the properties of the continuous-time-input circuit.

To get a correct description, the system at hand can instead be represented by the system in Figure 5.47, where the continuous-time input signal  $x_a(t)$  is prefiltered through a continuous-time system  $G_p$  before being sampled uniformly. The resulting sampled signal and the system output signal

**FIGURE 5.47**

State-space representation of the system in Figure 5.48.

are then used as input signals to a linear discrete-time system  $G_s$ , usually represented in state-space form [12,58]. It is then required to determine a corresponding input-output difference equation using state variable representation. To that end, a state matrix,  $A$ , of  $G_s$  is needed, requiring the computation of the power series

$$A = e^{A_c} = \sum_{k=0}^{\infty} \frac{1}{k!} A_c^k, \quad (5.175)$$

where  $A_c$  is the state matrix of the system  $N$  in Figure 5.45, as well as the inversion of two particular matrices. This method gives a correct description of the circuit at hand but requires the computation of (5.175), which can be a non-trivial task, and the above mentioned matrices often are singular. In fact, this is always the case when  $F_0(s)$  and  $F_1(s)$  represent ideal integrators  $1/s$ .

In this section, we discuss an alternative method for the analysis of the external stability as well as the frequency responses from the inputs  $x_a(t)$  and  $e(n)$  to the output  $y(n)$  of the general system in Figure 5.47 [56]. This is done by using the models shown in Figure 5.48. It is readily shown that all linear time-invariant systems belonging to the class of systems that can be represented by the system in Figure 5.45, can be represented as in Figure 5.48. It should however be noted that the systems in Figure 5.48 are only used for input/output analysis purposes and do not capture the internal properties of the underlying system of interest. From the input/output stability and frequency response points of view, the systems in Figure 5.48 are equivalent to their underlying system in Figure 5.45.

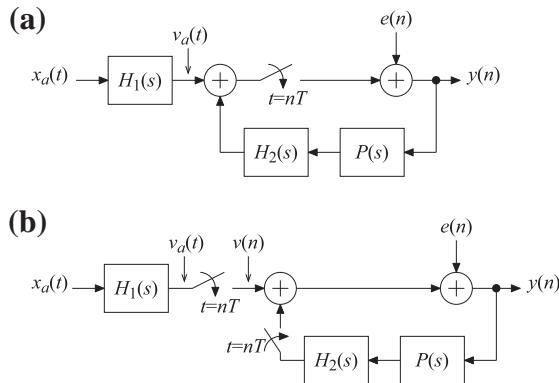

### 1.05.8.1 Input/output relations

For mixed-signal systems, direct use of transfer functions is less appropriate as they depend on two variables ( $s$  and  $z$ ). Therefore, the analysis becomes somewhat more involved than for pure discrete-time or continuous-time systems. The mixed-signal systems are analyzed here by using equivalent discrete-time systems that produce the same output samples as the actual mixed-signal system.

To be precise, stability is analyzed by first determining  $G(z)$  in the  $z$ -transform relation between  $y(n)$ ,  $v(n)$ , and  $e(n)$  given as

$$Y(z) = G(z)V(z) + G(z)E(z). \quad (5.176)$$

Stability is then investigated by considering the poles of  $G(z)$  and the boundedness of the resulting output signal. As to the frequency responses, as seen from  $x_a(t)$  and  $e(n)$  to the output  $y(n)$ , it is

**FIGURE 5.48**

Two equivalent models for the system in Figure 5.45.

appropriate to express the output Fourier transform as

$$Y(e^{j\Omega T}) = H(j\Omega) \frac{1}{T} X_a(j\Omega) + G(e^{j\Omega T}) E(e^{j\Omega T}), \quad (5.177)$$

where  $H(j\Omega)$  represents the signal frequency response whereas  $G(e^{j\Omega T})$  represents the noise frequency response. The latter is immediately obtained from the noise transfer function  $G(z)$  by evaluating it for  $z = e^{j\Omega T}$ .

In order to arrive at (5.176) and (5.177), the models of Figure 5.48 are used to represent the system in Figure 5.45. In Figure 5.48,  $P(s)$  represents pulse amplitude modulation.

### 1.05.8.2 Determining $G(z)$

We will make use of the generalized Poisson's summation formula which relates the Laplace transform of a signal  $x_a(t)$  with the corresponding  $z$ -transform of its uniformly sampled version  $x(n) = x_a(nT)$  according to

$$X(e^{sT}) = \frac{1}{T} \sum_{p=-\infty}^{\infty} X_a \left( s - j \frac{2\pi p}{T} \right). \quad (5.178)$$

with the  $z$ -transform evaluated for  $z = e^{sT}$ . Further, we will make use of the following equation that relates the output  $x_r(t)$  of the pulse amplitude modulator  $p(t)$  with its input  $x(n)$ :

$$X_r(s) = P(s) X(e^{sT}). \quad (5.179)$$

Using the above relations, the  $z$ -transform of the output signal  $y(n)$  in Figure 5.48a is easily derived as

$$\begin{aligned} Y(e^{sT}) &= E(e^{sT}) \\ &+ \frac{1}{T} \sum_{p=-\infty}^{\infty} H_1 \left( s - j \frac{2\pi p}{T} \right) X_a \left( s - j \frac{2\pi p}{T} \right) \\ &- Y(e^{sT}) \frac{1}{T} \sum_{p=-\infty}^{\infty} H_2 \left( s - j \frac{2\pi p}{T} \right) P \left( s - j \frac{2\pi p}{T} \right), \end{aligned} \quad (5.180)$$

where  $E(z)$  is the  $z$ -transform of  $e(n)$  and  $P(s)$  is defined by the PAM used. Here, a rectangular pulse  $p(t)$  is assumed according to

$$p(t) = \begin{cases} 1, & 0 \leq t \leq T, \\ 0, & \text{otherwise,} \end{cases} \quad (5.181)$$

which is commonly used in D/A conversion. This gives

$$P(s) = \frac{1 - e^{-sT}}{s}. \quad (5.182)$$

Equation (5.180) can be rearranged according to (5.176) with

$$V(e^{sT}) = \frac{1}{T} \sum_{p=-\infty}^{\infty} H_1 \left( s - j \frac{2\pi p}{T} \right) X_a \left( s - j \frac{2\pi p}{T} \right), \quad (5.183)$$

which corresponds to the  $z$ -transform of  $v(n)$  in Figure 5.48b, i.e., a uniformly sampled version of  $v_a(t)$ , and

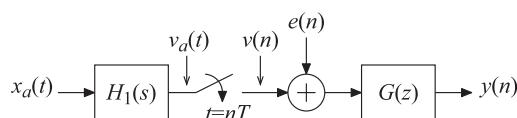

$$G(z) = \frac{1}{1 + L(z)} = \frac{N(z)}{D(z)} \quad (5.184)$$

with

$$L(e^{sT}) = \frac{1}{T} \sum_{p=-\infty}^{\infty} H_2 \left( s - j \frac{2\pi p}{T} \right) P \left( s - j \frac{2\pi p}{T} \right). \quad (5.185)$$

Equation (5.176) can, further, be interpreted as shown in Figure 5.49.

In Figure 5.48,  $H_1(s)$  models the output signal dependency of the input signal whereas  $H_2(s)$  describes the behavior of the feedback signal. Eqs. (5.176) and (5.183)–(5.185) do not give us suitable

**FIGURE 5.49**

Representation of the system in Figure 5.48 in view of (5.176).

expressions for the stability analysis. In order to express  $L(z)$  in a more suitable form for this purpose, we make use of the observation that  $L(z)$  is the  $z$ -transform of the sequence  $l(n) = l_a(nT)$ , i.e., a uniformly sampled version of the signal  $l_a(t)$ . Further, from (5.185), it is seen that  $l_a(t)$  is the inverse Laplace transform of  $H_2(s)P(s)$ . Hence, a more convenient representation of  $L(z)$  and thereby  $G(z)$  can be found using the following procedure.

Starting with  $H_2(s)P(s)$ , its inverse Laplace transform gives  $l_a(t)$  from which  $l(n) = l_a(nT)$  follows directly. A closed form expression for  $L(z)$  is then obtained through the computation of the  $z$ -transform of  $l(n)$ . The approach is applicable for general  $H_2(s)$  and  $P(s)$ , and is straightforward when  $H_2(s)$  and  $P(s)$  are rational functions in  $s$ .

### 1.05.8.3 Stability

In order to investigate the stability, it is convenient to first consider the system in Figure 5.50a, where the numerator and denominator polynomials of  $G(z)$  in Figure 5.49, i.e.,  $N(z)$  and  $D(z)$ , respectively, have been shown explicitly. The system of Figure 5.45 will be bounded-input/bounded-output (BIBO) stable if the following two conditions are satisfied:

1. The poles of  $G(z)$ , i.e., the roots of  $D(z)$ , lie inside the unit circle,
2. The signal  $w(n)$  in Figure 5.50 is bounded.

The first condition above is easily checked once  $G(z)$  is available. The second condition requires an analysis of  $H_1(s)$  and  $N(z)$ . We consider the following two different cases which are of practical interest.

**Case 1:**  $H_1(s)$  is stable. This gives directly that the second condition above is satisfied and BIBO stability is then ensured by also fulfilling the first condition.

**Case 2:**  $H_1(s)$  can be factored according to

$$H_1(s) = A(s) \frac{1}{s^{Q_1}} \prod_{q=1}^{Q_2} \frac{1}{s + p_q}, \quad (5.186)$$

where  $A(s)$  is stable and  $p_q$  are imaginary roots. Then,  $H_1(s)$  contains  $Q_1$  poles at  $s = 0$  and  $Q_2$  poles at  $s = -p_q$ . In order to investigate stability in this case, it is convenient to consider

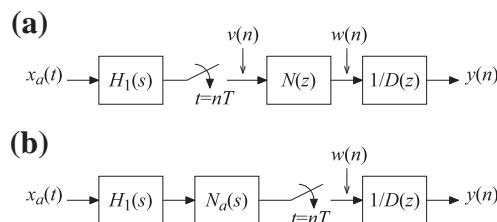

FIGURE 5.50

Representations of the system in Figure 5.49. They are useful in the stability analysis.

the system shown in Figure 5.50b, where

$$N_a(s) = N(e^{sT}). \quad (5.187)$$

Since  $N(z)$  is of the form

$$N(z) = \sum_{k=0}^K a_k z^{-k}, \quad (5.188)$$

the signal  $w(n)$  of Figure 5.50(a) is identical to that in Figure 5.50b. This follows from Poisson's summation formula together with the fact that  $N_a(s)$  above is periodic. It then remains to investigate if  $H_1(s)N_a(s)$  is stable, i.e., if it exists for all  $\Re\{s\} \geq 0$ , assuming a causal system, and if  $G(z)$  [or, equivalently,  $1/D(z)$ ] is stable.

#### 1.05.8.4 Frequency responses $H(j\Omega)$ and $G(e^{j\Omega T})$

The frequency response from  $e(n)$  to the output  $y(n)$  i.e.,  $G(e^{j\Omega T})$ , is directly obtained from  $G(z)$  in (5.176) if it exists for  $z = e^{j\Omega T}$ . It is then given by

$$G(e^{j\Omega T}) = \frac{N(e^{j\Omega T})}{D(e^{j\Omega T})} = \frac{1}{1 + \frac{1}{T} \sum_{p=-\infty}^{\infty} H_2\left(j\Omega - j\frac{2\pi p}{T}\right) P\left(j\Omega - j\frac{2\pi p}{T}\right)}. \quad (5.189)$$

As to the signal frequency response,  $H(j\Omega)$ , it is first noted from (5.176) and (5.177) that  $H(j\Omega)\frac{1}{T}X_a(j\Omega) = G(e^{j\Omega T})V(e^{j\Omega T})$ , where

$$V(e^{j\Omega T}) = \frac{1}{T} \sum_{p=-\infty}^{\infty} H_1\left(j\Omega - j\frac{2\pi p}{T}\right) X_a\left(j\Omega - j\frac{2\pi p}{T}\right). \quad (5.190)$$

Assume now that the input signal  $x_a(t)$  is bandlimited according to the Nyquist criterion for sampling with the sampling period  $T$ , i.e.,

$$X_a(j\Omega) = 0, \quad |\Omega| \geq \pi/T. \quad (5.191)$$

In this case only the term for  $p = 0$  in (5.190) is non-zero in the interval  $-\pi \leq \Omega T \leq \pi$ . Hence,  $V(e^{j\Omega T})$  can be written as in (5.177) with

$$H(j\Omega) = H_1(j\Omega)G(e^{j\Omega T}). \quad (5.192)$$

#### 1.05.8.5 Example 1

Consider the second-order continuous-time-input  $\Sigma\Delta$  modulator shown earlier in Figure 5.43. This is a special case of the system of Figure 5.44 with  $F_1(s)$  and  $F_2(s)$  being ideal integrators, i.e.,

$$F_1(s) = \frac{K_1}{s}, \quad F_2(s) = \frac{K_2}{s}. \quad (5.193)$$

In this case, one obtains that  $H_1(s)$  and  $H_2(s)$  are given by

$$H_1(s) = F_1(s)F_2(s), \quad H_2(s) = [1 + F_1(s)]F_2(s). \quad (5.194)$$

From this equation, we obtain

$$L_a(s) = H_2(s)P(s) = \left( \frac{K_2}{s^2} + \frac{K_1 K_2}{s^3} \right) (1 - e^{-sT}). \quad (5.195)$$

Taking the inverse Laplace transform, we get

$$l_a(t) = K_2[tu(t) - (t - T)u(t - T)] + \frac{K_1 K_2}{2}[t^2 u(t) - (t - T)^2 u(t - T)]. \quad (5.196)$$

Sampling  $l_a(t)$  at  $t = nT$  then gives us

$$\begin{aligned} l(n) = l_a(nT) &= K_2 T[n \times u(n) - (n - 1) \times u(n - 1)] \\ &\quad + \frac{K_1 K_2 T^2}{2}[n^2 \times u(n) - (n - 1)^2 \times u(n - 1)], \end{aligned} \quad (5.197)$$

where  $u(n)$  is the unit-step sequence. Then, taking the  $z$ -transform of  $l(n)$  gives us

$$L(z) = \frac{K_2 T z^{-1}}{1 - z^{-1}} \left[ 1 + \frac{K_1 T}{2} \frac{1 + z^{-1}}{1 - z^{-1}} \right], \quad (5.198)$$

whereby

$$G(z) = \frac{N(z)}{D(z)} = \frac{1}{1 + L(z)} = \frac{(1 - z^{-1})^2}{1 + az^{-1} + bz^{-2}}, \quad (5.199)$$

where

$$a = K_2 T + 0.5 K_1 K_2 T^2 - 2 \quad (5.200)$$

and

$$b = 1 - K_2 T + 0.5 K_1 K_2 T^2. \quad (5.201)$$

Further, with  $F_0(s)$  and  $F_1(s)$  as in (5.193), we get

$$H_1(s)N_a(s) = \frac{K_1 K_2}{s^2} (1 - e^{-sT})^2, \quad (5.202)$$

which is a stable system because the corresponding impulse response is finite. Hence, stability is in this case solely determined by the stability of  $G(z)$  given by (5.199). For example with  $K_1 = K_2 = K$ , it is straightforward to show that stability in this case is ensured by constraining  $K$  according to  $0 < K < 2/T$ . Using instead the often employed and so called “sampled-data equivalents,” where integrators  $1/s$  are replaced by the accumulators  $1/(1 - z^{-1})$ , and  $z^{-1}/(1 - z^{-1})$ , one obtains  $0 < K < 1.236/T$ . Hence, the accumulator-based structures are not appropriate models.

Furthermore, from (5.192), (5.194), and (5.199), we obtain the frequency response

$$H(j\Omega) = \frac{K_0 K_1}{(j\Omega)^2} \frac{(1 - e^{-j\Omega T})^2}{1 + ae^{-j\Omega T} + be^{-j2\Omega T}} \quad (5.203)$$

This expression differs from that obtained via the accumulator-based structures. Also the noise transfer functions are different. Again, this means that such structures are not appropriate. Figures 5.51 and 5.52 illustrate these differences by plotting the modulus of the signal and noise transfer functions in the two cases.

### 1.05.8.6 Example 2

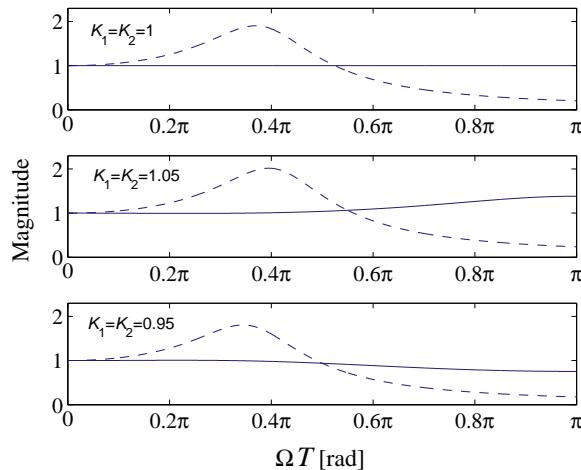

Consider the scheme in Figure 5.53 with  $F(s)$  being a second order transfer function according to

$$F(s) = \frac{K}{s(s + p)} \quad (5.204)$$

with a real-valued pole at  $s = -p$ , with  $p > 0$  assumed. For the equivalent representation of Figure 5.48,  $H_1(s) = H_2(s) = F(s)$ . Thus,  $H_1(s)$  follows (5.186) as  $H_1(s) = A(s)/s$  with  $A(s) = K/(s + p)$ .

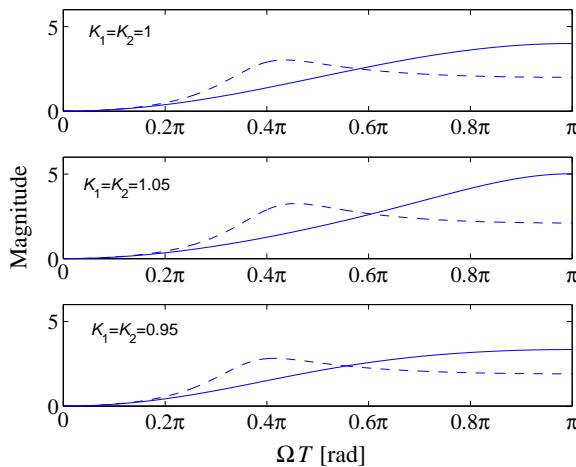

We first investigate the stability. We note that Case 2 applies here since  $H_1(s)$  has a pole at  $s = 0$ . To derive  $G(z)$ , we first note that  $H_1(s)P(s)$ , using partial fraction expansion, becomes

$$H_1(s)P(s) = \left( \frac{K/p}{s^2} - \frac{K/p^2}{s} + \frac{K/p^2}{s + p} \right) (1 - e^{-sT}). \quad (5.205)$$

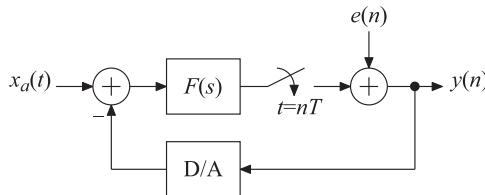

**FIGURE 5.51**

Modulus of the signal frequency responses for second-order continuous-time-input (dashed) and discrete-time-input  $\Sigma\Delta$ -modulators (solid).

**FIGURE 5.52**

Modulus of the noise frequency responses for second-order continuous-time-input (dashed) and discrete-time-input  $\Sigma\Delta$ -modulators (solid).

**FIGURE 5.53**

System with a single feedback loop.

Hence,  $l(n) = l_a(nT)$  is given by

$$l(n) = l_{a0}(nT) - l_{a0}(nT - T) \quad (5.206)$$

with  $l_{a0}(t)$  being

$$l_{a0}(t) = \left( \frac{K}{p}t - \frac{K}{p^2} + \frac{K}{p^2}e^{-pt} \right) u(t). \quad (5.207)$$

Hence, taking the  $z$ -transform of  $l(n)$ , we obtain

$$L(z) = \frac{KT}{p(z-1)} - \frac{K}{p^2} + \frac{K}{p^2} \frac{z-1}{z-e^{-pT}}. \quad (5.208)$$

Finally, this gives us

$$G(z) = \frac{1}{1 + L(z)} = \frac{(1 - z^{-1})(1 - z^{-1}e^{-pT})}{1 + az^{-1} + bz^{-2}}, \quad (5.209)$$

where

$$a = \frac{KT}{p} - (1 + e^{-pT}) - \frac{K}{p^2}(1 - e^{-pT}) \quad (5.210)$$

and

$$b = \frac{K}{p^2}(1 - e^{-pT}) + \left(1 - \frac{KT}{p}\right)e^{-pT}. \quad (5.211)$$

We note that

$$H_1(s)N_a(s) = \frac{A(s)(1 - e^{sT})(1 - e^{-(s+p)T})}{s} \quad (5.212)$$

which corresponds to a stable system, because it consists of (readily shown) stable subsystems. Hence, the stability is given by the poles of  $G(z)$ , which are most easily found numerically.

Further, we get the frequency responses

$$G(e^{j\Omega T}) = \frac{(1 - e^{-j\Omega T})(1 - e^{-j\Omega T}e^{-pT})}{1 + ae^{-j\Omega T} + be^{-j2\Omega T}} \quad (5.213)$$

and

$$\begin{aligned} H(j\Omega) &= H_1(j\Omega)G(e^{j\Omega T}) \\ &= \frac{K}{j\Omega(j\Omega + p)} \frac{(1 - e^{-j\Omega T})(1 - e^{-j\Omega T}e^{-pT})}{1 + ae^{-j\Omega T} + be^{-j2\Omega T}}. \end{aligned} \quad (5.214)$$

## 1.06.1 Introduction

There has been a clear trend over the past decades towards an increasing use of digital processing rather than analog processing of signals. This is in large part due to the inherent flexibility and reliability of digital processing. Other important factors, that support this trend, are the rapid development in integrated circuit technology and the associated tools, i.e., that simplifies and reduces the cost of implementing digital signal processing systems, and digital filters in particular. Of interest here is frequency-selective filters, for example, lowpass and bandpass filters.

### 1.06.1.1 Properties of digital filters

The following properties are characteristic of digital filters.

#### 1.06.1.1.1 Flexibility

The frequency response can easily and quickly be changed. This means that a digital filter implementation can be time-shared between a number of input signals and act as several filters. Furthermore, a digital filter can be multiplexed in such a way that it simultaneously acts as several filters with one input signal and realize, for example, a filter bank. The high flexibility is exploited in adaptive filters.

#### 1.06.1.1.2 Special transfer functions

Discrete-time and digital filters can realize special transfer functions that are not realizable with continuous-time, lumped element filters, for example filters with exact linear phase.

#### 1.06.1.1.3 Coefficient sensitivity

Digital filters are not affected by temperature variations, variations in the power supply voltage, stray capacitances, etc., which are major problems in analog filters. The reason for this is that the properties of a digital filter is determined by the numerical operations on numbers and not dependent on any tolerances of electrical components. For the same reason there is no aging or drift in digital filters. The independence of element sensitivity leads to high flexibility, miniaturization, and high signal quality.

#### **1.06.1.1.4 Reproducibility**

Exact reproducible filters can be manufactured. This is also a consequence of the fact that the properties of the filter are only dependent on the numerical operation and not on the tolerances of the electrical components. Thus, tolerance problems as such do not exist in digital filters. However, we will see that sensitivity of a filter structure to errors in the coefficient has a direct influence on the required signal wordlength and implementation cost. Furthermore, no trimming is necessary, which leads to low cost. Precision digital filters can be manufactured with, in principle, arbitrary precision, linearity, and dynamic range, however, at an increasing cost.

#### **1.06.1.1.5 Frequency range**

Digital filters can be manufactured to operate over a wide range of frequencies, from zero up to several hundred MHz, depending on the complexity of the filter and on the technology used for the implementation. However, the cost in terms of power consumption and the number of gates in the integrated circuits increases rapidly with the order of the filter and the sample frequency.

#### **1.06.1.1.6 Power consumption**

Digital filters have in general rather high power consumption, but filters with low power consumption can be implemented for applications with low sample frequencies. However, as the geometries of the CMOS process used for the implementation are reduced, the power consumption is also reduced. The power consumption compared with a corresponding analog filter counterpart is therefore often lower for a digital filter.

#### **1.06.1.1.7 Implementation techniques**

Digital filters can be implemented by using several techniques. At low sample rates and arithmetic workloads, typically below a few MHz, standard signal processors can be used while application-specific or algorithm-specific digital signal processors can be used up to a few tenth of MHz. For high sample rates specialized implementation techniques are required [1].

### **1.06.1.2 Design target**

The design should meet the requirements with minimal cost. The cost to be minimized, is typically composed of several different parameters, e.g., power consumption, chip area, design effort. To complicate the issue even further, the designer has many alternative design options available. Hence, filter design is a challenging task, and it typically involves several conflicting optimization problems.

#### **1.06.1.2.1 Power consumption**

Until recently throughput and chip area was the main metrics for evaluation of DSP algorithms and their implementations. However with the advancement of CMOS technology it is no longer a major problem to achieve high enough throughput and the cost of the chip area can usually be neglected, except in very high-volume products. Today, the focus should be placed on design efficiency and low power consumption since many implementations are battery-powered and a too high power dissipation may require more expensive packaging and cooling. Further, there is also a strong trend to use a more sophisticated and complex digital signal processing which tend to increase the power dissipation.

CMOS technology is currently and will continue to be the dominating implementation technology. The feature size is rapidly shrinking towards 10 nm and below. Circuits implemented using modern CMOS processes are no longer characterized by the number of transistors on the chip. Instead the overall throughput and power consumption are more appropriate metrics. Here we assume the digital filter is operated continuously and therefore the leakage and short-circuit currents can be neglected [2]. The power dissipation associated with switching in CMOS circuits is approximately given by

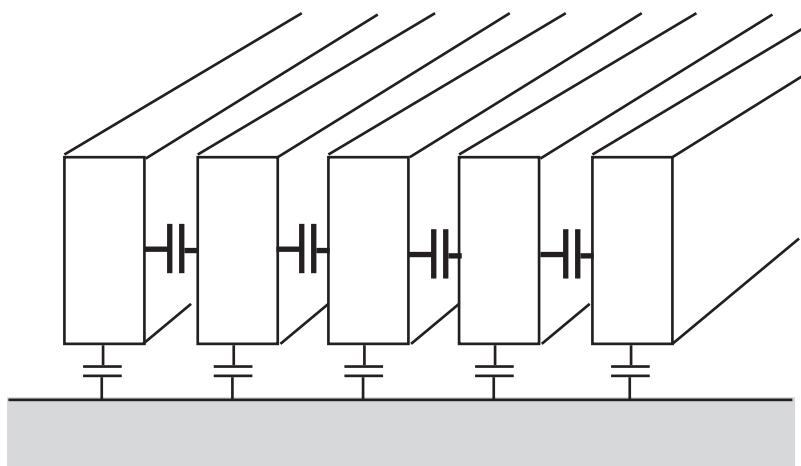

$$P = \alpha f_{CL} C_L V_{DD} \Delta V_{DD}, \quad (6.1)$$

where  $\alpha$  is the activity factor, i.e., the average number of transitions from 0 to 1 for the equivalent electrical node per clock cycle,  $f_{CL}$  is the clock frequency,  $C_L$  is the equivalent switched capacitance of the whole circuit,  $V_{DD}$  is the power supply voltage, and  $\Delta V_{DD}$  is the voltage swing. In most cases we use CMOS circuits with full swing, i.e.,  $\Delta V_{DD} = V_{DD}$ . Reducing any of the factors in (6.1) can reduce the power consumption. Below we briefly review various techniques that can be applied to reduce the power consumption in digital filters and are useful in many other DSP algorithms.

The activity factor  $\alpha$  can be reduced in several ways. Most techniques exploit known statistical properties of the signals. For example, operations to be executed on an adder or multiplier can be scheduled with respect to the correlation between successive operands so that the carry propagation and glitches are minimized. For example, in the first moment only the first full-adder (LSB) in a bit-parallel ripple-carry adder has correct inputs and performs a valid addition. The other full-adders have carry-ins that are not yet determined, hence, they may perform invalid additions that consume energy. In the next moment, the second full-adder has correct inputs and performs a valid addition while the first full-adder is idle. In each instance, the remaining full-adders may change their states and contribute with an increase in the power dissipation. Note that the bit-parallel ripple-carry adder performs a sequential bit-by-bit addition while in bit-serial arithmetic a bit-by-bit addition is performed sequentially on a single full-adder. The execution time for a bit-parallel addition using a ripple-carry adder is the same as for a bit-serial addition if the safety margins needed for the flip-flops that separate two successive bit additions are neglected.

The use of a redundant number representation [3] is another technique to avoid long carry propagation and glitches, which are costly in terms of power consumption. Glitches in logic circuits occur when the difference in arrival times of two logic signals to a common gate is so large that false transitions occur and change the states of some electrical nodes. Slowing down the signal paths that are too fast so that the signals arrive simultaneously can minimize this effect and may reduce the power consumption by up to 40% in a bit-parallel multiplier.

In older CMOS processes the equivalent switched capacitance is due to devices and wires. The dominant wire capacitance is between the wire and substrate. In deep submicron CMOS technologies the capacitance associated with the devices are relatively small and the dominant wire capacitance is instead dominated by interwire capacitance as illustrated in Figure 6.1. For long buses it is therefore important to order the transmission of successive data on the bus so that the charging/discharging of the interwire capacitors is minimized. A useful measure to minimize is the sum of the Hamming distances of the transmitted words. In speech signals, for example, it may be advantageous to use sign-magnitude representation on long buses, since most samples have small magnitudes, which causes only the least significant bits to vary while in two's-complement representation almost all bits change when a sample value changes sign.

**FIGURE 6.1**

Interwire and wire-to-substrate capacitance model.

The clock frequency,  $f_{CL}$ , of the circuitry should, of course, not be reduced since this would reduce the computational work performed by the circuitry and the inherent processing capacity of the circuitry would not be fully utilized. Generally, it is efficient to use minimum size transistors throughout the whole integrated circuit, except for a few critical paths in which slightly larger and thereby faster transistors are used. This strategy leads to a significant increase in the maximal clock frequency at the expense of a small increase in the switched capacitance.

If a long logic path requires gates with extra drive capacity in order to meet the throughput requirement, it may often be more efficient to break the long path into smaller paths in terms,  $n$  order to reduce the chip area and power consumption.

The required clock frequency for the algorithm may, however, be reduced at the expense of increased chip area, by exploiting computational parallelism of the algorithm by mapping the arithmetic operations to several processing elements (PEs) or by using multirate techniques in which parts of the digital filter operate at lower sample rates. Parts of the algorithm that operate at a lower rate can often be multiplexed onto a single hardware structure in order to save chip area.

The equivalent switched capacitance,  $C_L$ , can be made small by using a combination of different techniques. On the algorithm level most techniques focus on using filter structures with a small number of arithmetic operations per sample. Multirate filter structures are typical examples where a significant reduction in arithmetic workload can be obtained. Low-sensitivity structures require shorter data wordlengths and shorter and more favorable coefficients that allow fixed multipliers to be simplified [1]. Canonic signed-digit code (CSDC) [1,3], and multiple-constant techniques are efficient techniques to simplify the realization of fixed multipliers [4–11]. Trade-off between the two extremes, bit-parallel and bit-serial arithmetic, i.e., digit-serial arithmetic is a promising route to lower power consumption as well as smaller chip area [1]. As mentioned above, transmission of data over long buses is costly in terms of time and power consumption. Architectures with local computations are therefore preferred.

Digit-serial processing elements yield smaller chip area, and, hence, shorter communication distances and is a good compromise between the large number of glitches in bit-parallel arithmetic and many clock cycles per operation of the flip-flops in bit-serial arithmetic. At the logic level the use of efficient, low-power CMOS circuit and clocking techniques is important [2].

The power consumption can be significantly reduced by using a lower power supply voltage. Unfortunately, this has the effect that the maximal clock frequency of the CMOS circuit is reduced [2] according to

$$f_{CL} = \frac{k(V_{DD} - V_T)^\beta}{V_{DD}}, \quad (6.2)$$

where  $k$  is process-dependent constant,  $\beta$  is a constant slightly larger than one in modern CMOS processes, and  $V_T$  is the threshold voltage of an MOSFET. However, the reduction in throughput can often be compensated in parallel algorithms by exploiting more of the computational parallelism [1]. From (6.2) it is evident that from a speed point of view, a CMOS process with a low threshold voltage is to be preferred. In practice, many circuits are therefore manufactured with a process with two threshold voltages. Transistors with low threshold voltages are used for high-speed circuits while transistor with high threshold voltages are used for low speed circuits since the latter have smaller leakage currents.

### 1.06.1.2.2 Chip area

The required chip area is important since is directly affect the cost of manufacturing the filter. Moreover, the leakage current will be proportional to the chip area. A designer can minimize the required chip area by using filter structures with few arithmetic operations per sample, simplified arithmetic operations, and small memory requirement. That is, we are interested in structures that have low element sensitivity, i.e., a structure where a small error in the coefficients causes only a small error in the frequency response. Hence, it is possible to select favorable coefficient values that deviate slightly from their ideal values and still meet the requirements on the frequency response. We will later discuss filter structures with very low coefficient sensitivities that allows us to reduce the required chip area.

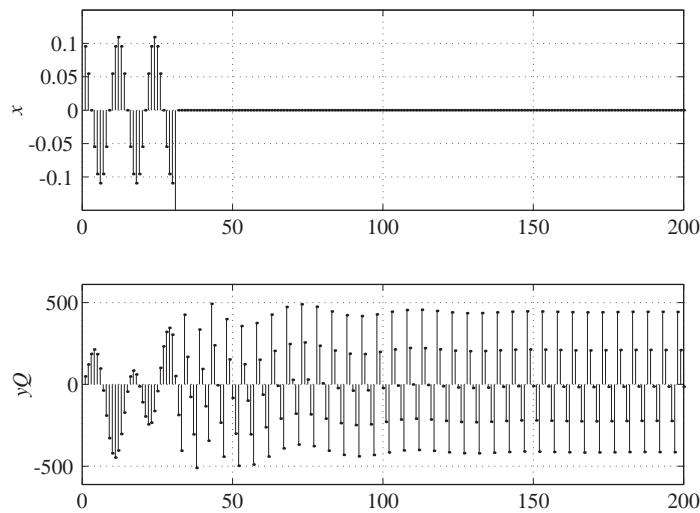

The data wordlength generally affects the execution time and the required chip area for the arithmetic operations. It has been shown by Jackson [12] that the roundoff noise is bounded from below by the coefficient sensitivities, i.e.,

$$\sigma^2 \geq \sum_i \sigma_{0i}^2 \left\| \frac{\partial |H(e^{j\omega T})|}{\partial c_i} \right\|_p^2, \quad (6.3)$$

where  $p = 1$  or  $p = 2$ ,  $\sigma_0^2$  is the variance of the roundoff noise sources, and the sum is over all noise sources due to rounding at the outputs of the coefficients,  $c_i$ . Hence, the right hand side of (6.3) is small for a low-sensitive structure and the roundoff noise at the output of the structure may be low. In fact, it will be low, even though there is no proof for it. A structure with high sensitivity will generate a large roundoff noise and it will therefore require a large data wordlength. To summarize, the element sensitivity affects both the required data and coefficient wordlengths.

### 1.06.1.2.3 Throughput

The throughput of a non-recursive algorithm is in principle unlimited. In practice, however, the amount of circuitry as well as the inherent speed of the used CMOS technology becomes a limit. Recursive algorithms have an inherent limit on the throughput.

**FIGURE 6.2**

Persistent parasitic overflow oscillation.

#### 1.06.1.2.4 Robustness

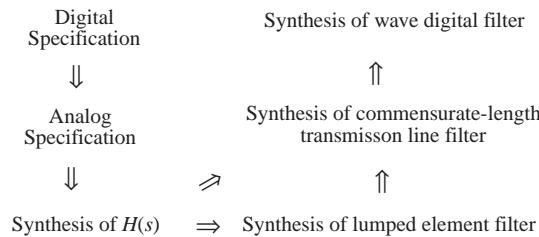

Recursive algorithms require that the data wordlength is rounded or truncated at least once in every recursive loop that contains at least one multiplication with a non-integer coefficient. Otherwise the data wordlength would increase to infinity. Rounding/truncation and overflow of the available signal range are non-linear operations that will in most cases cause parasitic oscillations. That is, the output of the filter will contain a periodic or even a chaotic signal component that is not due to the input signal [13, 14]. In fact, this unwanted distortion can be very large. Of course, this is highly undesirable and should be avoided. Figure 6.2 shows an example of the input and output of a recursive loop when the input signal overflows the signal range just before it becomes zero. Obviously this is not an acceptable behavior. We will later discuss a class of filter structures, i.e., wave digital filters, that have the property to suppress such undesirable oscillations.

#### 1.06.1.3 Design of digital filters

The design of digital filters can be done along several different routes.

##### 1.06.1.3.1 Design and realization of FIR filters

If the filter has a finite-length impulse response (FIR), then the frequency response is typically designed directly in the  $z$ -domain using computer-based optimization methods. In Section 1.06.2 we will briefly discuss the design of classical FIR filters and associated structures, which are suitable for cases when the transition band is not too small. Unfortunately, for requirements with narrow transition band, the filter

**FIGURE 6.3**

Design process for wave digital filters.

order and arithmetic workload becomes very large for FIR filters. In such cases, we instead recommend recursive structures (IIR), frequency-masking techniques, which are discussed in Section 1.06.8, or multirate techniques [14–16].

#### 1.06.1.3.2 Design and realization of IIR filters

In the case of infinite-length impulse response (IIR) filters there are many options available. For complex and non-standard requirements the frequency response is often determined directly in the  $z$ -domain using computer-based optimization methods [14, 17].

For frequency selective filters with standard requirements, i.e., filters with a passband that approximate a constant gain in the passband, it is favorable to employ the vast available knowledge of design of analog filters. There are a number of advantages of this approach, which is illustrated in Figure 6.3:

- Accurate numerical algorithms have been developed for analog filters [18–21].
- Classical analog attenuation approximations can be converted using the bilinear transformation to their digital counterparts. The bilinear transformation [14, 22–24] between the  $s$ - and  $z$ -domains is

$$s = \frac{2}{T} \frac{z - 1}{z + 1}. \quad (6.4)$$

Optimal highpass filters can be designed by frequency transformation of an optimal lowpass filter. Near optimal bandpass and bandstop filters can also be designed by frequency transformations. However, we will take an indirect route that will yield a low-sensitive digital filter algorithm:

- Once the analog transfer function,  $H(s)$ , (frequency response) is determined, it is realized using a lumped element ( $LC$ ) filter structure, e.g., a ladder structure. We will later show that a properly designed  $LC$  filter will have optimal element sensitivity in the passband. Unfortunately, this structure is not possible to simulate in the  $z$ -domain, because delay-free loops occur.
- To circumvent this problem, we use an analogy between a lumped element network and commensurate-length transmission line network. The latter contain sources, resistors, and lossless transmission lines of equal length. The transmission line network has a periodic frequency response and there is a one-to-one mapping between the continuous-time transmission line network and its digital counterpart. We will later discuss this in more detail.

- The digital algorithm is obtained by using a wave description, i.e., wave digital filters [25–27], consisting of a linear combination of voltages and current in the analog network. This allows us to simulate power in the analog filter, which we later will show is a necessity to obtain a low-sensitive algorithm.
- Moreover, the concept of pseudo-power in the digital domain allows us to suppress parasitic oscillations. That is, there exists a Lyapunov function for wave digital filters.

We will therefore describe various steps in the design process, illustrated in Figure 6.3, and options the designer has to minimize the implementation cost. First, we discuss in Section 1.06.3, the analog approximation problem and show that classical design recommendations are not always the best. In Section 1.06.4, we discuss the realization of the analog transfer function using a doubly resistively terminated network. We particularly discuss what the designer can do in order to minimize the element sensitivity. We also discuss the realization of commensurate-length transmission line filters. In Sections 1.06.5 and 1.06.6 we discuss two of the most common analog filter networks and their properties. In Section 1.06.7, we present the basic principles of wave digital filters and their building blocks. In addition we compare two types of wave digital filter realizations using an example. In Section 1.06.8 we discuss techniques that are particularly efficient for filters with very narrow transition bands. These techniques may employ both FIR and IIR structures, but first we discuss in the next section classical FIR filters. Finally, in Sections 1.06.9–1.06.12, we will discuss some computational properties of algorithms and some techniques for their implementation.

## 1.06.2 Digital FIR filters

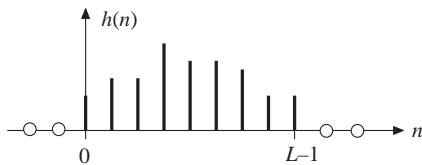

Digital filters can be categorized into FIR (Finite-length Impulse Response) and IIR (Infinite-length Impulse Response) filters. Advantages of FIR filters over IIR filters are that they can be guaranteed to be stable and may have a linear-phase response. Further, they require generally shorter data wordlength than the corresponding IIR filters. However, FIR filters usually require much higher orders than IIR filters for the same magnitude specification and they often introduce a large group delay, that make them unsuitable in many applications. FIR filters are well suited for many multirate filter realizations. An advantage is that FIR filters are always stable, except when they are used inside a recursive loop. High-order FIR filters can be realized efficiently using the FFT (Fast Fourier Transform) [14,28–30] and in some cases using multirate techniques [15,16,31–33].

The most common method to design a linear-phase FIR filter, that satisfies a specification of the magnitude response, is to use a numeric optimization procedure to determine the impulse response  $h(n)$  in (6.5). A widely used algorithm for designing linear-phase FIR filters with multiple passbands and stopbands is that of McClellan, Parks, and Rabiner [17,30,34,35].

The impulse response  $h(n)$  of a causal FIR filter of order  $N$  (length  $L = N + 1$ ) is nonzero for  $0 \leq n \leq L - 1$  and zero for all other values of  $n$  as illustrated in Figure 6.4.

The transfer function and frequency response of an  $N$ th order FIR filter is

$$H(z) = \sum_{n=0}^N h(n)z^{-n}. \quad (6.5)$$

**FIGURE 6.4**

Impulse response of a causal FIR filter of order  $N$  (length  $L = N + 1$ ).

The poles of the transfer function can only be placed at the origin of the  $z$ -plane for nonrecursive FIR filters. The zeros can be placed anywhere in the  $z$ -plane, but they are usually located on the unit circle or as pairs that are mirrored in the unit circle.

Of main interest among FIR filters are filters with linear-phase for which the impulse response exhibit symmetry or antisymmetry. Linear-phase FIR filters are widely used in digital communication systems, speech and image processing systems, spectral analysis and particularly in applications where nonlinear phase distortion cannot be tolerated. Most filter design software packages support the design of linear-phasePlease note that the Reference number seem to be missing. FIR filters [17,30,34,35].

A linear-phase FIR filter is obtained by letting the impulse response exhibit symmetry around  $n = N/2$ , i.e.,

$$h(n) = h(N - n) \quad (6.6)$$

or antisymmetry around  $n = N/2$ , i.e.,

$$h(n) = -h(N - n), \quad (6.7)$$

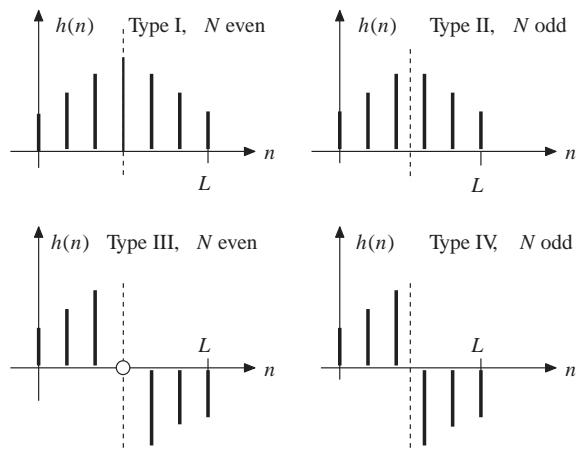

for  $n = 0, 1, \dots, N$ . Since the order  $N$  is either even or odd, there are four different types of FIR filters with linear phase. These are denoted as Type I, II, III, IV linear-phase FIR filters, respectively, according to the following:

Type I	$h(n) = h(N - n)$	$N$ even,
Type II	$h(n) = h(N - n)$	$N$ odd,
Type III	$h(n) = -h(N - n)$	$N$ even,
Type IV	$h(n) = -h(N - n)$	$N$ odd.

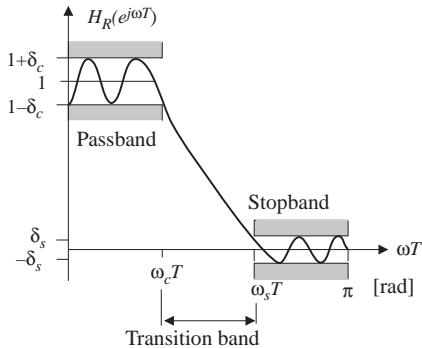

Figure 6.5 shows typical impulse responses for the different cases. Note that the centre value  $h(N/2)$  is always equal to zero for Type III filters. Also, when  $N$  is even, the point of symmetry is an integer corresponding to one of the sample values. When  $N$  is odd, the point of symmetry lies between two sample values.

A special case, is so-called half-band filters, where about half of the impulse response values are zero and, hence, they do not require any arithmetic operations. A half-band filter has a frequency response that is antisymmetric around  $\omega T = \pi/2$ . Hence,  $\omega_c T + \omega_s T = \pi$ .

Figure 6.6 show a typical specification of the zero-phase response for a lowpass linear-phase FIR filter. Several approximate expressions for the required filter order for equiripple, linear-phase FIR filters have been determined empirically.

**FIGURE 6.5**

Impulse responses for the four types of linear-phase FIR filters.

**FIGURE 6.6**

Specification of FIR filters.

One such simple estimate of the required filter order for a linear-phase lowpass (or highpass) filter that meets the specification shown in Figure 6.6, is

$$N \approx \frac{-4\pi}{3} \frac{\log(13\delta_c\delta_s)}{\Delta\omega T}, \quad (6.8)$$

where  $\Delta\omega T = \omega_s T - \omega_c T$  is the transition band. Note that the required filter order will be high for filters with narrow transition bands.

Here we are concerned with linear-phase FIR filters, that are frequency selective, i.e., lowpass, highpass, bandpass, and bandstop filters, etc. When designing such filters it is convenient to consider

the zero-phase frequency response  $H_R(e^{j\omega T})$ , which is defined by

$$H(e^{j\omega T}) = H_R(e^{j\omega T})e^{j\phi(\omega T)}. \quad (6.9)$$

Note that  $|H(e^{j\omega T})| = |H_R(e^{j\omega T})|$ .

The specification of a lowpass filter is commonly given as

$$\begin{aligned} 1 - \delta_c &\leq |H(e^{j\omega T})| \leq 1 + \delta_c & \omega T \in [0, \omega_c T] \\ |H(e^{j\omega T})| &\leq \delta_s & \omega T \in [\omega_s T, \pi]. \end{aligned} \quad (6.10)$$

For linear-phase FIR filters, the specification of (6.10) can be restated with the aid of  $H_R(e^{j\omega T})$  according to

$$\begin{aligned} 1 - \delta_c &\leq H_R(e^{j\omega T}) \leq 1 + \delta_c & \omega T \in [0, \omega_c T] \\ -\delta_s &\leq H_R(e^{j\omega T}) \leq \delta_s & \omega T \in [\omega_s T, \pi] \end{aligned} \quad (6.11)$$

The McClellan-Parks-Rabiners program will find a unique set of filter coefficients that minimizes a weighted error function. The algorithm solves the approximation problem

$$\min(E_\infty) = \max |E(e^{j\omega T})|, \quad \omega T \in \Omega, \quad (6.12)$$

where  $E(e^{j\omega T})$  is the weighted (Chebyshev) error function given by

$$E(e^{j\omega T}) = W(e^{j\omega T}) \left[ H_R(e^{j\omega T}) - D(e^{j\omega T}) \right], \quad \omega T \in \Omega \quad (6.13)$$

with  $\Omega$  being the union of the passband and stopband regions. In practice,  $\Omega$  is a dense set of frequency samples taken from the passbands and stopbands, including the bandedges. It should be stressed that all functions involved here,  $H_R(e^{j\omega T})$ ,  $E(e^{j\omega T})$ ,  $D(e^{j\omega T})$ , and  $W(e^{j\omega T})$  are real functions of  $\omega T$ . The desired function  $D(e^{j\omega T})$  is the one to be approximated by  $H_R(e^{j\omega T})$ . For example,  $D(e^{j\omega T})$ , is for the standard lowpass filter

$$D(e^{j\omega T}) = \begin{cases} 1 & \omega T \in [0, \omega_c T], \\ 0 & \omega T \in [\omega_s T, \pi]. \end{cases} \quad (6.14)$$

That is,  $D(e^{j\omega T})$  is for conventional filters equal to one in the passbands and zero in the stopbands. The weighting function  $W(e^{j\omega T})$  specifies the cost of the deviation from the desired function. The use of the weighting function makes it possible to obtain different ripples in different frequency bands. The larger the weighting function is, the smaller is the ripple. For example, for a standard lowpass filter,  $W(e^{j\omega T})$  is usually given as

$$W(e^{j\omega T}) = \begin{cases} 1 & \omega T \in [0, \omega_c T], \\ \frac{\delta_c}{\delta_s} & \omega T \in [\omega_s T, \pi]. \end{cases} \quad (6.15)$$

The specification of (6.11) is then satisfied if  $E_\infty \leq \delta_c$ . The resulting filter is optimized in the Cheby-shev (minimax) sense. MATLAB programs for design of FIR are found in [17, 36, 37]. Design of special cases of linear-phase FIR filters, as well as non-linear phase FIR filters, is discussed in detail in [14].

### 1.06.2.1 FIR structures

An FIR filter can be realized using both recursive or nonrecursive algorithms. The former, however, suffer from a number of drawbacks and should rarely be used in practice. An exception is so-called running-sum filters, which often are used in decimation filters for  $\sum \Delta$  converters.

Nonrecursive filters are always stable and cannot sustain parasitic oscillations, except when the filters are a part of a recursive loop. They generate little roundoff noise and can therefore be operated with short data wordlengths. However, they usually require a large number of arithmetic operations and a large amount of memory. Therefore large efforts have been directed towards developing methods to reduce the arithmetic workload.

This can be done by reducing the number of multiplications per sample, or by simplifying the coefficient values so that the multiplications becomes simpler to implement. The latter approaches results in what is referred to as multiplier-free structures, since all multiplications have been replaced with addition/subtraction and shift operations. That is, the coefficients are selected among a restricted set of values, i.e., as a sum-of-powers-of-two, SPOT,  $c = \pm 2^{\pm n_1} \pm 2^{\pm n_2} \pm \dots \pm 2^{\pm n_m}$ . Most FIR filters can be realized using no more than four powers of two. Today the arithmetic workload for a properly designed FIR structure is still relatively large, but the costs, i.e., chip area and power consumption, associated with the memory is becoming more and more significant.

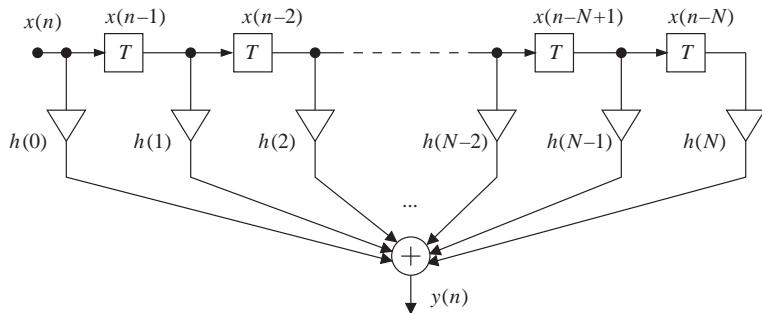

#### 1.06.2.1.1 Direct form FIR structures

There exist several structures that are of interest for the realization of FIR filters, particularly for filters with several sample frequencies so-called multirate filters. One simple structure is the direct form FIR, which has relatively small element sensitivity, i.e., the deviation in the frequency response due to a small change in any of the coefficients, is relatively small. This structure has many arithmetic operations and is therefore only suitable for relatively short FIR filters. The roundoff noise variance is  $(N + 1) \frac{Q^2}{12}$  if all products are rounded off. For filters with very narrow transition bands we recommend frequency-masking structures, which are discussed later.

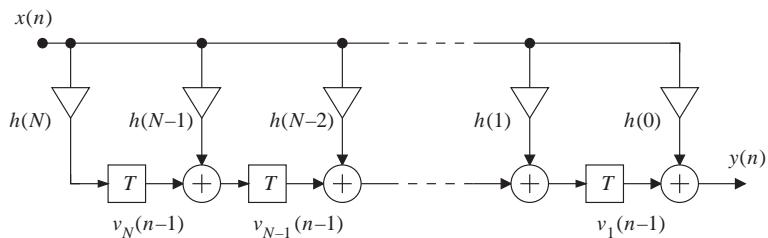

#### 1.06.2.1.2 Transposed direct form

The transposition theorem [33] can be used to generate new structures that realizes the same transfer function as the original filter structure. The transposed direct form FIR structure, shown in Figure 6.8, is derived from the direct form structure. The throughput is higher for the transposed form because the longest critical path is through only one multiplier and an adder, but the capacitive load at the input node is larger, since all multipliers load this node. The transposed structure is often preferred for an FPGA implementation.

The direct form structures requires in general  $N + 1$  multiplications, which may become a too large workload for high order FIR filters. However, the required amount of hardware can be significantly reduced, since many multiplications are performed with the same input value, or the transposed case where many signals are multiplied and then added. The internal signal level increases from left to right as more and more internal signals are added. Also in this structure the roundoff noise is  $(N + 1) \frac{Q^2}{12}$  if all products are rounded off.

**FIGURE 6.7**

Direct form FIR structure (Transversal filter).

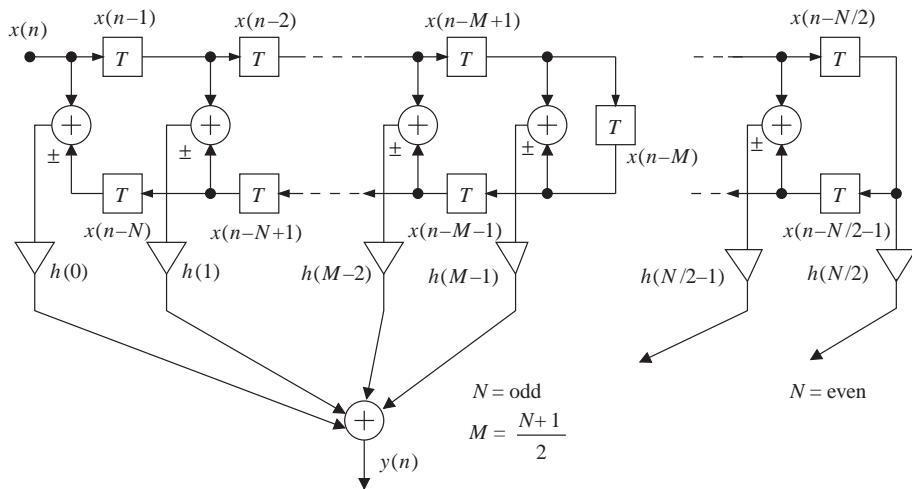

**FIGURE 6.8**

Transposed direct form FIR structure.

### 1.06.2.1.3 Linear-phase FIR structures

A major reason why FIR filters are used in practice is that they can realize an exact linear-phase response. Linear-phase implies that the impulse response is either symmetric or antisymmetric. An advantage of linear-phase FIR filters is that the number of multiplications can be reduced by exploiting the symmetry (or antisymmetry) in the impulse response, as illustrated in Figure 6.9. This structure is called a direct form linear-phase FIR structure since the phase response is independent of the coefficient values.

The number of multiplications for the direct form linear-phase structure is  $(N + 1)/2$  for  $N = \text{odd}$  and  $N/2 + 1$  for  $N = \text{even}$ . The number of multiplications is thus significantly smaller than for the more general structures in Figures 6.7 and 6.8, whereas the number of additions is the same. Subtractors are used instead of adders if the impulse response is antisymmetric. The signal levels at the inputs of the multipliers are twice as large at the input signal. Hence, the input signal should be divided by two and the filter coefficients should be scaled so that a proper out signal level is obtained. The roundoff noise is only  $(N + 1)Q^2/24$  and  $(N + 2)Q^2/24$  for  $N = \text{odd}$  and even, respectively, independently of the filter coefficients.

**FIGURE 6.9**

Direct form linear-phase FIR structure.

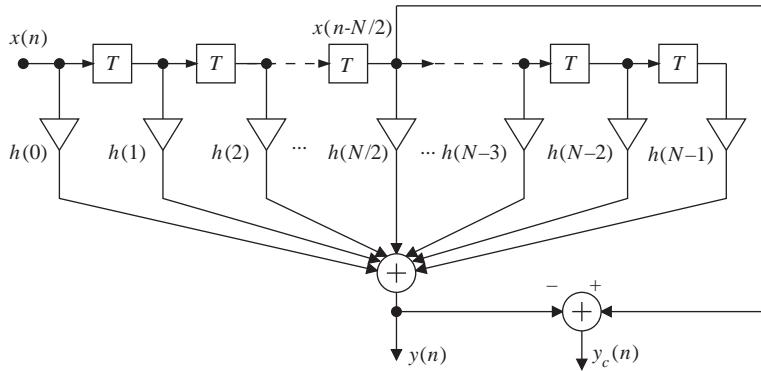

A major drawback is that the group delay for linear-phase FIR filters is often too large to be useful in many applications. Even-order FIR filters are often preferred since the group delay is an integer multiple of the sample period.

The number of arithmetic operations is further reduced in linear-phase, half-band filters. Each zero-valued coefficient makes one multiplication and one addition redundant. The number of actual multiplications in a linear-phase, half-band filter is only  $(N + 6)/4$ . The order is always  $N = 4m + 2$  for some integer  $m$ . A half-band filter is a special case of the Nyquist filters.

#### 1.06.2.1.4 Delay-complementary FIR structure

Even more dramatic reductions of the required amount of arithmetic operations is possible when a pair of delay-complementary FIR filters are needed. We illustrate the basic ideas by an example. The delay-complementary filter  $H_c(z)$  to an even-order linear-phase filter of type I or II can be obtained from the direct form linear-phase structure by subtracting the ordinary filter output from the delayed input value, as shown in Figure 6.10.

Odd order delay-complementary FIR filters are not feasible, since the symmetry axis, as shown in Figure 6.5, do not coincide with a sample in the impulse response. The cost of realizing the delay-complementary filter seems to be only one subtraction. However, the passband requirement on the FIR filter realizing  $H(z)$  must usually be increased significantly in order to meet the stopband requirements on the complementary filter,  $H_c(z)$ . Fortunately, a reduction of the passband ripple requires only a slight increase in the filter order, see (6.8). Furthermore, only even-order filters are useful. Hence, the arithmetic workload is somewhat larger than that for one single FIR filter, but is still significantly smaller than that for two separate filters. This technique can, of course, also be applied to linear-phase FIR filter structures, with either symmetric or antisymmetric impulse response, and their transposes.

**FIGURE 6.10**

Delay-complementary FIR filter with  $N = \text{even}$ .

Complementary half-band FIR filters are particularly useful, since the saving in arithmetic workload is substantial.

In many applications the need arises to split the input signal into two or more frequency bands. For example, in certain transmission systems for speech, the speech signal is partitioned into several frequency bands using a filter bank. A filter bank is a set of bandpass filters with staggered center frequencies so that the whole frequency range is covered. The first and the last filter are lowpass and highpass filters, respectively. The filtered signals are then processed individually to reduce the number of bits that has to be transmitted to the receiver, where the frequency components are added into an intelligible speech signal.

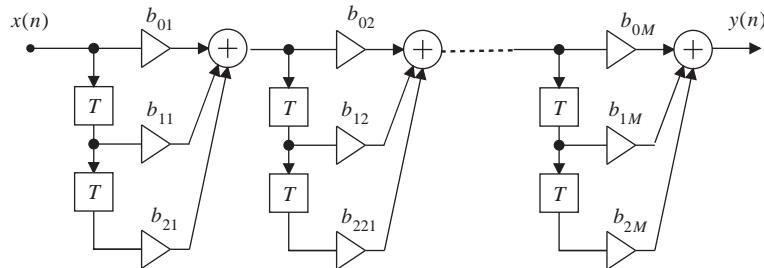

A special case of band splitting filters, a lowpass and highpass filter pair, is obtained by imposing the following symmetry constraints. Let  $H(z)$  be an even order FIR filter ( $N$  even). The delay-complementary transfer function  $H_c(z)$  is defined by

$$|H(e^{j\omega T}) + H_c(e^{j\omega T})| = 1. \quad (6.16)$$

This requirement can be satisfied by two FIR filters that are related according to

$$H(z) + H_c(z) = z^{-N/2}. \quad (6.17)$$

Hence, the two transfer functions are complementary. A signal is split into two parts so that if the two parts are added they combine into the original signal except for a delay corresponding to the group delay of the filters. Note that the attenuation is 6.02 dB at the cross-over. The output of the complementary filter  $H_c(z)$  can be obtained, as shown in Figure 6.10, by subtracting the ordinary filter output from the central value  $x(n - N/2)$ , which reduces the arithmetic workload significantly. However, the complementary filter is not obtained for free, because if the stopband attenuation is large, then the passband ripple of the ordinary filter must be very small. Hence, the filter order must be increased. The complementary FIR filters considered here cannot be of odd order since the center value of the impulse response in that case is not available.

**FIGURE 6.11**

FIR filter in cascade form.

#### 1.06.2.1.5 Cascade form FIR structures

High-order FIR and IIR filters may be realized in cascade form, i.e., as a cascade of several lower-order subfilters, as shown in Figure 6.11 for an FIR filter. The overall transfer function is

$$H(z) = \prod_{k=1}^M H_k(z), \quad (6.18)$$

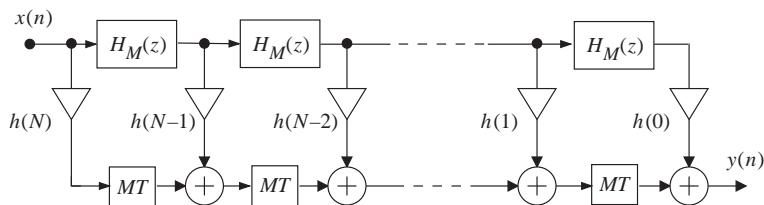

where the subfilters  $H_k(z)$  usually have order one, two, or four. Cascading of two minimum-phase filters yields an overall minimum-phase filter. Moreover cascading linear-phase filter also results in an overall linear-phase filter.

The benefit of cascading several filters is that the stopband attenuations of the filters adds. Hence, each subfilter need only to contribute with a small fraction of the overall stopband attenuation and they can therefore be simplified. The coefficients in the subfilters need not to be as accurate, i.e., the coefficient sensitivity in the stopband is small. The benefit obtained in the stopband sensitivity is, however, offset by an increased sensitivity in the passband since errors in the lower-order filters add. Furthermore, the cascade form suffers from a decrease in the dynamic signal range. Hence, the internal data wordlength must be increased. The ordering of the sections is important, since it affects dynamic signal range significantly. There is  $M!$  possible ways to order the sections for an FIR filter realized with  $M$  sections.

A minimum-phase filter can be partitioned into a linear-phase filter and a filter with nonlinear phase in cascade form [14].

#### 1.06.2.1.6 Lattice FIR structures

Lattice FIR structures are used in a wide range of applications, for example, speech and image processing, adaptive filters, and filter banks [31]. The lattice structure can be of FIR or IIR type. Note, however, the lattice structures discussed in this section are a different type of structure compared to the lattice wave digital filter structures that will be discussed in Section 1.06.7.9, although confusingly they have the name lattice in common.

**FIGURE 6.12**

FIR filter with identical subnetworks.

#### 1.06.2.1.7 FIR filters with identical subnetworks

Saramäki has developed a general theory for the design of structural frequency transformation of linear-phase FIR filters. The resulting structures consist of a tapped cascaded interconnection of identical FIR subfilters [37–39]. Figure 6.12 shows an example of these structures where the subfilters are identical, even-order linear-phase filters.

#### 1.06.2.1.8 Recursive frequency-sampling structures

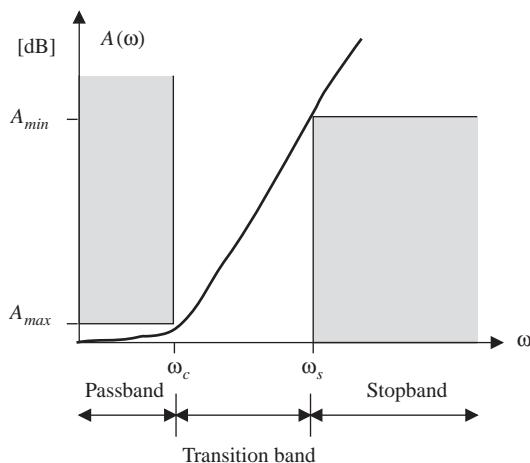

Traditionally, most textbooks [24,29,40] contain a discussion of so-called frequency-sampling FIR filter structures. These realizations are recursive algorithms that rely on pole-zero canceling techniques. Although they may seem to be interesting they are not recommended due to their high coefficient sensitivity, low dynamic range, and severe stability problems [14].

#### 1.06.2.1.9 Shifted permuted difference coefficient structure

The PDC approach was proposed by Nakayama [41]. This method was proposed for implementation of FIR filters, but it can be used to compute any sum-of-products. The basic idea is to exploit the fact, that the adjacent values in the impulse response have similar magnitudes, to simplify the multiplier network into a network consisting of only add/subtractors and shift operations. The shifted permuted difference method (SPDC) [14,42] is a generalization of the PDC method that yields fewer arithmetic operations. These approaches are simple alternatives to using more sophisticated multiple-constant multiplier techniques, which often yields better results. Multiple-constant multiplier techniques are discussed further in Section 1.06.12.1.

#### 1.06.2.1.10 Multirate FIR filters

Multirate filters are efficient in terms of arithmetic workload since a large part of the arithmetic operations can be performed at a lower rate [15,16]. Polyphase structures are efficient for decimation and interpolation since redundant arithmetic operations are avoided. FIR and IIR filters with narrow transition bands can be realized by methods based on decimation-filtering-interpolation schemes [14]. Common to these techniques is that the effective number of arithmetic operations per sample is reduced.

**FIGURE 6.13**

Standard specification of a digital lowpass filter.

### 1.06.3 The analog approximation problem

Frequency selective filters are specified in the frequency domain in terms of an acceptable deviation from the desired behavior of the magnitude or attenuation function. Figure 6.13 shows a typical attenuation specification for an analog lowpass filter. The variation (ripple) in the attenuation (loss) function in the passband may not be larger than  $A_{max}$  and the attenuation in the stopband may not be smaller than  $A_{min}$ . Usually the acceptable tolerances are piecewise constant. It is convenient during the early stages of the filter design process to use a normalized filter with unity gain, i.e., the minimum attenuation is normalized to 0 dB. The filter is provided with the proper gain in the later stages of the design process.

#### 1.06.3.1 Typical requirements

*Passband:* The frequency band occupied by the wanted signal is referred to as the passband. In this band the ideal requirement for the filter is to provide constant loss and constant group delay so that the wanted signal will be transmitted with no distortion. The passband frequency and the acceptable tolerance  $A_{max}$  for an analog lowpass filter is from 0 to  $\omega_c$ .

*Stopband:* The frequency bands occupied by the unwanted signals are referred to as the stopbands. In these bands the common form of specification merely requires the attenuation relative to the lower limit set for the passband, to be equal to or greater than some minimum amount. The stopband begins at  $\omega_s$  for an analog lowpass filter and extends towards infinity. For a digital lowpass filter the stopband begins at  $\omega_s T$  and extends to  $\pi$  rad. It is normally of no interest whether the actual filter loss in the stopband exceeds the specified amount by 1 dB or even 20 dB, and in this sense

stopband attenuations have only lower limits, in contrast to passbands where there are both upper and lower limits.

*Transition band:* The transition band is from  $\omega_c$  to  $\omega_s$ . There are no requirements on the attenuation in the transition band. The loss function of a filter is a continuous function of frequency and is thus unable to have jump discontinuities. For this reason there must always be some interval in the frequency spectrum, separating the edge of the passband from the edge of the stopband, in which the loss can raise from the low value in the passband to that required in the stopband. The bandwidth allocated to the transition band is one of the main factors determining the order of the filter needed to meet the specification. Moreover, as the width of the transition bands are decreased, not only does the complexity of the filter increase, but it becomes also more difficult to meet the specification for the passband. Narrower transition bands mean that the attenuation has to change more rapidly near the passband edges, and this causes the passband response to be more sensitive to both component losses and component tolerances.

*Phase response:* Linear-phase or near linear-phase response is often desirable or even required in many filter applications. However, this is usually specified in terms of the group delay.

*Group delay:* For the same reason that one cannot get exactly constant loss over a finite band, it is also impossible to get exactly constant group delay over a finite band with lumped element filters. However it is possible to get exactly linear-phase with filters built with distributed elements and with digital FIR filters.

*Impulse response:* The impulse response is mainly used as a theoretical concept and very rarely the impulse response is specified.

*Step response:* In most applications frequency domain characteristics such as phase and group delay requirements must be met, but in some cases additional requirements in the time domain are used. For example, step response and intersymbol interference requirements.

### 1.06.3.2 Standard lowpass approximations

Many filter approximations, have been developed to meet different requirements, particularly for analog filters. The main work has focused on approximations of lowpass filters, since highpass, bandpass, and bandstop filters can be obtained from lowpass filters through frequency transformations [18,20,43]. It is also possible to use these results to design digital filters. The classical lowpass filter approximations (standard approximations), which can be designed by using most standard filter design programs [21] are:

*Butterworth:* The magnitude function is maximally flat at the origin and monotonically decreasing in both the passband and the stopband. The group delay and variation within the passband is large. This approximation requires a larger filter order to meet a given specification than the filter approximations discussed below.

*Chebyshev I:* The magnitude function has equal ripple in the passband and decreases monotonically in the stopband. The group delay and the variation of the group delay within the passband is somewhat less than for a Butterworth approximation that meets the same attenuation requirement. A lower filter order is required compared to the Butterworth approximation.

*Chebyshev II (Inverse Chebyshev):* The magnitude function is maximally flat at the origin, decreases monotonically in the passband, and has equal ripple in the stopband. The group delay is smallest

of the four approximations and it has the smallest variation within the passband. The same filter order is required as for the Chebyshev I approximation.

*Cauer:* The magnitude function has equal ripple in both the passband and the stopband. The group delay and its variation is almost as low as the for Chebyshev II approximation. The Cauer filter, also called elliptic filter, requires the smallest order to meet a given magnitude specification.

#### 1.06.3.2.1 Comparison of the standard approximations

In comparing the standard approximations Butterworth, Chebyshev I, Chebyshev II, and Cauer filters, we find that the two latter has lower variations in the group delay. In literature it is often stated that Cauer filters have larger variation in the group delay than, i.e., Butterworth filters and that this is a valid reason for using the Butterworth approximation. The mistake in this argument is that the two filter approximations are compared using the same filter order. This is obviously not correct, which is evident of the following example, since Cauer filters can handle a considerably stricter requirement on the magnitude function. Even the step response for a Cauer filter is better. The difference between Chebyshev II and Cauer filters is however relatively small, the former has a somewhat smaller group delay, but the order is on the other hand larger.

#### 1.06.3.2.2 Example 1

Compare the Butterworth, Chebyshev I, Chebyshev II, and Cauer approximations, which meet the same standard LP specification:  $A_{\max} = 0.00695 \text{ dB}$  ( $\rho = 4\%$ ),  $A_{\min} = 45 \text{ dB}$ ,  $\omega_c = 1 \text{ rad/s}$  and  $\omega_s = 2 \text{ rad/s}$ .

As will be further discussed in Section 1.06.4.5,  $A_{\max}$  has been chosen very small in order to achieve low passband sensitivity and we may use components with large tolerances  $\varepsilon$  at the expense of a slightly higher filter order.

We get the following filter orders with the four standard approximations:

*Butterworth:*  $N_B = 12.12 \implies N_B = 13$ ,

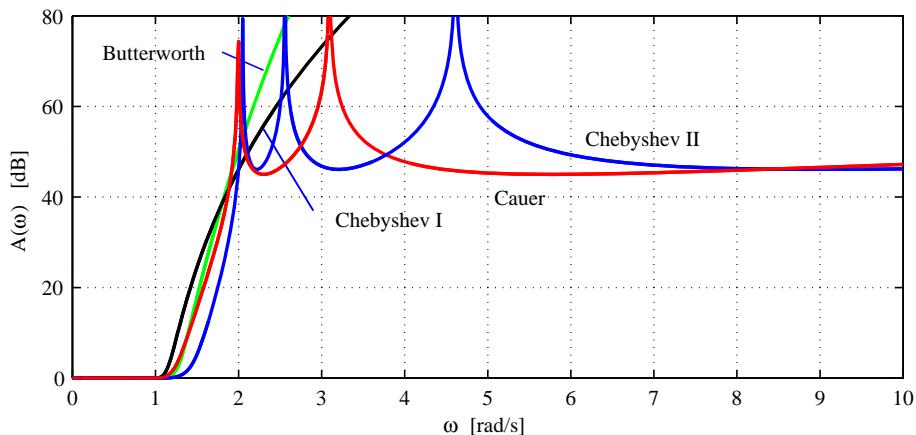

*Chebyshev I and Chebyshev II:*  $N_C = 6.904 \implies N_C = 7$ ,

*Cauer:*  $N_{Ca} = 4.870 \implies N_{Ca} = 5$ .

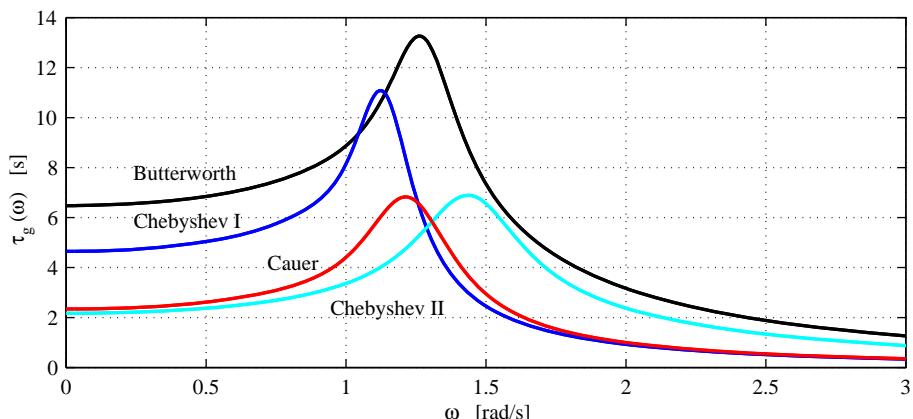

Note the large difference between the required orders for the standard approximations that meet the same requirement. The difference tends to increase if the transition band is reduced.

Figure 6.14 shows the attenuation for the four approximations. The allowed passband ripple is very small and we are only interested in that the requirement is met, and not in detailed variation inside the passband.

The attenuation in the transition band and the stopband varies between the different filters. The Chebyshev II filter has a more gradual transition between the passband and stopband compared with the Chebyshev I filter in spite of the fact that they have the same order. Note that the Cauer filter has a smaller transition band than required. The attenuation approaches, in this case, i.e., odd order filters, infinity for all of the filters. Figure 6.15 shows the corresponding group delays. The difference in the group delay is large between the different approximations and the group delays maximum lies above the passband edge  $\omega_c = 1 \text{ rad/s}$ . The Butterworth and Chebyshev I filters have larger group delay in the passband while the Chebyshev II and Cauer filters have considerably smaller group delay and

**FIGURE 6.14**

Attenuation for the four standard approximations.

**FIGURE 6.15**

Group delays for the four approximations.

the difference between the latter two is relatively small. In literature, it is commonly stated that the Butterworth filter has the best group delay properties. This is obviously not correct and is based on an unfair comparison between the standard approximations of the same order. According to Figure 6.15, Chebyshev II and Cauer filters have considerably lower group delays.

The element sensitivity for an *LC* filter is proportional to the group delay. The group delays at the passband edge and the passband variations are shown in Table 6.1. Notice that the Chebyshev II

**Table 6.1** Group Delays [s]

	$\tau_g(\omega_c)$	$\tau_g(\omega_c) - \tau_g(0)$
Butterworth	8.87115	2.39415
Chebyshev I	8.15069	3.4990
Chebyshev II	3.36427	1.1934
Cauer	4.41338	2.0718

approximation have the smallest variation. We will in Section 1.06.4.5 discuss the affect of the group delay on the sensitivity of a class of filter structures.

### 1.06.3.3 Frequency transformations

Optimal highpass filters can be derived from an optimal lowpass filter using frequency transformations [18, 20, 43]. However, the frequency transformations yield suboptimal bandpass and bandstop filters. Optimal bandpass and stopband filters require more advanced methods [18, 20, 21, 43].

---

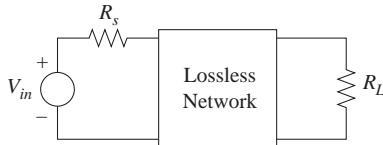

## 1.06.4 Doubly resistively terminated lossless networks

Passive *LC* filters belongs to the oldest implementation technologies, but they still plays an important role since they are being used as prototypes for the design of advanced frequency selective filters. A drawback with *LC* filters is that it is difficult to integrate resistors and coils with sufficiently high quality in integrated circuit technology. *LC* filters are for this reason not well suited for systems, that are implemented in an integrated circuit.

A more important aspect is, that *LC* filters are used as basis for realizing high-performance frequency selective filters. This is the case for mechanical, active, discrete-time, and *SC* filters as well as for digital filters. Examples of such methods are: imittance simulation using generalized imittance converters and inverters, Gorski-Popiel's, Bruton's, wave active filters, and topological simulations methods like leapfrog structures [20]. The main reason is, that the magnitude function for a well-designed *LC* filter has low sensitivity in the passband for variations in the element values. It is important that the reference filter is designed for low sensitivity, since the active and digital filters inherits its sensitivity properties. In fact, the sensitivity properties of the reference filter become a “lower” bound for the active and digital counterparts.

### 1.06.4.1 Maximal power transfer

To explain the good sensitivity properties of correctly designed *LC* filters, we first consider the power transferred from the source to the load in the circuit shown in Figure 6.16. A lossless reciprocal network can be realized by using only lossless circuit elements, e.g., inductors, capacitors, transformers, gyrators, and lossless transmission lines. Although, these filters are often referred to as *LC* filters. The maximal power that can be transferred to the load, which occur when the input impedance to the lossless network

**FIGURE 6.16**

Doubly resistively terminated lossless network.

equals  $R_s$ , is

$$P_{L\max} = \frac{|V_{in}|^2}{4R_s}. \quad (6.19)$$

The ratio of the output power and the maximal output power is

$$\frac{P_{out}}{P_{out\max}} = \frac{4R_s}{R_L} \left| \frac{V_{out}(j\omega)}{V_{in}(j\omega)} \right|^2 \leq 1, \quad (6.20)$$

where  $V_{in}(j\omega)$  is a sinusoidal input signal. An important observation is that the power, that the signal source can deliver to the load, is limited. The upper bound for the maximal power transfer is the base for the design of filter structures with low element sensitivity.

We define the frequency response as the ratio between input and output voltages, i.e., the relation between signal quantities and corresponding physical signal carrier, according to

$$H(j\omega) = \sqrt{\frac{4R_s}{R_L}} \frac{V_{out}(j\omega)}{V_{in}(j\omega)}. \quad (6.21)$$

It is convenient to normalize the magnitude response to  $|H(j\omega)| \leq 1$ .

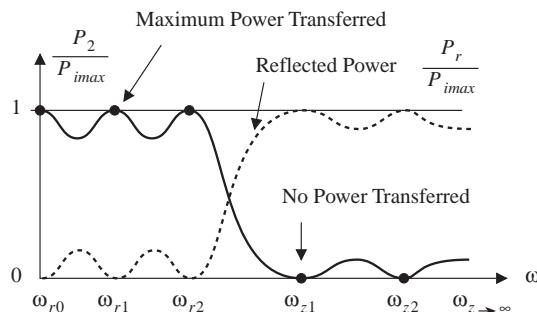

### 1.06.4.2 Reflection function

Note that the signal source, shown in Figure 6.16, does not deliver maximal power for all frequencies, since the input impedance to the reactance network is in general not equal to  $R_s$ . This can be interpreted as a fraction of the maximally available power is reflected back to the source. The relationship between the power that is absorbed in  $R_L$  and the power, which is reflected back to the source, is illustrated in Figure 6.17. Feldtkeller's equation, which is based on the assumption that the source delivers constant power, relate the power delivered to the load and the power reflected back to the source using the reflection function,  $\rho(j\omega)$ . We have

$$\frac{4R_s}{R_L} |H(j\omega)|^2 + |\rho(j\omega)|^2 = 1. \quad (6.22)$$

The reflection function is defined

$$\rho(j\omega) = \frac{Z(j\omega) - R_s}{Z(j\omega) + R_s}, \quad (6.23)$$

**FIGURE 6.17**

Transferred and reflected power.

where  $Z(j\omega)$  is the input impedance to the lossless network in Figure 6.16. The magnitude of the reflection function will be small in the passband. We will later show that the reflection function is a key to design of low sensitive filter structures.

#### 1.06.4.3 Element sensitivity

A measure of sensitivity is relative sensitivity of the magnitude function

$$\frac{|H(j\omega)|}{S_x} = \frac{\frac{\partial |H(j\omega)|}{\partial x}}{\frac{|H(j\omega)|}{x}}. \quad (6.24)$$

It is difficult to find a simple and good measure of how the attenuation changes, when several circuit element varies at the same time. The reason for this is that the influence of errors in different element values interacts. In fact, for a doubly resistively terminated reactance network we will demonstrate, that they tend to cancel. We shall therefore use and interpret sensitivity measures according to (6.24) with care. It is very difficult to compare different filter structures in a fair way.

#### 1.06.4.4 Passband sensitivity

The sensitivity of, for example, the magnitude function with respect to a circuit element,  $x$ , is a function of the angular frequency. The sensitivity in the passband can be determined from the derivative of the Feldtkeller's equation with respect to an arbitrary circuit element,  $x$ . We get

$$\frac{|H(j\omega)|}{S_x} = -\frac{R_L}{4R_s} \left| \frac{\rho(j\omega)}{H(j\omega)} \right| \frac{|\rho(j\omega)|}{S_x}. \quad (6.25)$$

For a doubly resistively terminated  $LC$  filter we have

$$|\rho_1(j\omega)| = |\rho_2(j\omega)| = \sqrt{10^{0.1A_{\max}} - 1}, \quad (6.26)$$

where  $A_{\max}$  is the acceptable ripple in the passband. Hence, the magnitude of the reflection function will be small in the passband if  $A_{\max}$  is small.

Fettweis showed (1960) that the sensitivity becomes minimal if the filter is designed for maximal power transfer at a number of angular frequencies in the passband. At these angular frequencies, the reflection function  $\rho(j\omega)$  is zero, since input impedance to the network in Figure 6.16 is  $Z(j\omega) = R_s$ . The sensitivity at these frequencies is therefore, according to (6.25), zero. If  $A_{\max}$  is small, both the reflection coefficient, according to (6.23) and the magnitude of the reflection function  $|\rho(j\omega)|$ , according to (6.26), will be small throughout the passband. Hence, the sensitivity will be small. If the ripple is decreased in the passband, the sensitivity is also decreased.

The fact that a doubly resistively terminated  $LC$  filter has low element sensitivity can also be realized through the following reasoning. Irrespective of if the element value is increased or decreased from its nominal value,  $P_{\text{out}}$  will decrease, since  $P_{\text{out}} = P_{\text{outmax}}$  for the nominal element value. Since the derivative is zero where the function has a maximum, i.e., for  $\omega = \omega_k$  with nominal element values. If there are many angular frequencies,  $\omega_k$ , with maximal power transfer, the sensitivity will be low throughout the passband. This line of reasoning is referred to as Fettweis-Orchard's argument [20, 44].

#### 1.06.4.5 Errors in the elements in doubly terminated filters

Figure 6.18 shows the typical deviation in the attenuation for a doubly resistively terminated  $LC$  filters due to errors in the reactive elements.

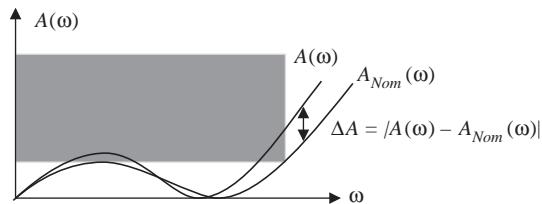

It can be shown that the deviation in the passband attenuation, as shown in Figure 6.18, for a doubly resistively terminated filter is [45].

$$\Delta A(\omega) \leq 8.69 \varepsilon \frac{|\rho(j\omega)|}{|H(j\omega)|^2} \omega \tau_g(\omega), \quad (6.27)$$

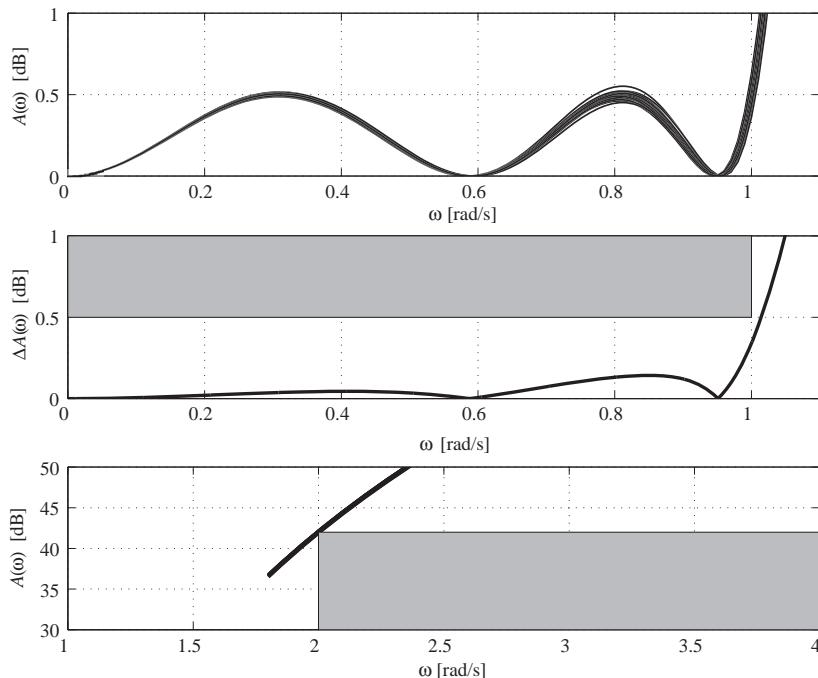

where  $e = |\Delta L/L| = |\Delta C/C|$  represent the uniformly distributed errors in the inductors and the capacitors, i.e.,  $(1 - \varepsilon)L \leq L \leq (1 + \varepsilon)L$ , etc. It can be shown that  $\Delta A(\omega)$  is proportional to the electric and magnetic energy stored in the capacitors and inductors and that (6.27) also holds for commensurate-length transmission line filters as well. The deviation will, according to (6.27), be largest for frequencies where  $\omega \tau_g(\omega)$  is largest, since the reflection function,  $|\rho(j\omega)|$ , is small and  $|H(j\omega)| \approx 1$  in the passband. Hence, a doubly resistively terminated filter with 3 dB ripple in the passband is significantly more sensitive for element errors, than a filter with smaller passband ripple, e.g., 0.01 dB. Moreover, the  $Q$  factors of the poles will be small if the passband ripple is small. Thus, it is often better to design a filter with a small ripple at the expense of a slightly higher filter order. Note that (6.27) is not valid for singly resistively terminated filters.

#### 1.06.4.6 Errors in the terminating resistors

The sensitivities with respect to  $R_s$  and  $R_L$  are proportional to the reflection function. Hence, the sensitivities are small in the passband, since  $|\rho(j\omega)| \ll 1$ , and equals zero for the frequencies at maximal power transfer. In addition, the errors will essentially appear as a small change in the gain of the filter and not affect the frequency selectivity.

**FIGURE 6.18**

Deviation in the attenuation due to element errors.

**FIGURE 6.19**

Deviation in the passband attenuation (top), bound on the attenuation (middle), and deviation in the stopband attenuation (bottom).

#### 1.06.4.7 Effects of lossy elements

The effect on the attenuation of lossy reactive elements can be estimated in terms of their  $Q$  factors, where we assume that all inductor have the same  $Q$  factor and the same holds for the capacitors [43,45].

$$\Delta A(\omega) = \frac{8.69}{2} \left( \frac{1}{Q_L} + \frac{1}{Q_C} \right) \omega \tau_g(\omega) + \frac{8.69}{2} \left( \frac{1}{Q_L} - \frac{1}{Q_C} \right) |\rho|_{\max}. \quad (6.28)$$

Also in this case it is favorable to select a small passband ripple. The deviation will be largest at the passband edge, i.e., where  $\omega\tau_g(\omega)$  is largest. However, in the case of wave digital filters, which will be discussed later, the components do not have any losses.

#### 1.06.4.7.1 Example 2

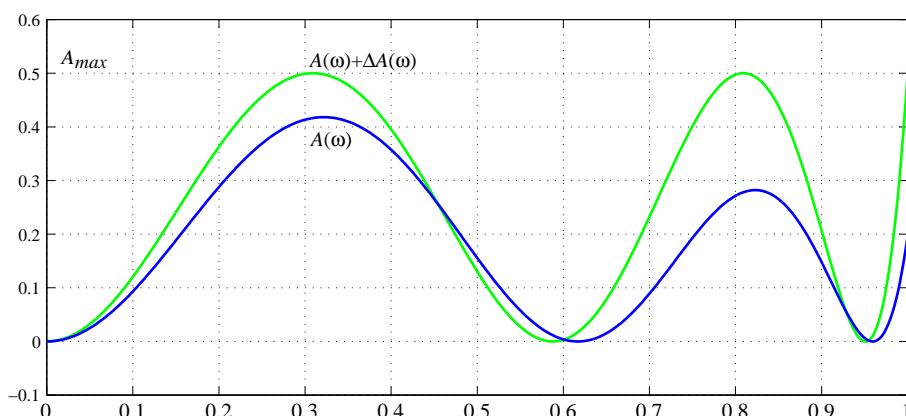

Consider a fifth-order Chebyshev I filter with  $A_{\max} = 0.5$  dB,  $A_{\min} = 42$  dB,  $\omega_c = 1$  rad/s, and  $\omega_s = 2$  rad/s and we assume that the components errors are uniformly distributed with  $\varepsilon = \pm 1\%$ .

Figure 6.19 shows the deviations in the attenuation in the passband and stopband as well as the bound on the deviation according to (6.27).

A significant number of filters do not meet the specification, since the design margin is very small. In practice, a design margin should be allocated to the two bands as well as to the bandedges [46]. Obviously, the deviation increases towards the passband edge while it is insignificant at low frequencies. Moreover, the sensitivity at the bandedge is large, and the cutoff frequency is sensitive to component errors.

#### 1.06.4.8 Filters with diminishing ripple

Due to deviations in the attenuation, caused by errors in the element values, a part of the allowed ripple in the passband,  $A_{\max}$  must be reserved to allow for errors in the component values. The filter must therefore be synthesized with a design margin, i.e., with a ripple, which is less than required by the application. According to (6.27), the deviation is smaller for low frequencies and increases towards the passband edge. In practice, however, in order to simplify the synthesis, the design margin is for the standard approximations distributed evenly in the passband, even though the margin will not be exploited for lower frequencies. In order to exploit the allowed passband ripple better, we may let the reflection function  $|\rho(j\omega)|$  of the synthesized filter decrease at the same rate as the other factors in  $\Delta A(\omega)$  increases so that  $A(\omega) + \Delta A(\omega) \leq A_{\max}$ , as shown in Figure 6.20. The ripple will decay

**FIGURE 6.20**

Passband attenuation for a fifth-order Chebyshev I filter with diminishing ripple and equiripple  $A(\omega) + \Delta A(\omega) \leq A_{\max}$  (green) (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this book.).

towards the passband edge and the corresponding *LC* filter can be implemented with components with larger tolerances, i.e., the filter can be implemented with a lower overall cost. The group delay of a filter with diminishing ripples is slightly smaller than for the original filter. An additional advantage is that this will reduce the thermal noise as well [47].

#### 1.06.4.8.1 Example 3

The deviation due to losses and component errors, for the filters in Example 1, with  $Q_L > 200$  and  $Q_C > 50$ , are shown in Table 6.2.

Using a Chebyshev II or Cauer filter, instead of a Butterworth filter, reduces the group delay with a factor of 2.64 and 2, respectively. Hence, the component tolerances can be increased with the same factor. An additional improvement of a factor 2 to 3 can be obtained by using a diminishing ripple approximation, that allocate a larger design margin and reduces the sensitivity at the upper part of the passband. Components, with large tolerances, are considerably cheaper than those with small tolerances. In addition, the number of components is fewer; 9 and 7 compared to 13 for Butterworth. Therefore it is important to use an approximation with small group delay. Cauer is often the preferred approximation, since the required order is significantly lower than for Chebyshev II and the group delay is almost a low.

In addition, Chebyshev II or Cauer filters have lower  $Q$  factors as well. The  $Q$  factors for the four filters are shown in Table 6.3.

**Table 6.2** Deviation in the Attenuation

	$\Delta A(\omega)$ according to (6.28)	$\Delta A(\omega)$ according to (6.27)
Butterworth	0.4080 $\epsilon$ dB	3.0880 $\epsilon$ dB
Chebyshev I	0.2479 $\epsilon$ dB	2.8380 $\epsilon$ dB
Chebyshev II	0.1023 $\epsilon$ dB	1.1713 $\epsilon$ dB
Cauer	0.1342 $\epsilon$ dB	1.5365 $\epsilon$ dB

**Table 6.3**  $Q$  Factors for the Four Filters

Butterworth	Chebyshev I	Chebyshev II	Cauer
$N = 13$	$N = 7$	$N = 7$	$N = 5$
0.50000	0.50000	0.50000	0.50000
0.51494	0.68955	0.60835	0.83127
0.56468	1.33370	1.03162	3.12162
0.66799	4.34888	3.19218	
0.88018			
1.41002			
4.14812			

The conclusion is that Cauer is the best approximation in most cases, i.e., when we have requirements on both the attenuation and group delay. In addition, the Cauer approximation yields *LC* filter with fewer components and with almost as low sensitivity to errors in the element values as Chebyshev II filters.

#### 1.06.4.9 Design of doubly resistively terminated analog filters

Instead of using expensive components with low tolerances and large  $Q$  factor, we can compensate for an increase in  $\varepsilon$ , i.e., using components with larger tolerances, using some or all of the following possible trade-offs:

- Use a doubly resistively terminated reactance network that is designed for maximal power transfer, i.e., (6.27) is valid.
- Reduce  $|\rho(j\omega)|$  by reducing the passband ripple,  $A_{\max}$ , of the filter more than required by the application. However, this requires that the filter order is increased. That is, we can use a few more, but cheaper components to reduce the overall cost of the implementation.
- Use an approximation that have low group delay, i.e., Chebyshev II and Cauer filters are preferred over Butterworth and Chebyshev I filters.
- Use an approximation with diminishing ripple.

### 1.06.5 Ladder structures

*LC* ladder structures are often used to realize filters with transfer functions with zeros on the  $j\omega$ -axis or in the left-hand side of the  $s$ -plane. Zeros in the right-hand side of the  $s$ -plane cannot be realized by ladder structures, i.e., only minimum-phase transfer functions can be realized. Doubly terminated ladder structures have low element sensitivity in the passband, as discussed above, and relatively small sensitivity in the stopband.

#### 1.06.5.1 Structures for lowpass filters

Figures 6.21 and 6.22 show ladder structures of  $T$  and  $\pi$  type for realization of lowpass filters without finite zeros, respectively.  $T$  and  $\pi$  type refer to the leftmost stage of the ladder. These ladder structures can realize Butterworth and Chebyshev I lowpass filters.

Figures 6.23 and 6.24 show ladder structures that can realize transfer functions with finite zeros, e.g., Chebyshev II and Cauer filters.

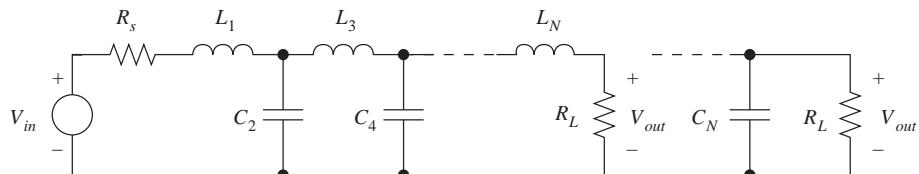

FIGURE 6.21

$N$ th-order  $T$  ladder structure for lowpass filters without finite zeros.

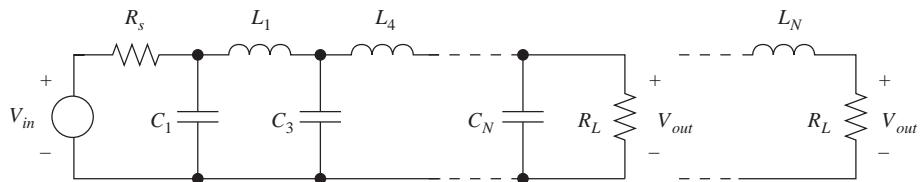

FIGURE 6.22

$N$ th-order  $\pi$  ladder structure for lowpass filters without finite zeros.

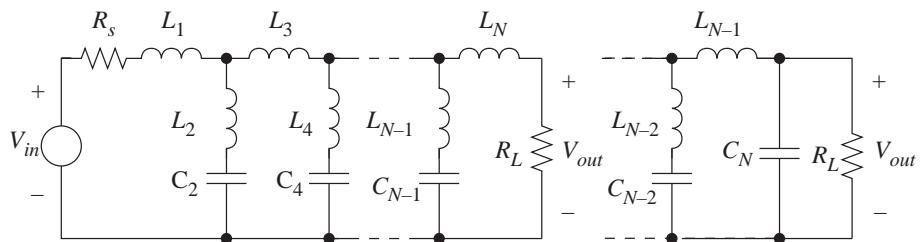

FIGURE 6.23

$N$ th-order  $T$  ladder structure with finite zeros.

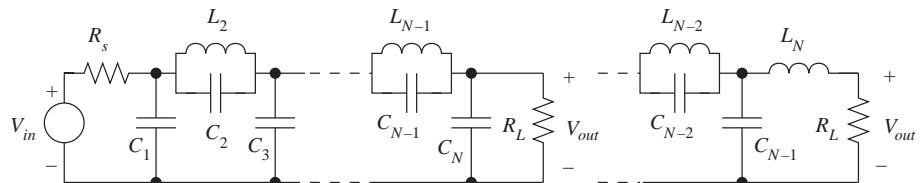

FIGURE 6.24

$N$ th-order  $\pi$  ladder structure with finite zeros.

There are two main methods for creating transmission zeros. The best method is to use series or parallel resonance circuits in the shunt and series arms in a ladder structure, respectively. The transmission zeros are created by reflecting the signal at the resonance circuits back to the source. The stopband sensitivity will be small if the transmission zeros are created by reflection. In fact, a zero pair on the  $j\omega$ -axis is determined by only two elements. The passband sensitivity and the ratio of the largest and smallest element value, depends on the ordering of the transmission zeros. For lowpass filters, are minimal sensitivity obtained if the transmission zeros closest to the passband edge is positioned in the center of the ladder structure. The positioning of the zeros is very important in narrow-band bandpass filters.

In lattice filters, which will be discussed in Section 1.06.7.9, the transmission zeros are instead created by cancellation. In fact, lattice filters have low passband sensitivities, but very poor stopband

sensitivities. The lattice structure is nevertheless useful for piezoelectric and ceramic resonator filters and as reference filter for digital filters, since the element errors in these technologies are small.

To summarize, we conclude that creating transmission zeros by means of power reflection at the shunt or series arms is a superior method compared to methods based on signal cancellation or dissipation.

A singly resistively terminated reactive network do not adhere to Feldtkeller's equation and the power transferred is either zero or upwards unbounded. It is well known that singly terminated filters are much more sensitive than doubly terminated filters. Hence, singly terminated filters are not recommended as reference filters.

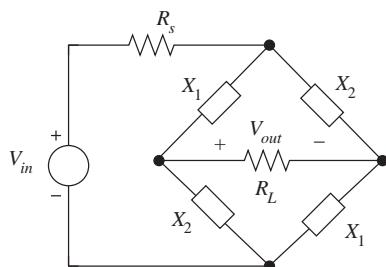

#### 1.06.5.1.1 Design of ladder structures

Doubly terminated ladder structures are generally designed by using the insertion loss method. This method involves long, complicated, and numerically ill-conditioned calculations, which must be done by a computer. Two exceptions are the Butterworth and Chebyshev I lowpass filters for which analytical solutions have been found. See [20] for details on the synthesis of ladder structures as well as design of highpass, bandpass, and bandstop  $LC$  filters. Efficient MATLAB functions for synthesis of ladder filters have been implemented in the toolbox [21].

## 1.06.6 Lattice structures

Lattice structures can be used to derive digital filter structures with low roundoff noise, high degree of parallelism, and modular circuitry that are suitable for implementation. The problems associated with unstable and inaccurate element values are not present in digital filters, since the coefficients are fixed binary values.

Figure 6.25 shows a symmetric analog lattice filter with the lossless reactances  $X_1$  and  $X_2$  and  $R_s = R_L$ . An analog lattice filter is in practice unusable, because of its high sensitivity in the stopband, except if the reactances are realized by highly stable and accurate components, for example quartz and ceramic resonators. In fact, due to the high stopband sensitivity, the lattice structure is often used as a measuring device. Lattice filters, which are designed for maximal power transfer, have, however, low coefficient sensitivity in the passband.

**FIGURE 6.25**

Analog lattice filter.

Lattice structures can be used to derive digital filter structures with low roundoff noise, high degree of parallelism, and modular circuits that are suitable for implementation. The problems associated with unstable and inaccurate element values are not present in digital filters, since the coefficients are fixed binary values.

### 1.06.6.1 Wave description of two-ports

Instead of using voltages and currents to describe electrical networks, it is convenient to use a linear combination thereof. One such linear combination is voltage waves. An impedance  $Z$  is normally described by the ratio  $Z = V_1/I_1$ , but it can also be uniquely described using voltage waves, i.e.,

$$\begin{cases} A_1 = V_1 + RI_1, \\ B_1 = V_1 - RI_1, \end{cases} \quad (6.29)$$

where  $R$  is a positive constant. Other possibilities are, for example, current waves and power waves [14,48]. The latter is often used to describe distributed networks.

#### 1.06.6.1.1 Analog lattice structure

Consider the lattice structure shown in Figure 6.26 where we have added a second optional input signal source.

The lattice structure can be described by the incident ( $A_1$  and  $A_2$ ) and reflected ( $B_1$  and  $B_2$ ) voltage waves

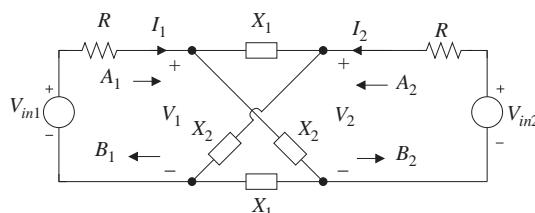

$$\begin{cases} A_1 = V_1 + RI_1 = V_{in1}, \\ B_1 = V_1 - RI_1, \end{cases} \quad (6.30)$$

and

$$\begin{cases} A_2 = V_2 + RI_2 = V_{in2}, \\ B_2 = V_2 - RI_2. \end{cases} \quad (6.31)$$

We define the (voltage wave) scattering matrix by

$$\begin{bmatrix} B_1 \\ B_2 \end{bmatrix} = \begin{bmatrix} s_{11} & s_{12} \\ s_{21} & s_{22} \end{bmatrix} \begin{bmatrix} A_1 \\ A_2 \end{bmatrix} = S \begin{bmatrix} A_1 \\ A_2 \end{bmatrix}. \quad (6.32)$$

**FIGURE 6.26**

Symmetric analog lattice filter.

We get after elimination of voltages and currents in (6.30) through (6.32)

$$\begin{cases} 2B_1 = S_1(A_1 - A_2) + S_2(A_1 + A_2), \\ 2B_2 = S_1(A_2 - A_1) + S_2(A_1 + A_2), \end{cases} \quad (6.33)$$

where

$$S_1 = \frac{X_1 - R}{X_1 + R}, \quad (6.34)$$

$$S_2 = \frac{X_2 - R}{X_2 + R} \quad (6.35)$$

are the reflectance functions for  $X_1$  and  $X_2$ . Note that  $S_1$  and  $S_2$  are allpass functions if  $X_1$  and  $X_2$  are reactances. We can rewrite (6.33) as

$$\begin{cases} B_1 = \frac{S_1 + S_2}{2} A_1 + \frac{S_2 - S_1}{2} A_2, \\ B_2 = \frac{S_2 - S_1}{2} A_1 + \frac{S_1 + S_2}{2} A_2 \end{cases} \quad (6.36)$$

from which it follows that

$$s_{11} = \frac{S_1 + S_2}{2}, \quad (6.37)$$

$$s_{21} = \frac{S_2 - S_1}{2}. \quad (6.38)$$

The scattering parameter  $s_{21}(s)$  correspond to the transfer function and  $s_{11}(s)$  to the reflection function. Feldtkeller's equation can be expressed in terms of the scattering parameters  $s_{11}$  and  $s_{21}$  as

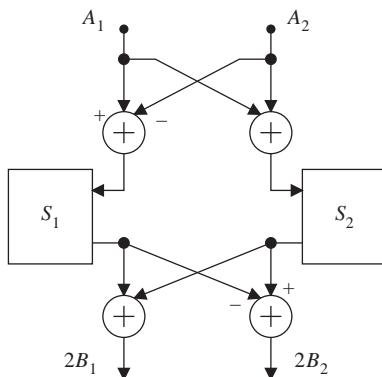

$$|s_{11}|^2 + |s_{21}|^2 = 1 \quad (6.39)$$

Hence,  $s_{11}$  and  $s_{21}$  are power-complementary transfer functions. Figure 6.27 shows the wave-flow diagram for the lattice filter. Note that the filter consists of two allpass filters in parallel and that the two outputs are obtained by adding and subtracting the outputs of the allpass filters. The normal output is  $B_2$ . Only odd-order lowpass filters can be realized using a lattice structure. Hence,  $S_1$  and  $S_2$  are odd (even) and even (odd), respectively. See [14,49,50] how to select  $S_1$  and  $S_2$  for more general cases.

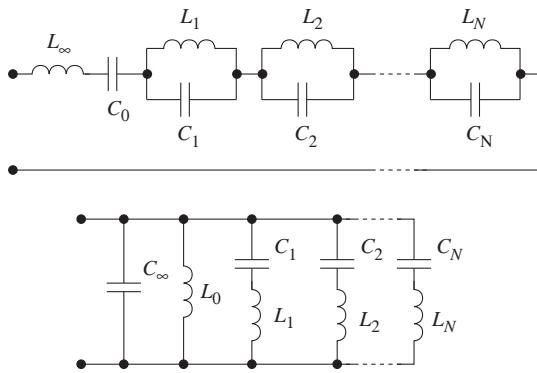

### 1.06.6.2 Realization of reactances

The reflectance functions  $S_1$  and  $S_2$  correspond according to (6.34) and (6.35) to the reactances  $X_1$  and  $X_2$ . A reactance,  $X(s)$  can be realized in several canonic ways, see [20] for more design details and MATLAB programs. For example, Foster I and II realizations are shown in Figure 6.28. Alternative realizations are Cauer I and II ladders, which are shown in Figure 6.29.

An arbitrary  $N$ th-order reactance  $X(s)$  can be realized by  $N$  lossless commensurate-length transmission lines (unit elements) using a Richards' structure, which is shown in Figure 6.30. The structure is terminated with either a short-circuit or open-circuit.

**FIGURE 6.27**

Wave-flow diagram for a lattice filter.

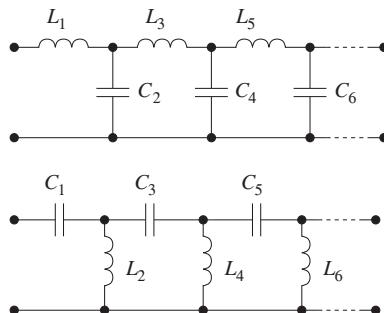

**FIGURE 6.28**

Foster I (upper) and II (lower) structures.

### 1.06.6.3 Design of analog lattice structures

Note that both  $S_1$  and  $S_2$  are allpass functions. The scheme of splitting an odd-order lowpass transfer function into two allpass sections, is as follows:

- Assign the real pole to  $S_1$  and remove it from the set of poles. Note that only odd-order lowpass and highpass filters are feasible.
- Next, assign to  $S_2$  the pole pair with the smallest angle between the negative real axis and the vector from the origin to the positive pole and remove the pole pair from the set of pole.
- Continue in the same way by alternating assigning the pole pair with the smallest angle to  $S_1$  and  $S_2$  until all poles have been assigned.

**FIGURE 6.29**

Cauer I (upper) and II (lower) structures.

**FIGURE 6.30**

Realization of an  $N$ th-order reactance.

- The two allpass filters are obtained by adding the zeros according to  $s_z \leftarrow -s_p$ . That is, each pole has a corresponding zero, but in the right-hand side half-plane.
- Determine the reflectance functions from the allpass functions.
- Finally, select suitable realizations of the two reactances.

#### 1.06.6.4 Commensurate-length transmission line networks

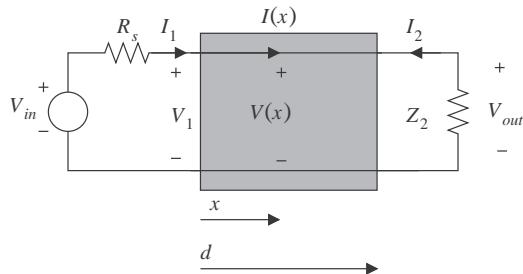

In a commensurate-length transmission line networks, all transmission lines have a common electrical propagation time. Commensurate-length transmission line networks constitutes a special case of distributed element networks that can easily be designed by using a mapping to a lumped element structure, which can be designed using common analytical or computer-aided tools. This mapping is based on a one-to-one mapping between the lumped element network and the transmission line network expressed in terms of a complex frequency variable, Richards' variable,  $\Psi$ . Lossless commensurate-length transmission lines can be used to build low sensitivity filters.

A commensurate-length transmission line with length  $d$  is illustrated in Figure 6.31. The voltage and current at various positions along the line can be described by an incident and a reflected wave. Under stationary conditions we have

$$\begin{cases} V(x) = Ae^{-\gamma x} + Be^{\gamma x}, \\ I(x) = \frac{1}{Z_0}(Ae^{-\gamma x} - Be^{\gamma x}), \end{cases} \quad (6.40)$$

where  $A$  and  $B$  are constants, which can be determined by the boundary conditions. For example,  $V_1 = V(0)$  and  $I_1 = I(0)$ . Further we have

$$\gamma^2 = (r + j\omega l)(g + j\omega c) \quad (6.41)$$

**FIGURE 6.31**

Transmission line.

and

$$Z_0^2 = \frac{r + j\omega l}{g + j\omega c}, \quad (6.42)$$

where  $r$ ,  $l$ ,  $g$ , and  $c$  are the primary constants for the line: resistance, inductance, and conductance per unit length, respectively.  $\gamma$  is the propagation constant and  $Z_0$  is the characteristic impedance.  $Z_0$  is real-valued positive constant,  $Z_0 = R = \sqrt{\frac{l}{c}}$ , for lossless transmission lines and is therefore sometimes called characteristic resistance.

#### 1.06.6.4.1 Richards' variable

Commensurate-length transmission line filters constitute a special case of distributed element networks that can easily be designed by mapping them to a lumped element structure. This mapping involves Richards' variable, which is defined

$$\Psi = \frac{s^{sT} - 1}{s^{sT} + 1} = \tanh\left(\frac{sT}{2}\right), \quad (6.43)$$

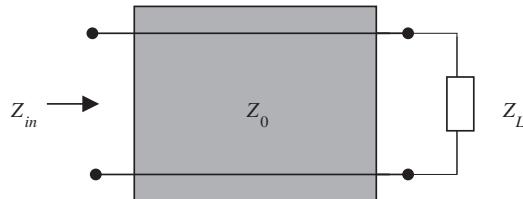

where  $\Psi = \Sigma + j\Omega$  and  $T$  is the propagation time for a wave through the transmission line and back. Richards' variable is a dimensionless complex-valued variable. The real frequencies in the  $s$ - and  $\Psi$ -domains are related by

$$\Omega = \tan\left(\frac{\omega T}{2}\right). \quad (6.44)$$

Note the similarity between the bilinear transformation and Richards' variable. In fact, commensurate-length transmission line filters have the same periodic frequency responses as digital filters. Substituting Richards' variable into the chain matrix for a transmission line we get [14]

$$K = \frac{1}{\sqrt{1 - \Psi^2}} \begin{bmatrix} 1 & Z_0\Psi \\ \Psi & 1 \end{bmatrix}. \quad (6.45)$$

The matrix in (6.45) has element values that are rational functions in Richards' variable, except for the square-root factor. However, this factor can be handled separately during the synthesis. The synthesis procedures (programs) used for lumped element design can therefore be used with small modifications for synthesis of commensurate-length transmission line filters.

**FIGURE 6.32**

Terminated transmission line (UE–Unit Element).

#### 1.06.6.4.2 Unit elements

The transmission line filters of interest are with a few exceptions built using only one-ports. At this stage it is therefore interesting to study the input impedance of the one-port shown in Figure 6.32. A lossless transmission line described by (6.45) is called a unit element (UE). The input impedance to a unit element, which is terminated by the impedance  $Z_L$ , can be derived from (6.45).

We get the input impedance to a transmission line, with characteristic impedance  $Z_0$  and loaded with an impedance  $Z_L$ , as

$$Z_{in}(\Psi) = \frac{Z_L + Z_0\Psi}{Z_0 + Z_L\Psi}. \quad (6.46)$$

We are interested in the input impedance of a lossless transmission line with characteristic impedance  $Z_0 = R$  that is terminated by an impedance in the following three cases.

#### 1.06.6.4.3 $Z_L = Z_0$ (**matched termination**)

For case,  $Z_L = Z_0$ , we have according to (6.46)

$$Z_{in} = R. \quad (6.47)$$

Hence, we have a matching between the unit element and the load, and an incident wave to the load, will not be reflected.

#### 1.06.6.4.4 $Z_L = \infty$ (**open-ended**)

We get

$$Z_{in} = \frac{R}{\Psi}. \quad (6.48)$$

Hence, an open-ended unit element can be interpreted as a new kind of capacitor, i.e., a  $\Psi$ -plane capacitor with the value  $1/R$ .

#### 1.06.6.4.5 $Z_L = 0$ (**short-circuited**)

A short-circuited unit element has the input impedance

$$Z_{in} = R\Psi \quad (6.49)$$

which can be interpreted as a  $\Psi$ -plane inductor with the value  $R$ .

## 1.06.7 Wave digital filters

In this section we discuss the design of wave digital filters based on different classes of doubly resistively terminated networks consisting of lossless commensurate-length transmission lines. Wave digital filters inherit the low element sensitivity properties from their analog counterparts, which should be designed for maximal power transfer in the passband [14, 20]. Hence, simple and short coefficients can be used in the wave digital filters. In addition, the dynamic signal range is large and the roundoff noise is low in these low-sensitivity structures.

Wave digital filters constitute a wide class of digital IIR filters and in some special cases FIR filters. Wave digital filters have many advantageous properties, and they are therefore the recommended type of IIR filters. A wave digital filter is derived from an analog filter, which is referred to as its reference filter. Due to this relationship between the wave digital filter and the corresponding analog reference filter, wave digital filter structures inherit many fundamental properties from their analog counterparts. Of foremost interest are favorable stability properties and low sensitivity with respect to variations in element values. Furthermore, the approximation problem for the wave digital filter can be carried out in the analog domain using well-known design programs. Wave digital filters comprise a whole variety of subclasses, derived from the corresponding analog filter structures.

In order to retain the low element sensitivity and robustness of the analog reference filter it is necessary to adhere to the maximal power transfer principle, which was discussed in Section 1.06.4.1. For the representation of power, or energy, it is necessary to use two variables, e.g., voltage and current [51]. Thus the signal-flow graphs discussed in Section 1.06.2.1 can not represent power.

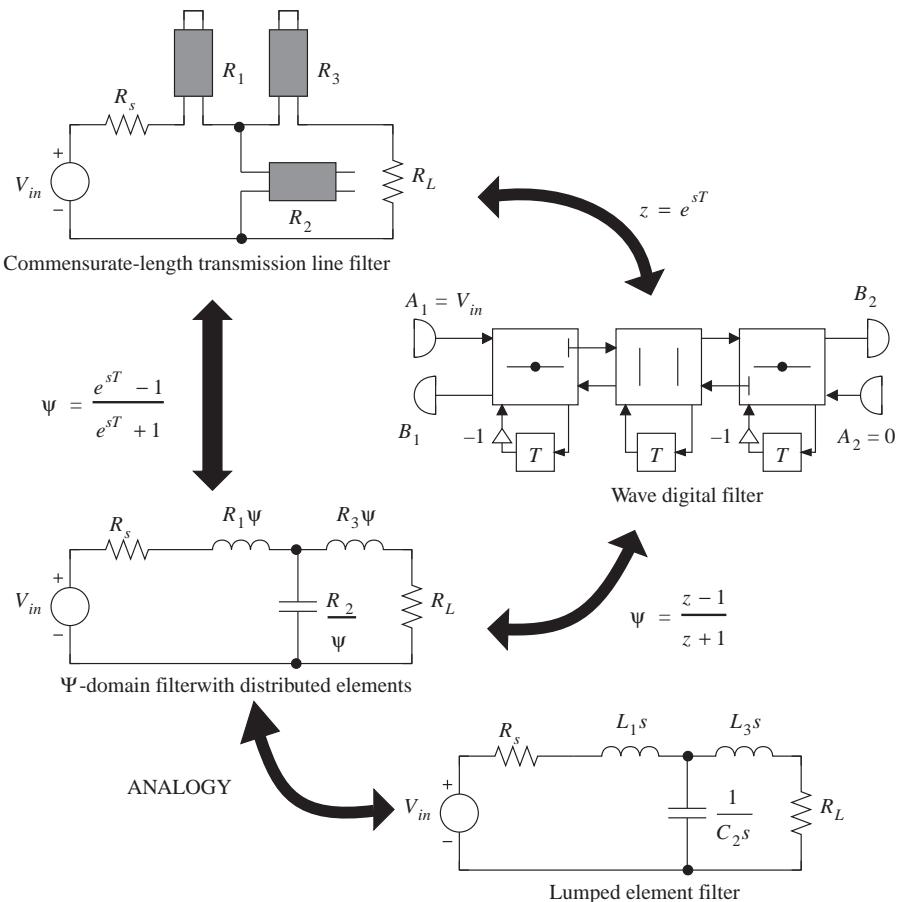

Alfred Fettweis has developed a comprehensive theory, so-called wave digital filter theory, which solves these problems [27, 48, 52]. In fact, this theory is not only a digital filter design theory, it is a general theory describing the relations between distributed element and discrete-time networks. Furthermore, it inherently contains an energy concept, which is important for stability analysis of nonlinear digital networks as well as for retaining the low-sensitivity properties of the reference filter.

An important property of wave digital filters is the guaranteed stability, which is inherited from the reference filter. In practice, the inductors in an *LC* ladder filter are nonlinear. Such nonlinearities may cause and sustain parasitic oscillations. However, in the passive *LC* filter such oscillations are attenuated, since the filter dissipates signal power. Hence, any oscillation will eventually vanish. This property is retained in the wave digital filter.

Wave digital filters, particularly wave digital lattice and circulator-tree filters, are suitable for high-speed applications. They are modular and possess a high degree of parallelism, which makes them easy to implement in hardware.

### 1.06.7.1 Design of wave digital filters

A wave digital filter is derived from an analog reference filter. The basic relations between the wave digital filter, the corresponding reference filter, i.e., the transmission line filter, and the lumped element filter, are summarized in Figure 6.33. The purpose of the lumped element filter is only to simplify the design process by allowing the use of conventional, lumped element filter theory and design tools. In principle, all commensurate-length transmission line networks can be used as reference filters for wave

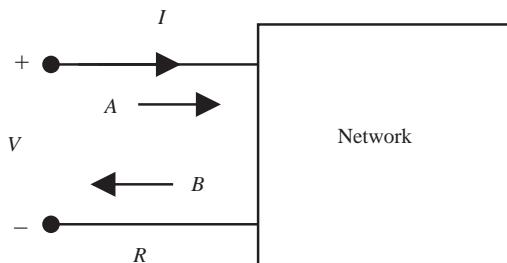

**FIGURE 6.33**

Summary of the design process for wave digital filters.

digital filters. Furthermore, wave digital filters representing classical filter structures are also viable since all lumped element networks can be uniquely mapped onto commensurate-length transmission line networks using Richards' variable.

However, certain reference structures result in wave digital filter algorithms that are not sequentially computable, because the wave-flow graph contains delay-free loops. Therefore, one of the main issues is to avoid these delay-free loops. There are three main approaches to avoid delay-free loops in wave digital filters [20, 27, 48]. Naturally, combinations of these methods can also be used. The main approaches to avoid delay-free loops are:

1. By using cascaded transmission lines, so called Richards' structures, and certain types of circulator filters.

**FIGURE 6.34**

Incident and reflected waves into a port with a port resistance  $R$ .

2. By introducing transmission lines between cascaded two-ports.
3. By using reflection-free ports.

### 1.06.7.2 Wave descriptions

It is necessary to use two variables to represent power [25,51]. In the analog domain we usually use voltages and currents, but we may also use any linear combination of voltage and current to describe a network [27,48]. In fact, a network can be described using incident and reflected waves instead of voltages and currents. Scattering parameter formalism has been used in microwave theory for a long time for describing networks with distributed circuit elements.

#### 1.06.7.2.1 Voltage waves

The one-port network shown in Figure 6.34 can be described by the incident and reflected waves instead of voltages and currents.

The voltage waves are defined as

$$\begin{cases} A = V + RI, \\ B = V - RI, \end{cases} \quad (6.50)$$

where  $A$  is the incident wave,  $B$  is the reflected wave, and  $R$  is a positive real constant, called port resistance. The port resistance corresponds to the characteristic impedance in a transmission line.

#### 1.06.7.2.2 Current waves

In a similar way, current waves can be defined, but they results in the same digital filter structure as voltage waves if we instead used the dual reference filter. Since the current wave description do not provide any additional structures we will not discuss current waves any further. There are also simple relations between wave digital filters derived using voltage, current, and power waves [27].

### 1.06.7.2.3 Power waves

In microwave theory, so-called power waves are used

$$\begin{cases} A = \frac{V}{\sqrt{R}} + \sqrt{RI}, \\ B = \frac{V}{\sqrt{R}} - \sqrt{RI}. \end{cases} \quad (6.51)$$

The name power waves comes from the fact that their squared values have the dimension of power. We will mainly use voltage waves, because they provide simpler digital realizations compared to using a power wave description.

### 1.06.7.2.4 Reflectance function

A one-port can be described by the reflectance function which is defined by

$$S = \frac{B}{A}. \quad (6.52)$$

The reflectance function serves a similar purpose as impedances when voltages and currents are used to describe a network. For example the reflectance for an impedance  $Z$  is

$$S = \frac{Z - R}{Z + R}. \quad (6.53)$$

The reflectance is an allpass function for a reactance.

## 1.06.7.3 Wave-flow building blocks

The basic building blocks for the reference filter are unit elements, that are either open- or short-circuited at the far end. The frequency response of such a unit element filter is periodic with a period of  $2\pi/\tau$ , i.e., the same as for a digital filter. The signals and components of the unit element filter can be mapped to a digital filter by sampling with the sample period,  $T = \tau$ , where  $\tau$  is the round-trip for a wave through the unit element. In the following sections, we will derive the wave-flow equivalents to some common circuit elements and interconnection networks.

### 1.06.7.3.1 Circuit elements

In this section we derive the wave-flow representation for some basic circuit elements.

### 1.06.7.3.2 Open-ended unit element

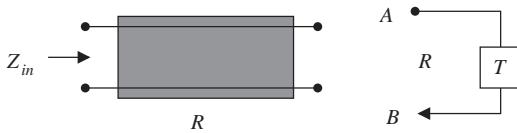

The input impedance to an open-circuited lossless unit element with  $Z_0 = R$  (a  $\Psi$ -plane capacitor) is given in (6.48). The reflectance is

$$S(\Psi) = \frac{Z_{in} - R}{Z_{in} + R} = \frac{1 - \Psi}{1 + \Psi} = e^{-sT} \quad (6.54)$$

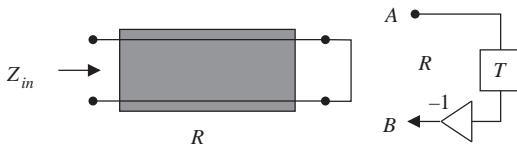

and

$$S(z) = z^{-1}. \quad (6.55)$$

Figure 6.35 show the wave-flow of an open-ended, lossless transmission line and its wave-flow equivalent.

**FIGURE 6.35**

Open-ended lossless transmission line and its wave-flow equivalent.

**FIGURE 6.36**

Short-circuited lossless transmission line and its wave-flow equivalent.

#### 1.06.7.3.3 Short-Circuited Unit element

The input impedance to a short-circuited, lossless unit element with  $Z_0 = R$  (a  $\Psi$ -plane inductor) is given by (6.49). The reflectance is

$$S(\Psi) = \frac{Z_{in} - R}{Z_{in} + R} = \frac{\Psi - 1}{\Psi + 1} = -e^{-s\tau} \quad (6.56)$$

and

$$S(z) = -z^{-1}. \quad (6.57)$$

Figure 6.36 shows the short-circuited lossless transmission line and its wave-flow equivalent.

For sake of simplicity we will not always distinguish between wave-flow graphs in the time and frequency domains. Hence, the wave variables in the figures are denoted  $A$  and  $B$ , but we will when convenient use the notation  $a(n)$  and  $b(n)$ .

An open-ended unit element corresponds to a pure delay, while a short-circuited unit element corresponds to a delay and a  $180^\circ$  phase shift.

#### 1.06.7.3.4 Matched termination

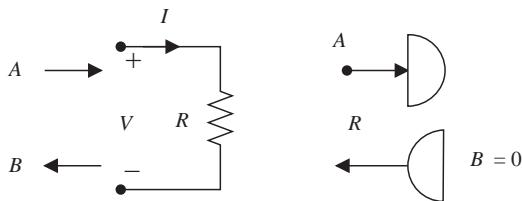

The reflectance for a lossless unit element terminated at the far end with a resistor with  $Z_0 = R$  (matched termination) is

$$S(\Psi) = 0. \quad (6.58)$$

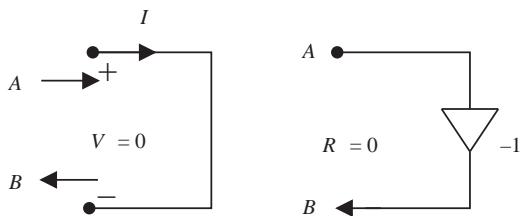

Hence, an input signal to the unit element is not reflected back to the input.

#### 1.06.7.3.5 Resistive load

The reference filters of interest are, for sensitivity reasons, doubly resistively terminated. The load resistor and its corresponding wave-flow equivalent, a wave sink, are shown to the right in Figure 6.37.

**FIGURE 6.37**

Wave-flow equivalent for a resistor,  $R$ .

**FIGURE 6.38**

Wave-flow equivalent for a short-circuit.

### 1.06.7.3.6 Short-circuit

For a short-circuit, we have  $V = 0$ , which yields

$$S(\Psi) = -1 \quad (6.59)$$

and  $B = -A$ . Note that this holds independently of the port resistance. The corresponding wave-flow graph is shown to the right in Figure 6.38.

### 1.06.7.3.7 Open-circuit

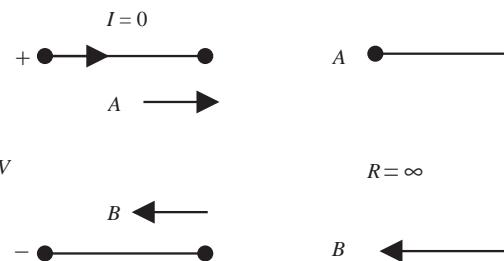

For an open-circuit, we have  $I = 0$ , which yields  $B = A$ . This result holds independently of the port resistance  $R$ . An open-circuit has the reflectance

$$S(\Psi) = 1. \quad (6.60)$$

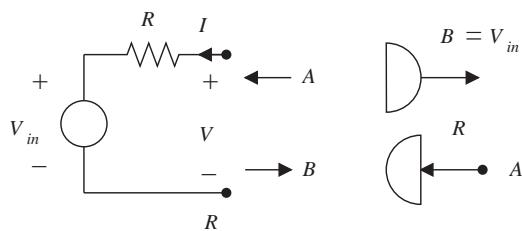

The wave-flow graph for an open-circuit is shown to the right in Figure 6.39.

### 1.06.7.3.8 Voltage signal source

For a signal source with a source resistance we have  $V_{in} = V - RI$ , which yields  $B = V_{in}$ . The incident wave is not reflected by the source since the source resistance equals the port resistance. The corresponding wave-flow graph is shown to the right in Figure 6.40.

**FIGURE 6.39**

Wave-flow equivalent for an open-circuit.

**FIGURE 6.40**

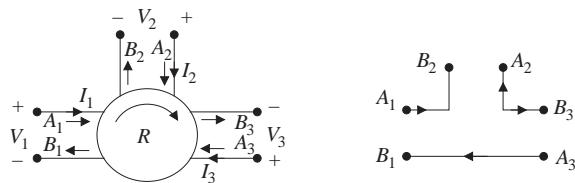

Wave-flow equivalent for a voltage source with source resistance.

### 1.06.7.3.9 Circulator

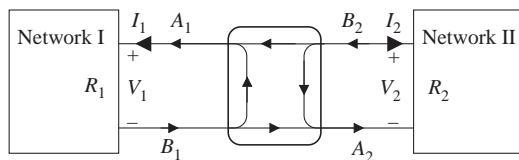

The symbol for a three-port called circulator and its corresponding wave-flow graph is shown in Figure 6.41. The name comes from the fact that an incident wave is “circulated to the next port as shown in Figure 6.41. Note that an incident wave to port 1 is reflected to port 2, and an incident wave to port 2 is reflected to port 3, and so on. Hence, the circulator “circulates the incident waves to the next port in order. Circulators can be realized in the microwave range by using ferrites. Circulators are used, for example, to direct the signals from the transmitter to the antenna and from the antenna to the receiver in a radar. The circulator is a useful component that is inexpensive to implement in wave digital filter.

### 1.06.7.4 Interconnection networks

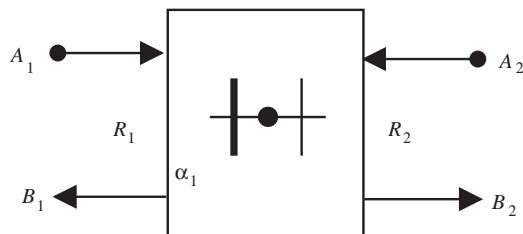

In order to interconnect different wave-flow graphs it is necessary to obey the Kirchhoff's laws at the interconnection. Generally, at the point of connection, the incident waves are partially transmitted and reflected as illustrated in Figure 6.42. The transmission and reflection at the connection port is described by a wave-flow graph called an adaptor. There are several types of adaptors corresponding to different types of interconnection networks [53]. It can be shown that any interconnection network can be decomposed into a set of interconnected two-port and three-port adaptors. Since the interconnection network is lossless, therefore the corresponding adaptor network will also be lossless (see Figure 6.43).

**FIGURE 6.41**

Three-port circulator and the corresponding wave-flow graph.

**FIGURE 6.42**

Connection of two ports.

**FIGURE 6.43**

Symmetric two-port adaptor.

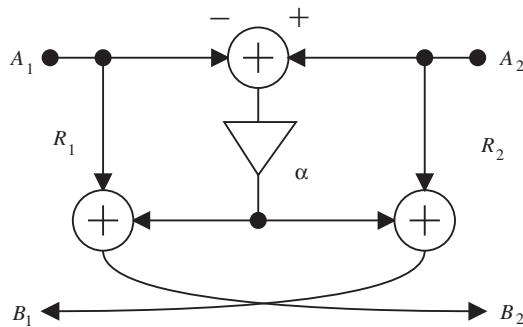

#### 1.06.7.4.1 Symmetric two-port adaptor

Figure 6.44 shows the symbol for the symmetric two-port adaptor. The incident and reflected waves for the two-port are

$$\begin{cases} A_1 = V_1 + RI_1, \\ B_1 = V_1 - RI_1 \end{cases} \quad (6.61)$$

and

$$\begin{cases} A_2 = V_2 + RI_2, \\ B_2 = V_2 - RI_2. \end{cases} \quad (6.62)$$

**FIGURE 6.44**

Symmetric two-port adaptor.

At the point of interconnection we have according to Kirchhoff's current and voltage laws

$$\begin{cases} I_1 = -I_2, \\ V_1 = V_2. \end{cases} \quad (6.63)$$

By elimination of the voltages and currents, we get the following relations between incident and reflected waves for the symmetric two-port adaptor

$$\begin{cases} B_1 = A_2 + \alpha(A_2 - A_1), \\ B_2 = A_1 + \alpha(A_2 - A_1) \end{cases} \quad (6.64)$$

and

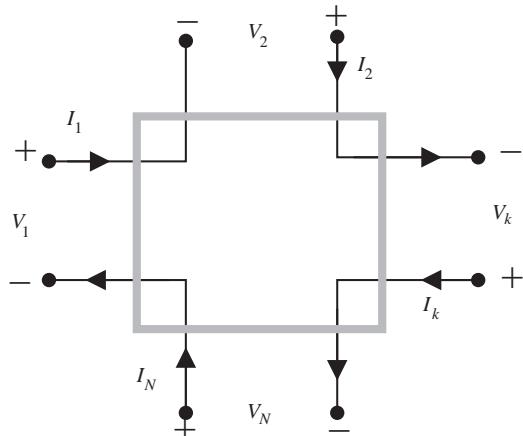

$$\alpha = \frac{R_1 - R_2}{R_1 + R_2}, \quad (6.65)$$

which are illustrated by the wave-flow graph in Figure 6.44.

Note that  $|\alpha| \leq 1$ . The adaptor coefficient  $\alpha$  is usually written on the side corresponding to port 1 and/or one of the parallel lines are thicker. As can be seen, the wave-flow graph is almost symmetric.

Note that  $\alpha = 0$  for  $R_1 = R_2$  and that the adaptor degenerates into a direct connection of the two ports and the incident waves are not reflected at the point of interconnection. For  $R_2 = 0$  we get  $\alpha = 1$  and the incident wave at port 1 is reflected and multiplied by  $-1$  while for  $R_2 = \infty$  we get  $\alpha = -1$  and the incident wave at port 1 is reflected without a change of sign.

Several different adaptor types exist that correspond to interconnections between circuit elements [53]. Symmetric adaptors are commonly used in the first step in the design of wave digital filters. In subsequent design steps these adaptors can be transformed into other types in order to optimize the dynamic signal range.

**FIGURE 6.45**

Series connected ports.

#### 1.06.7.4.2 Series adaptors

Consider the network topology shown in Figure 6.45 with  $N$  ports where the currents that flow through the ports are the same. Hence, the ports are connected in series. We have

$$\begin{cases} I_1 = I_2 = \cdots = I_N, \\ V_1 + V_2 + \cdots + V_N = 0. \end{cases} \quad (6.66)$$

After elimination of voltages and currents we get

$$\begin{cases} B_k = A_k - \alpha_k A_0, \\ A_0 = \sum_{k=1}^N A_k, \end{cases} \quad (6.67)$$

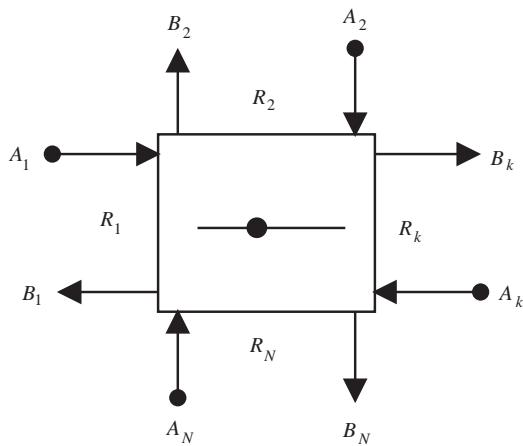

where

$$\alpha_k = \frac{2R_k}{\sum_{n=1}^N R_n}.$$

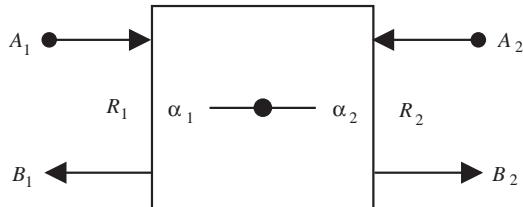

The symbol used for an  $N$ -port series adaptor is shown in Figure 6.46. It is straightforward to show that the sum of the adaptor coefficients is

$$\sum_{k=1}^N \alpha_k = 2. \quad (6.68)$$

Hence, the adaptor coefficients are linearly dependent and one of the coefficients can therefore be eliminated, i.e., expressed in terms of the others. A port for which the adaptor coefficient has been eliminated is called dependent port. It is favorable to select the port with the largest adaptor coefficient as dependent port. The number of different adaptor coefficients can be reduced further if some of the port resistances are the same.

**FIGURE 6.46**

Series adaptor.

**FIGURE 6.47**

Two-port series adaptor.

#### 1.06.7.4.3 Two-port series adaptor

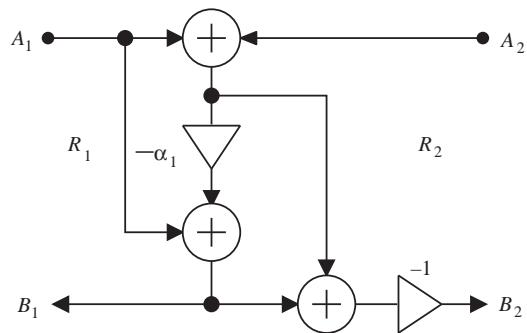

Figure 6.47 shows the symbol for the two-port series adaptor. In this case, we have only two adaptor coefficients and one of them can be eliminated since they are linearly dependent. The resulting wave-flow graph, where  $\alpha_2$  has been eliminated, is shown in Figure 6.48. The remaining adaptor coefficient is

$$\alpha_1 = \frac{2R_1}{R_1 + R_2} \quad (6.69)$$

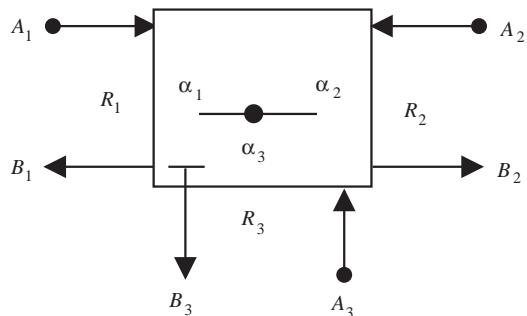

and  $0 \leq \alpha_1 \leq 2$ .

#### 1.06.7.4.4 Three-port series adaptor

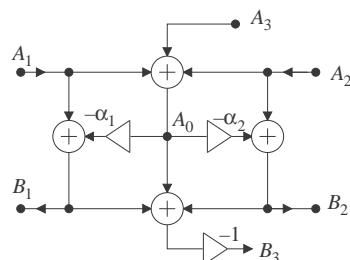

A symbol for the three-port series adaptor is shown in Figure 6.49 and in Figure 6.50 the corresponding realization of the three-port series adaptor, where adaptor coefficient  $\alpha_3$  has been eliminated. Hence, port 3 depends on the adaptor coefficients for the two other ports.

**FIGURE 6.48**

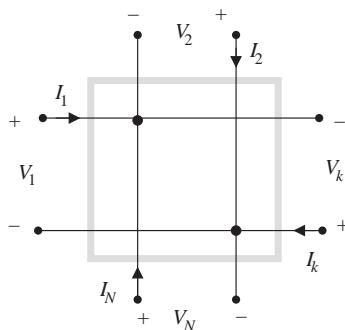

Wave-flow graphs for a two-port series adaptor.

**FIGURE 6.49**

Three-port series adaptor.

**FIGURE 6.50**

Three-port series adaptor with port 3 as the dependent port.

**FIGURE 6.51**

Parallel connection of ports.

This three-port series adaptor requires two multiplications and six additions. It is often favorable, since it required multiplications with shorter coefficient wordlength, to eliminate the adaptor coefficient with the largest magnitude. Hence, the corresponding port is select as the dependent port.

#### 1.06.7.4.5 Parallel adaptors

If all ports have the same voltage, as illustrated in Figure 6.51, then the ports are connected in parallel. We get by using the definition of parallel connection of the ports, i.e.,

$$\begin{cases} V_1 = V_2 = \dots = V_N, \\ I_1 + I_2 + \dots + I_N = 0. \end{cases} \quad (6.70)$$

By elimination of voltages and currents we get

$$\begin{cases} B_k = A_0 - A_k, \\ A_0 = \sum_{k=1}^N \alpha_k A_k, \end{cases} \quad (6.71)$$

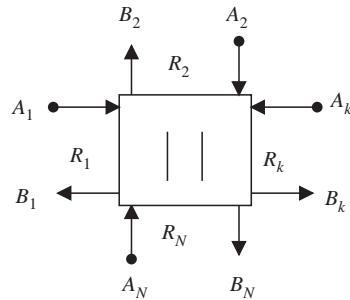

where

$$\alpha_k = \frac{2G_k}{\sum_{n=1}^N G_n}$$

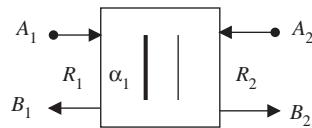

and  $G_k = 1/R_k$ . The symbol for an  $N$ -port parallel adaptor is shown in Figure 6.52. Also for the parallel adaptor we have

$$\sum_{k=1}^N \alpha_k = 2. \quad (6.72)$$

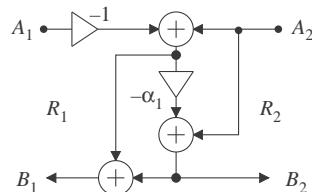

Hence, one of the adaptor coefficients can be expressed in terms of the others. The number of multiplications can be reduced further if some of the port conductances are equal.

**FIGURE 6.52**

*N*-port parallel adaptor.

**FIGURE 6.53**

Two-port parallel adaptor.

**FIGURE 6.54**

Wave-flow graph for two-port parallel adaptor.

#### 1.06.7.4.6 Two-port parallel adaptor

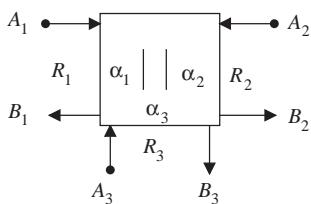

Figure 6.53 shows the symbol for a two-port parallel adaptor and the corresponding wave-flow graph is shown in Figure 6.54.

The sum of the adaptor coefficients in an adaptor is always equal to 2 with the exception of the symmetric two-port adaptor. Hence, one of the coefficients can be expressed in terms of the others and can therefore be eliminated.

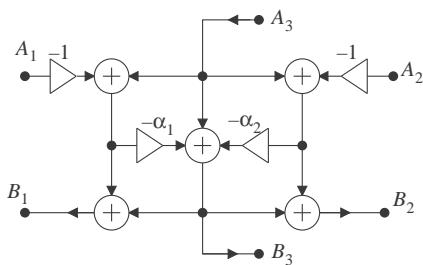

The adaptor coefficient in Figure 6.54 is

$$\alpha_1 = \frac{2G_1}{G_1 + G_2} \quad (6.73)$$

and  $0 \leq \alpha_1 \leq 2$ .

**FIGURE 6.55**

Three-port parallel adaptor.

**FIGURE 6.56**

Three-ports parallel adaptor with port 3 as dependent port.

#### 1.06.7.4.7 Three-port parallel adaptor

A general three-port parallel adaptor requires two multiplications and six additions. The symbol for the three-port parallel adaptor is shown in Figure 6.55.

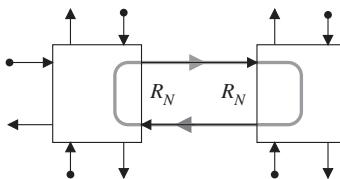

Figure 6.56 shows the wave-flow graph for the corresponding three-port parallel adaptor with port 3 as the dependent port.

#### 1.06.7.4.8 Direct interconnection of adaptors

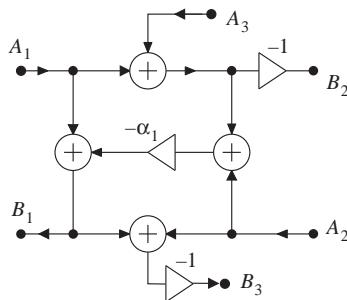

Arbitrary interconnection networks can be built using only two- and three-port series and parallel adaptors. However, in some cases also four-port adaptors are used. Unfortunately, delay-free loops will in general occur if two adaptors are connected, as illustrated in Figure 6.57. The port resistances of the two connected ports must, of course, be equal. This problem can, however, be solved by a judicious choice of the port resistances in one of the connected adaptors.

By selecting the port resistance so that one of the adaptor coefficients, corresponding to the connected ports, becomes equal to unity. We select, for example,  $\alpha_N = 1$ , which for the series adaptor is equivalent to

$$R_N = \sum_{k=1}^{N-1} R_k \quad (6.74)$$

**FIGURE 6.57**

Potentially delay-free loop.

**FIGURE 6.58**

Series adaptor with port 3 and 2 as dependent and reflection-free port, respectively.

and

$$B_N = - \sum_{k=1}^{N-1} A_k. \quad (6.75)$$

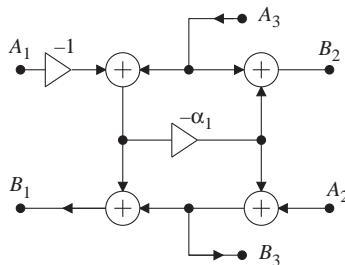

Hence, the reflected wave  $B_N$  is independent of the incident wave  $A_N$  and the delay-free loop is broken. For a parallel adaptor we have

$$G_N = \sum_{k=1}^{N-1} G_k \quad (6.76)$$

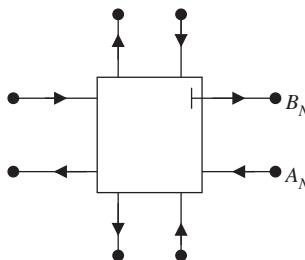

and

$$B_N = \sum_{k=1}^{N-1} \alpha_k A_k. \quad (6.77)$$

In both cases, the expression for  $B_N$  is independent of  $A_N$ , i.e., a direct path from  $A_N$  to  $B_N$  in the wave-flow graph does not exist. Hence, the two ports can be connected without that a delay-free loop occurs. There are no restrictions on the adjacent adaptor. The port with the coefficient equal to unity is called a reflection-free port. Since  $\alpha_N = 1$ , one of the remaining coefficients can be eliminated. Figure 6.58 shows a three-port series adaptor with  $\alpha_3 = 1$  and port 2 as the dependent port.

**FIGURE 6.59**

Parallel adaptor with port 3 as dependent port and port 2 is reflection-free, respectively.

**FIGURE 6.60**

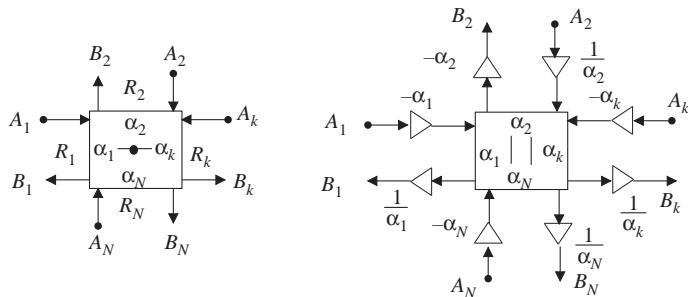

Adaptor with reflection-free port.

Note the non-existent path between A<sub>3</sub> and B<sub>3</sub>. A three-port parallel adaptor with  $\alpha_2 = 1$  and port 3 as dependent port is shown in Figure 6.59. We denote a reflection-free port with the symbol as shown in Figure 6.60.

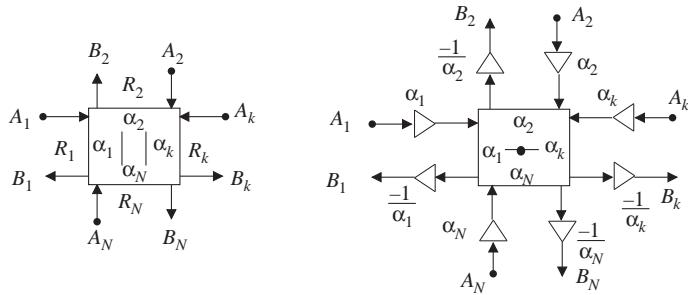

### 1.06.7.5 Adaptor transformations

Adaptor transformations, i.e., replacing series adaptors with parallel adaptors and vice versa, yet with the same adaptor coefficients, can be used to improve the dynamic signal range, lower roundoff noise, and improve the computational properties of the algorithm [53]. Replacing a series adaptor with a parallel adaptor corresponds in the reference filter to replacing an impedance in a series and with a shunt impedance embedded between two gyrators [20]. Thus, a series adaptor is replaced by a parallel adaptor with a pair of inverse multipliers at each port and an inverter at each output terminal as shown in Figure 6.61.

Figure 6.62 shows an N-port parallel adaptor and its equivalent series adaptor. A pair of inverse multipliers can be eliminated, or replaced with any other pair of inverse multipliers, and thereby changing the signal levels in the parallel adaptor network. Note that a pair of inverse multipliers correspond to a transformer in the reference filter. These equivalences transformation changes neither the adaptor coefficients nor the transfer functions, except for a possible change in the gain. Note however, inserting

**FIGURE 6.61**

$N$ -port series adaptor and its equivalent parallel adaptor.

**FIGURE 6.62**

$N$ -port parallel adaptor and its equivalent series adaptor.

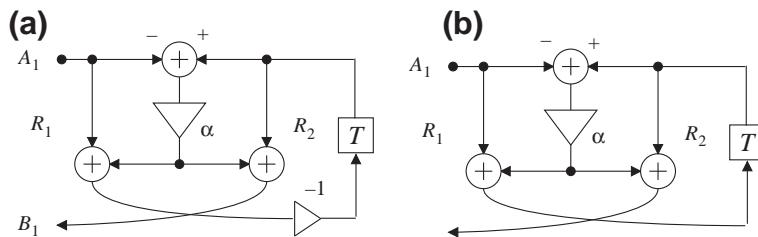

a pair of inverse multipliers requires that the coefficients are of the form  $c = 2^{\pm n}$ , where  $n$  is an integer, since the product  $c(1/c)$ , were both factors are in binary representation, must be equal to 1. A network with  $n$  adaptors, have  $2n$  equivalent realizations, which, however differ with respect to roundoff noise and overflow probability and dynamic signal range.

### 1.06.7.6 Resonance circuits

First- and second-order resonance circuits play an important role as building blocks for frequency selective filters. We are in practice only interested in low order resonance circuits, i.e., first- and second-order circuits. In this section we discuss the design and properties of some resonance circuits and their wave digital counterparts.

#### 1.06.7.6.1 First-order circuits

A first-order wave digital circuit can be derived from a  $\Psi$ -plane capacitor or inductor using series, parallel, or symmetric adaptors. Note that a  $\Psi$ -plane capacitor represents an open-ended unit element

**FIGURE 6.63**

First-order section with (a) inductor, (b) capacitor.

while a  $\Psi$ -plane inductor represents a short-circuited unit element. Figure 6.63 show a first-order circuit corresponding to (a) an inductor and (b) a capacitor realized using the symmetric adaptor.

The reflectance function for the inductor,  $R_2\Psi$ , is

$$S_L(z) = -\frac{\alpha z + 1}{z + \alpha}. \quad (6.78)$$

The reflectance function for the capacitor,  $R_2/\Psi$ , is

$$S_C(z) = \frac{1 - \alpha z}{z - \alpha}, \quad (6.79)$$

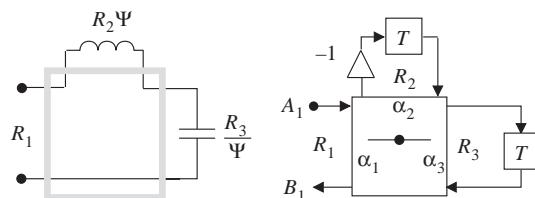

where  $\alpha$  is given by (6.69). Alternatively, first-order circuits corresponding to an inductor or a capacitor can be derived using series or parallel adaptors [14, 27, 53].

#### 1.06.7.6.2 Second-order series resonance circuit

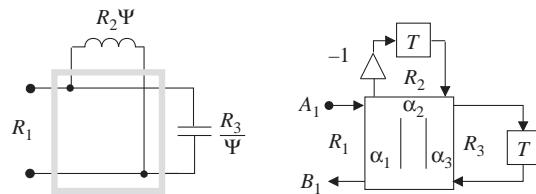

Figure 6.64 shows a second-order series resonance circuit and its wave digital realization using a three-port series adaptor. The reflectance function is

$$S = \frac{B_1}{A_1} = \frac{(1 - \alpha_1)z^2 - (2\alpha_2 + \alpha_1 - 2)z + 1}{z^2 - (2\alpha_2 + \alpha_1 - 2)z + 1 - \alpha_1}. \quad (6.80)$$

Note that the reflection function is an allpass function.

**FIGURE 6.64**

Realization of a series resonance circuit.

**FIGURE 6.65**

Parallel resonance circuit and its WDF counterpart.

### 1.06.7.6.3 Second-order parallel resonance circuit

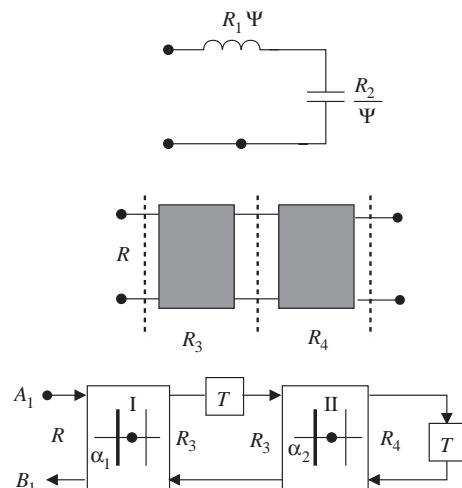

Figure 6.65 shows a parallel resonance circuit and its wave digital realization using a three-port parallel adaptor. The reflectance function is

$$S = -\frac{(1 - \alpha_1)z^2 + (2\alpha_3 + \alpha_1 - 2)z + 1}{z^2 + (2\alpha_3 + \alpha_1 - 2)z + 1 - \alpha_1}. \quad (6.81)$$

The pole density is the same as for the series resonance circuit [14].

### 1.06.7.6.4 Second-order Richards' structures

As discussed in Section 1.06.6.2 a Richards' structure that is either open-circuited or short-circuited at the far end can realize an arbitrary reactance. Figure 6.66 shows second-order Richards' structure

**FIGURE 6.66**

Richards' structure equivalent to second-order series resonance circuit with corresponding wave-flow graph.

and its wave digital counterpart. It can be shown by using Kuroda-Levy identities that this Richards' structure corresponds to a series resonance circuit in the  $\Psi$ -domain [14,27].

The reflectance function is

$$S(z) = \frac{-\alpha_1 z^2 + (\alpha_1 - 1)\alpha_2 z + 1}{z^2 + (\alpha_1 - 1)\alpha_2 z - \alpha_1}. \quad (6.82)$$

A Richard's parallel resonance circuit has the same reflectance function, except that  $\alpha_1$  has changed sign. Hence, the two structures have the same pole density.

### 1.06.7.7 Parasitic oscillations

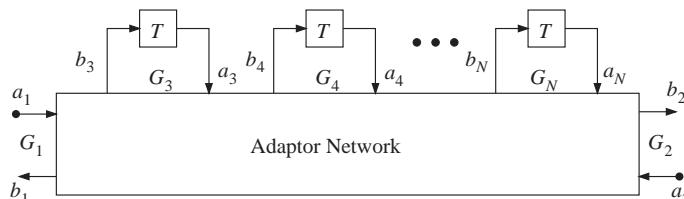

Parasitic oscillations can occur only in recursive structures. Nonrecursive digital filters can have parasitic oscillations only if they are used inside a closed loop. Nonrecursive FIR filters are therefore robust filters structures that do not support any kind of parasitic oscillation. Among the IIR filter structures, wave digital filters, and certain related state-space structures, are of major interest as they can be designed to suppress parasitic oscillations. A. Fettweis has shown that overflow oscillations can be suppressed completely in wave digital filters by placing appropriate restrictions on the overflow characteristic [27,54–57]. To show that a properly designed wave digital filter suppresses any parasitic oscillation we use the concept of pseudo-power, which corresponds to power in analog networks. Note that the pseudo-power concept is defined only for wave digital filters and not for arbitrary filter structures.

The instantaneous pseudo-power entering the adaptor network, shown in Figure 6.67, is defined

$$p(n) = \sum_{k=1}^N G_k (a_k(n)^2 - b_k(n)^2). \quad (6.83)$$

Ideally,  $p(n) = 0$ , since the adaptors are lossless and an arbitrary network of adaptors is also lossless.

Now, in order to suppress a disturbance (error signal component) caused by a nonlinearity, it is sufficient to introduce losses in each port of the network such that the nonlinearities corresponds to pure losses. This can be accomplished by making each term  $a_k(n)^2 - b_k(n)^2 > 0$ , i.e., each recursive loop will be lossy. Note that all recursive loops must contain at least one delay element for a sequentially computable algorithm. Any parasitic oscillation will therefore by necessity appear at one or several of the ports with delay elements. Hence, a parasitic oscillation, which, of course, has finite pseudo-energy

**FIGURE 6.67**

Wave digital filter.

and is not supported from an external signal source will decay to zero since it will dissipate energy in the lossy ports of the adaptor network. Lossy ports can be obtained by quantizing the reflected waves such that their magnitudes are always decreased. Hence, for each nonzero reflected wave we required that

$$\begin{cases} |b(n)_Q| < b(n)_{\text{exact}}, \\ b(n)_Q b(n)_{\text{exact}} \geq 0, \end{cases} \quad (6.84)$$

where the second constraint is to assure that the signals have the same sign.

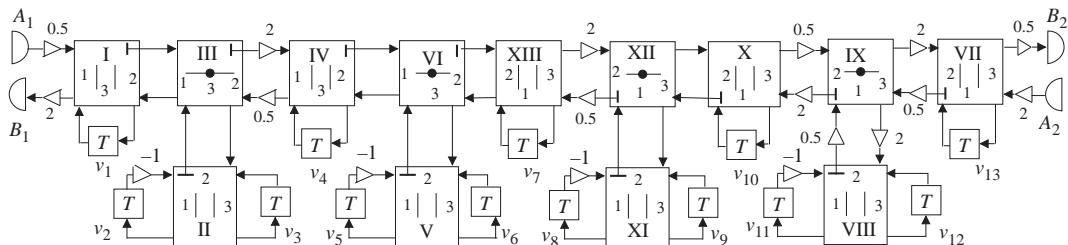

In order to suppress parasitic oscillations, all of the output signals from the adaptors should be sign-magnitude truncated. It can be shown that the sign-magnitude truncation can be substituted by truncation of the signals after the multiplications inside the adaptors and by adding a correcting term at the outputs of the adaptors [14]. This implies considerable hardware simplifications. In practice, it seems to be sufficient that the correcting terms are added only at those ports to which delays are connected

### 1.06.7.8 Ladder wave digital filters

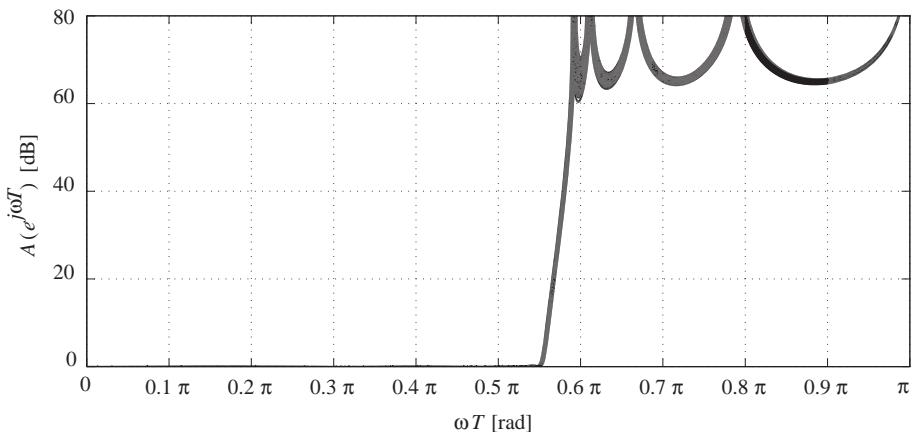

Doubly resistively terminated ladder structures, which are designed for maximal power transfer in the passband, are characterized by their low element sensitivity. A corresponding wave digital filter inherits the sensitivity properties as well as the stability properties of the analog reference filter. The positions of the transmission zeros are also relative insensitive since they are realized by reflections in the resonance circuits. This is true for filters that approximate a constant passband gain. However, it is not true for, for example, a filter that approximate a differentiator.

There are several alternative ladder design techniques:

- Unit elements can be inserted between the branches in the ladder structure in order to avoid delay-free loops [14, 25, 27, 52, 58]. These filters are of less importance.
- Reference filters of Richards' type, i.e., cascaded transmission lines, may be used to realize lowpass and highpass filters and a restricted set of bandpass and stopband filters [14]. Also these filters are of less importance.
- A commonly used class of wave digital filters are derived from a singly resistively terminated Richards' structure [14, 59–62]. The corresponding wave digital filter is used to realize the denominator. The numerator is realized by either injecting the input signal into several nodes in the recursive wave digital filter structure or using linear combination of the signal in several nodes, or a combination thereof. Singly resistively terminated filter has very high element sensitivity [20] and they are not recommended for use as frequency-selective filters. Moreover, these structures suffer from large variations in the internal signal levels and they also generate large roundoff noise. The design of the above wave digital filters is discussed in detail in [14, 17].
- Here we recommend wave digital filters derived from a doubly resistively terminated ladder and we use the technique with reflection-free ports to obtain a wave digital filter without delay-free loop.
- Alternatively we may select a wave digital filter derived from a doubly resistively terminated lattice filter, and use reflection-free ports or a cascade of allpass sections, to obtain a wave digital filter without delay-free loop.

**FIGURE 6.68**

Ninth-order ladder wave digital filter.

**FIGURE 6.69**

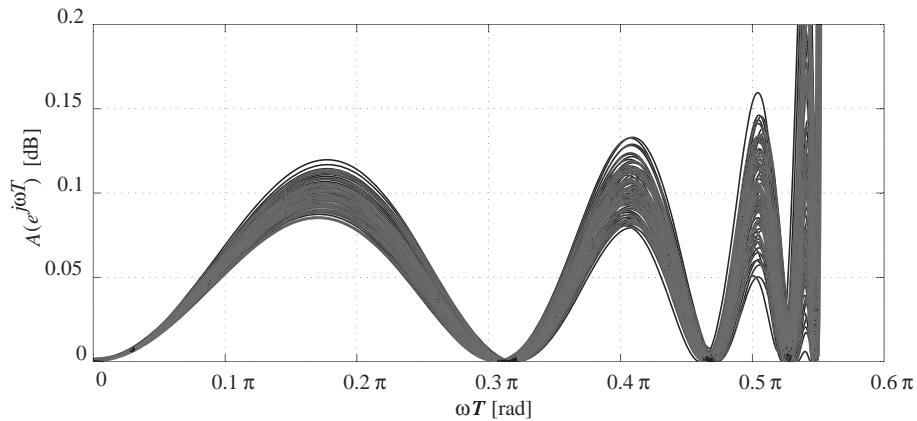

Variation in the attenuation for the ninth-order ladder filter.

#### 1.06.7.8.1 Example 4

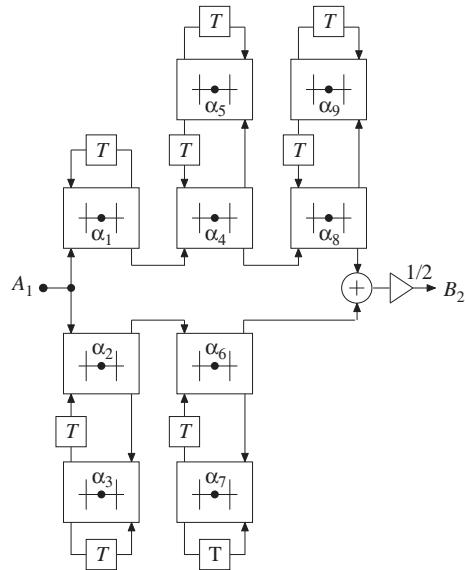

Consider a lowpass filter with the following specification  $A_{\max} = 0.1$  dB,  $A_{\min} = 65$  dB,  $\omega_c T = 0.55\phi$  rad, and  $\omega_s T = 0.6\phi$  rad. Minimum order is  $N_{\min} = 8.499$ , which we increase to  $N = 9$ .

The ladder structure can be scaled by inserting transformers between adjacent adaptors. Each transformer allows one node in an adaptor to be scaled. The adaptors with a reflection-free port have only one critical node, i.e., the input to the multiplier. Hence, all critical nodes can be scaled, except one node in adaptor XIII, which have two critical nodes. The  $L_2$ -norm scaled structure is shown in Figure 6.68. Note that filters should be scaled in order to fairly compare the sensitivity properties (see Figure 6.69).

In order to illustrate and make a crude comparison of the coefficient sensitivity of a  $\pi$ -ladder and lattice filter with cascaded allpass sections, we generate 100 frequency responses where we randomly vary the coefficients in the range  $-2^{-8}$  to  $2^{-8}$  around their nominal values. The overall variation in the attenuation is shown in Figure 6.72.

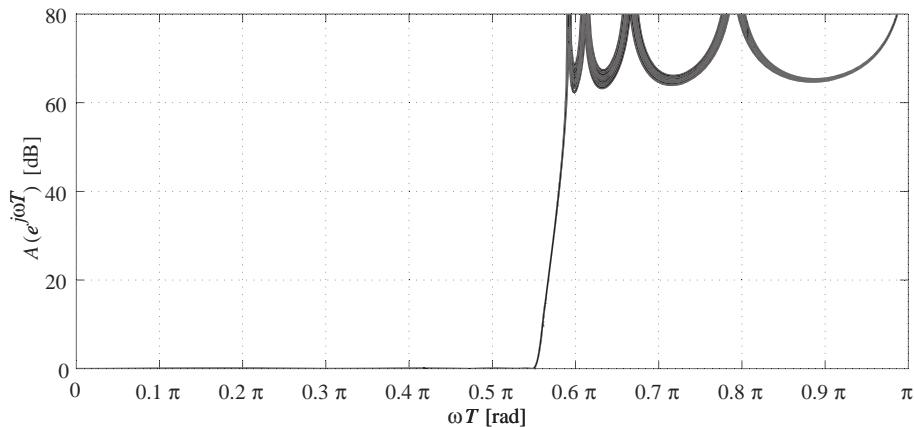

**FIGURE 6.70**

Passband variation in the attenuation for the ninth-order ladder filter.

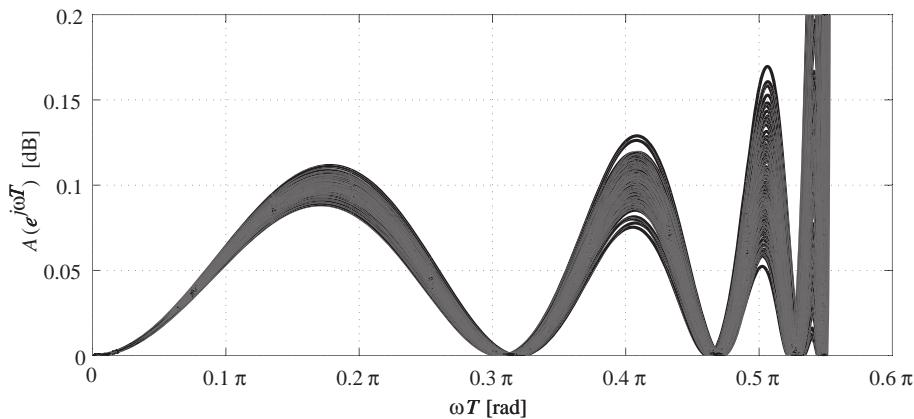

**FIGURE 6.71**

Ninth-order lattice WDF.

The variation is most significant close to the stopband edge. In fact, we will later see that the variation in the positions of the zeros is smaller for the ladder structure compared to a corresponding lattice structure. The variations in the zeros are relatively small, because a zero is determined by only one coefficient. For example, consider the structure, shown in Figure 6.68. Port 2 of adaptor II is

**FIGURE 6.72**

Variation in the attenuation for the ninth-order lattice filter.

**FIGURE 6.73**

Passband variation in the attenuation for the ninth-order lattice filter.

reflection-free and hence  $\alpha_2 = 1$  and therefore we have  $\alpha_1 + \alpha_3 = 1$ . Thus, the transmission zero, which is restricted to the unit circle, is determined by only a single coefficient and the accuracy is determined by the coefficient wordlength. The variation in the attenuation in the passband is shown in Figure 6.73.

The variation increases towards the passband edge, which is in agreement with (6.27). A realization, possibly with somewhat shorter coefficient wordlength, may have been found if the filter instead was synthesized with a diminishing passband ripple. Note that it is most likely that a set of coefficients can be found with shorter wordlength than 9 bit. Typically, the coefficients can be represented using only two or three nonzero bits, i.e., requiring only one or two adders. 14 multipliers are required for the ladder

structure. Wave digital ladder structures appear to yield complicated wave-flow graphs that may make them difficult to implement efficiently. However, a detailed analysis shows that this is not the case [14].

### 1.06.7.9 Lattice wave digital filters

Lattice wave digital filters are derived from an analog bridge structure and have therefore very high stopband sensitivity. Different wave digital lattice structures are obtained depending on how the lattice branches are realized. We may use Forster and Cauer networks or high-order Richards' structures. A realization consisting of a set of interconnected three-port circulators that are loaded with first- and second-order reactances have become popular, mainly due to the fact that they are easy to design and that they consist of simple allpass sections [14, 63–65].

#### 1.06.7.9.1 Example 5

Figure 6.71 shows a ninth-order lattice wave digital filter where the two allpass branches has been realized by a circulator structures [20] that is loaded with first- and second-order sections of the types shown in Figure 6.66 (see Figure 6.70).

In order to get a similar deviation in the stopband attenuation as in Figures 6.72 and 6.73, we restrict the error range of  $-2^{-15}$  to  $2^{-15}$ . That is, to about  $2^7 = 128$  times smaller range. The resulting variation in the attenuation is shown in Figure 6.72. It is evident that the stopband sensitivity is much larger compared to the sensitivity for the corresponding ladder structure and that the precision in the adaptor coefficients is not enough. The passband variation, when the error range is decreased to  $-2^{-8}$  to  $2^{-8}$ , is shown in Figure 6.73.

---

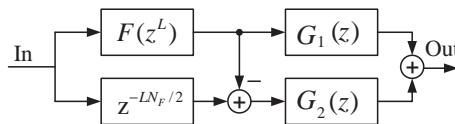

## 1.06.8 Frequency response masking (FRM) structure

For given passband ripple and stopband attenuation, the filter order, as well as the number of non-trivial coefficients, of a direct form FIR filter, is according to (6.8) inversely proportional to the transition width. Therefore, sharp filters suffer from high computational complexity due to the high filter orders. Lim [66] proposed a frequency response masking (FRM) FIR filter structure in 1986 for the design of sharp FIR filters with low computational complexity. The structure was thereafter modified and improved by many researchers to achieve even further computation savings, and has been extended to the design of various types of filters, such as half-band filters, multirate filters, recursive filters, and two-dimensional filters.

### 1.06.8.1 Basic FRM structure

Just as the name implies, FRM uses masking filters to obtain the desired frequency responses. The overall structure of an FRM is a subfilter network, consisting of three subfilters, as shown in Figure 6.74. The three subfilters are a bandedge shaping prototype filter with  $z$ -transform transfer function  $F(z)$  and two masking filters with  $z$ -transform transfer functions  $G_1(z)$  and  $G_2(z)$ , respectively; their corresponding frequency responses are denoted as  $F(e^{j\omega T})$ ,  $G_1(e^{j\omega T})$ , and  $G_2(e^{j\omega T})$ , respectively.

In FRM structure, every delay of the bandedge shaping prototype filter  $F(z)$  is replaced by  $L$  delays. The frequency response of the resulting filter,  $F(z^L)$ , is a frequency compressed (by a factor of  $L$ ) and periodic version of  $F(z)$ , as shown in Figures 6.75 a and b; the transition band of  $F(z)$  is mapped to

**FIGURE 6.74**

Structure of the frequency response masking filter.

$L$  transition bands with transition width shrunk by a factor of  $L$ . The complementary filter of  $F(z^L)$  is obtained by subtracting  $F(z^L)$  from a pure delay term,  $z^{-LN_F/2}$ , where  $N_F$  is the order of  $F(z)$ . (To avoid a half delay,  $N_F$  is chosen to be even.) Thus, the entire frequency region from DC to Nyquist frequency is decomposed into  $L$  bands;  $F(z^L)$  and its complement hold alternate band respectively, as shown in Figure 6.75b. Using two masking filters  $G_1(z)$  and  $G_2(z)$ , whose frequency responses are given in Figure 6.75c, to filter the outputs of  $F(z^L)$  and its complement, the desired frequency bands are kept and then combined to obtain the final frequency response, shown in Figure 6.75d.

Throughout this chapter, for simplicity, the number of delays replacing one delay in the impulse response of the bandedge shaping prototype filter,  $L$ , is referred to as the compression factor of the FRM filter.

The overall  $z$ -transform transfer function of the FRM structure,  $H(z)$ , is given by,

$$H(z) = F(z^L)G_1(z) + \left( z^{-LN_F/2} - F(z^L) \right) G_2(z) \quad (6.85)$$

In a synthesis problem, the passband and stopband edges of the overall filter  $H(z)$ , denoted as  $\omega_c T$  and  $\omega_s T$ , respectively, are given, whereas the passband and stopband edges of the prototype filter  $F(z)$ , denoted as  $\theta$  and  $\varphi$ , have to be determined. Depending on, if the transition band is generated from  $F(z^L)$  or its complement, as shown in Figures 6.75d and f, respectively,  $\omega_c T$  and  $\omega_s T$  are given by

$$\omega_c T = \frac{2l\pi + \theta}{L}, \quad \omega_s T = \frac{2l\pi + \varphi}{L} \quad (6.86)$$

and

$$\omega_c T = \frac{2l\pi - \varphi}{L}, \quad \omega_s T = \frac{2l\pi - \theta}{L} \quad (6.87)$$

respectively. Denoting the two cases as Case A and Case B, for a given  $L$ , it is shown that only one or none of the above two cases results in an  $F(e^{j\omega T})$ , so that  $0 \leq \theta \leq \varphi \leq \pi$  is satisfied.

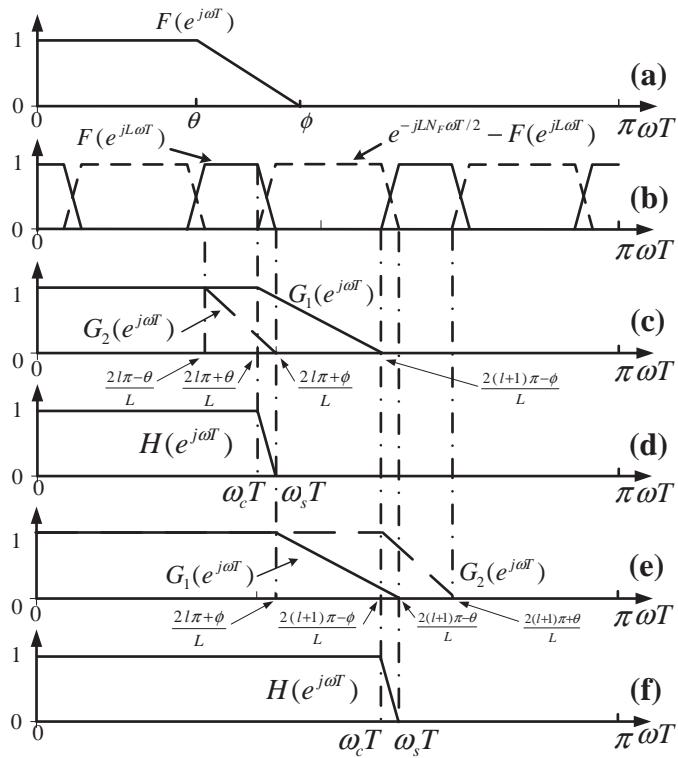

Case A,

$$\theta = \omega_c TL - 2l\pi, \quad \varphi = \omega_s TL - 2l\pi \quad \text{for } l = \lfloor \omega_c TL / 2\pi \rfloor.$$

Case B,

$$\theta = 2l\pi - \omega_s TL, \quad \varphi = 2l\pi - \omega_c TL \quad \text{for } l = \lceil \omega_s TL / 2\pi \rceil,$$

where  $\lfloor x \rfloor$  is the largest integer less than  $x$ , and  $\lceil x \rceil$  is the smallest integer larger than  $x$ . Figures 6.75c and d show a Case A example, whereas Figures 6.75e and f show a Case B example.

**FIGURE 6.75**

Frequency response of FRM subfilters.

Since the transition width of  $F(z)$  is  $L(\omega_s T - \omega_c T)$  for given  $\omega_c T$  and  $\omega_s T$ , and the sum of the transition width of  $G_1(z)$  and  $G_2(z)$  is  $2\phi/L$ , the complexity of  $F(z)$  decreases with increasing  $L$ , while the complexity of  $G_1(z)$  and  $G_2(z)$  increases with increasing  $L$ . The best  $L$  minimizing the arithmetic complexity in terms of the number of multipliers is achieved by

$$L = \frac{1}{\sqrt{2\beta(\omega_s T - \omega_c T)/\pi}}, \quad (6.88)$$

where  $\beta = 1$  if the subfilters are optimized separately [67], and  $\beta = 0.6$  if the subfilters are optimized jointly [68].

The basic FRM structure, utilizing the complementary periodic filter pairs and masking filters, synthesizes sharp filter with low arithmetic complexity. When [67]

$$\omega_s T - \omega_c T < 0.126\pi \text{ rad}$$

the arithmetic complexity saving is achieved by using FRM structure, compared with the direct form FIR structures. In a typical design with  $\omega_s T - \omega_c T < 0.002\pi \text{ rad}$ , the FRM structure reduces the

number of multipliers by a factor of 10, and the price paid for the arithmetic saving is a less than 5% increase in the overall filter order [68].

A special case of FRM filter, named as interpolated FIR (IFIR) filter [69], was earlier developed by Neuvo et al. IFIR consists of the upper branch of the FRM structure, and can therefore only be used to design narrow and wide band sharp FIR filters.

Some modified FRM structures were proposed in [70–72] for further complexity reductions mainly of the masking filters.

### 1.06.8.2 Multistage FRM structure

In the above basic FRM structure, if the order of  $F(z)$  is too high due to a sharp transition width of  $F(z)$ , the FRM technique can be used recursively to form a multistage FRM structure to reduce the complexity.

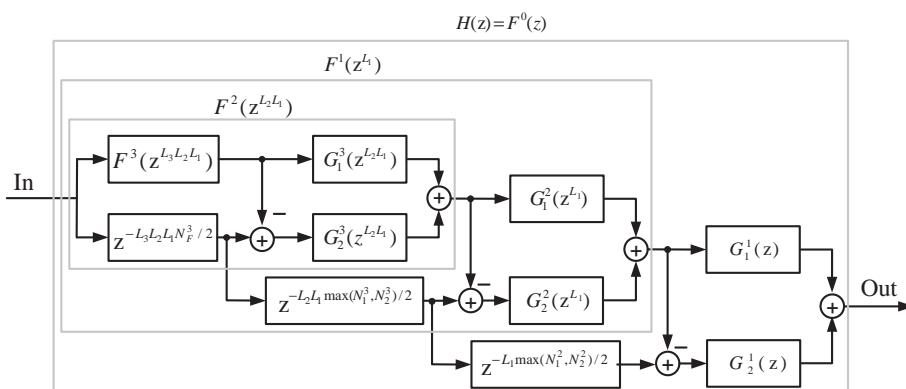

In a  $K$ -stage FRM structure, the  $z$ -transform transfer function of the overall system  $H(z)$  is recursively constructed as

$$H(z) = F^0(z),$$

$$F^{k-1}(z) = F^k(z^{L_k})G_1^k(z) + \left[ z^{-\frac{L_k N_F^k}{2}} - F^k(z^{L_k}) \right] G_2^k(z),$$

for  $k = 1, 2, \dots, K$ , where  $N_F^k$  is the filter order of the  $k$ th stage bandedge shaping prototype filter  $F^k(z)$ ,  $G_1^k(z)$  and  $G_2^k(z)$  are the  $k$ th stage masking filters, with orders of  $N_1^k$  and  $N_2^k$ , respectively. An example of a 3-stage FRM structure is shown in Figure 6.76.

It was discovered theoretically in [67] that the optimum number of stages to achieve the minimum arithmetic complexity is independent of the band ripple requirements, but solely determined by the

**FIGURE 6.76**

A 3-stage FRM structure.

transition width. The optimum value of the number of stage  $K$  satisfies the constraint

$$\beta_b(K) \leq \omega_s T - \omega_c T \leq \beta_b(K - 1), \quad (6.89)$$

where  $\beta_b(K) \cong \frac{1}{4} \left( \frac{K+1}{K+2} \right)^{(K+1)(K+2)}$ . When a filter is constructed in FRM structure with the optimum number of stage  $K_{\text{opt}}$  satisfying the constraint in (6.89), the compression factors of  $L_k$  for  $k = 1, 2, \dots, K$ , tends to be equal, and are given by

$$\left( \frac{K_{\text{opt}} + 1}{K_{\text{opt}}} \right)^{K_{\text{opt}}} \leq L_k \leq \left( \frac{K_{\text{opt}} + 2}{K_{\text{opt}} + 1} \right)^{K_{\text{opt}} + 2}. \quad (6.90)$$

It is interesting to note that both the lower bound and upper bound in (6.90) approaches  $e(\cong 2.7$ , the base of the nature logarithm) when  $K$  is large.

Practical design experience showed that for a given filter transition width and a given stage  $K$ , the minimum arithmetic complexity is achieved when [68]

$$L_k = \left\lceil \frac{1}{\sqrt[(K+1)]{2\beta(\omega_s T - \omega_c T)/\pi}} \right\rceil, \quad (6.91)$$

for  $k = 1, 2, \dots, K$ , where  $\beta = 1$  if the subfilters are optimized separately [67], and  $\beta = 0.6$  if the subfilters are optimized jointly [68].

Considering both the theoretic analysis in [67] and the practical design experience in [68], the overall arithmetic complexity of a given filter specification is in proximity to the minimum if  $K$  in (6.91) is chosen such that  $L_k$  is 2 or 3.

### 1.06.8.3 FRM structure for half-band filter and Hilbert transformer

The synthesis of half-band filters using FRM has to ensure, that the alternate coefficient values are trivial except, that the centre coefficient has a value of 0.5 [73].

Consider a zero phase half-band bandedge shaping prototype filter of order  $N_F = 4N - 2$ , and transfer function  $F(z)$  given by

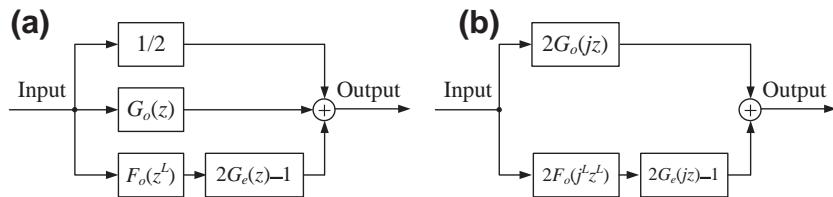

$$F(z) = 1 + F_0(z), \quad (6.92)$$

where  $F_0(z)$  consists of only odd powers of  $z$ . A half-band FRM filter  $H(z)$  can be constructed from this prototype filter by

$$H(z) = \left[ 1 + \frac{1}{2} F_0(z^L) \right] G_1(z) + \left[ 1 - \frac{1}{2} F_0(z^L) \right] [1 - G_1(-z)] \quad (6.93)$$

for odd  $L$ , where  $G_1(z)$  is an even order lowpass masking filter. Let  $G_o(z)$  consist of odd power terms of  $z$ , and  $G_e(z)$  consist of even power terms of  $z$ , of the masking filter  $G_1(z)$ , respectively. Hence  $G_1(z) = G_o(z) + G_e(z)$ , and we have

$$H(z) = \frac{1}{2} + G_o(z) + F_0(z^L)[2G_e(z) - 1]. \quad (6.94)$$

**FIGURE 6.77**

Structure for synthesizing (a) half-band filter and (b) Hilbert transformer.

Thus,  $H(z)$  consisting of a constant term and terms with odd power of  $z$ , is a half-band filter. The filter structure is shown in Figure 6.77a.

A Hilbert transformer may be derived from a unity half-band filter by subtracting the constant  $1/2$  from its transfer function, modulating the remaining coefficients by  $e^{j\pi/2}$ , and then scaling the response by 2. Thus, the transfer function of the Hilbert transformer  $H_H(z)$  can be written from (6.94) to [74]

$$H_H(z) = 2G_o(jz) + 2F_o(j^L z^L)[2G_e(jz) - 1] \quad (6.95)$$

The structure of Hilbert transformer is shown in Figure 6.77 (b).

#### 1.06.8.4 FRM structure for multirate filter and filter bank

##### 1.06.8.4.1 Decimator and interpolator

In polyphase implementation of multirate filters, such as interpolators and decimators with a sampling rate change factor of  $M$ , that are realized as a cascade of two filters, generally only one of the two filters may achieve the “factor of  $M$ ” reduction in computational complexity, unless the output of the first filter is nonzero only at intervals of  $M$ . In the original FRM structure shown in Figure 6.74, if  $L$  is an integer multiple of  $M$ , the outputs of  $F(z^L)$  and its complementary filter can be nonzero only at intervals of  $M$ . However, to synthesize a filter with transition band centered at  $\pi/M$  as in the interpolator and decimator, the original FRM has constraints on the selection of the compression factor  $L$  that neither  $L\omega_c T/\pi$  nor  $L\omega_s T/\pi$  is an integer according to (6.86) and (6.87), and  $\lfloor L\omega_c T/\pi \rfloor = \lfloor L\omega_s T/\pi \rfloor$ . Therefore, due to these two constraints,  $L$  cannot be selected as an integer multiple of  $M$  to achieve a “factor of  $M$  reduction” in computational complexity in multirate filters.

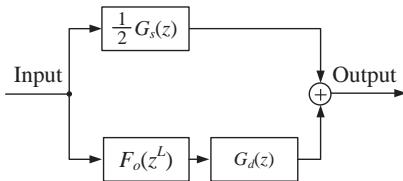

A variant of the FRM structure proposed in [74] achieves the “factor of  $M$  reduction” in a multirate filter with sampling rate change factor  $M$ . The following is an illustration of an interpolator with an upsampling rate  $M$ . The same technique applies to decimators as well. The variant of the FRM is constructed from

$$H(z) = \frac{1}{2}G_s(z) + F_o(z^L)G_d(z), \quad (6.96)$$

where

$$G_s(z) = G_1(z) + G_2(z),$$

$$G_d(z) = G_1(z) - G_2(z),$$

**FIGURE 6.78**

FRM structure for the synthesis of decimation and interpolation filters.

and  $F_o(z)$  is given in the condition of (6.92) for a half-band prototype bandedge shaping filter  $F(z)$ ;  $G_1(z)$  and  $G_2(z)$  are the masking filters as that in Figure 6.74. The factor  $M$  interpolation or decimation filter, constructed in such a manner, has a transition band centered at  $\pi/M$ . The filter structure is shown in Figure 6.78.

For  $M$  even,  $2L$  has to be an odd multiple of  $M$ , while for  $M$  odd,  $2L$  has to be an even multiple of  $M$ . In addition, when  $M$  is odd,  $F(z)$  is replaced by  $F(ze^{-j\frac{\pi}{2L}})$ , and  $G_1(z)$  and  $G_2(z)$  are replaced by  $G_1(ze^{-j\frac{2\theta}{L}})$  and  $G_2(ze^{j\frac{2\theta}{L}})$ , respectively, where  $G(z)$  is a prototype masking filter specified by passband and stopband edges of  $\theta_G = \frac{(2L-M)\pi}{2LM}$  and  $\varphi_G = \frac{(2L+M)\pi}{2LM}$ , respectively.

In implementation, both  $G_s(z)$  and  $F_o(z^L)$  can be decomposed into  $M$  polyphase components efficiently using polyphase structures since the inputs are nonzero only at intervals of  $M$ . For  $G_d(z)$ , besides the fact that the output of  $F_o(z^L)$  is nonzero at intervals of  $M$  samples, only the first polyphase component of  $F_o(z^L)$  has nonzero coefficients, because it is a function of  $z^{-2L}$  and  $2L$  is an integer multiple of  $M$ . Therefore,  $G_d(z)$  may be decomposed into  $M$  polyphase components efficiently as well.

In [75], two alternative FRM structures are proposed for the design of interpolation and decimation by a factor of  $M$ , where the transition band is not restricted to include  $\pi/M$ . In this approach, additional constraints are imposed to the masking filters, such that

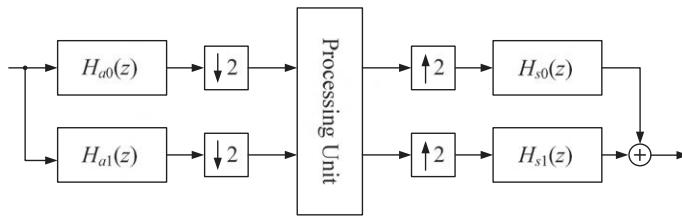

$$G_2(z) = G_1(z) - \frac{M}{M-1}G_{10}(z^M) + \frac{1}{M-1} \quad (6.97)$$

or

$$G_1(z) = G_2(z) - \frac{M}{M-1}G_{20}(z^M) + \frac{1}{M-1}, \quad (6.98)$$

where  $G_{10}(z)$  and  $G_{20}(z)$  are the 0-th polyphase components in the polyphase representations of  $G_1(z)$  and  $G_2(z)$ , respectively. The relations in (6.97) and (6.98) specify the class I and class II FRM structures. These relations impose further constraints on the selection of  $l$  and  $L$  in (6.86) and (6.87). However, the available choices are sufficient to obtain arbitrary frequency selectivity in the filter design and meanwhile achieve complexity reduction.

When the masking filters are related to each other as those shown in (6.97) and (6.98), both the bandedge shaping filter and the masking filters can be decomposed into polyphase structure, such that all filters are working at the lower sampling rate involved in the interpolation or decimation.

**FIGURE 6.79**

Two-channel maximally decimated filter bank.

It is interesting to note that both (6.97) and (6.98) are reduced to  $G_2(z) = 1 - G_1(z)$  when  $M = 2$ ; this relation is the same as that in the half-band FRM structure given in (6.93). In fact, when the transition band is restricted to include  $\pi/M$ , the proposed approach is a generalization of that in [73] and an  $M$ th band filters are obtained.

Besides the above two FRM filter structures, a factor of two interpolation and decimation filters are developed in [76], based on a recursive filter structure introduced in next section.

#### 1.06.8.4.2 Filter banks

A two-channel maximally decimated filter bank utilizing the FRM structure is proposed in [77]. In the diagram of a two-channel filter bank shown in Figure 6.79, each analysis and synthesis filter of the proposed technique is realized through a modified FRM structure with the same bandedge shaping prototype filter. The transfer functions of the analysis and synthesis filters are given by

$$\begin{aligned} H_{ak}(z) &= F(z^L)G_{k1}(z) + F_c(z^L)G_{k2}(z), \\ H_{sk}(z) &= F(z^L)G_{k1}(z) - F_c(z^L)G_{k2}(z), \end{aligned}$$

for  $k = 0, 1$ .

In this FRM structure, the original magnitude complementary filter of the bandedge shaping filter,  $1 - F(z)$ , is modified to an approximately power complementary filter, i.e.,  $F_c(z)$  is related to  $F(z)$  in a form of

$$F_c(z) = F(-z)$$

and the filter order is constrained to odd order. In addition, the compression factor  $L$  is selected to be odd. By relating the masking filters in the lower branch,  $G_{11}(z)$  and  $G_{12}(z)$ , to that in the upper branch,  $G_{01}(z)$  and  $G_{02}(z)$ , respectively as

$$G_{11}(z) = -G_{02}(-z)$$

and

$$G_{12}(z) = G_{01}(-z)$$

an aliasing free filter bank is constructed.

This technique is further extended to a modulated  $M$ -channel filter banks by using the analysis and synthesis filters in the upper branch of the two-channel filter bank as the prototype filters for

modulation [78]. Together with a cosine modulation block and a sine modulation block, a near perfect reconstructed  $M$ -channel maximally decimated filter bank is developed.

Other FRM structures for filter banks are mainly developed for two-channel filter banks, including non-uniform filter banks with rational sampling factor [79] and multi-plet perfect reconstruction filter banks [80]. In addition, a non-multirate fast filter bank (FFB) is developed in [81], to realize the function of sliding FFT filter bank with low computational complexity, but achieving high frequency selectivity and passband performance.

#### 1.06.8.4.3 Cosine-modulated transmultiplexer

Due to the same constraints on the selection of the compression factor  $L$ , the prototype bandedge shaping filter for an  $M$  band transmultiplexer (TMUX) is not realizable if  $L$  is an integer multiple of  $M$ . Unlike the variant structure proposed in [74], in [82], an implementation of an  $M$  band cosine-modulated TMUX (CMT) for

$$L = 2K_a M + \frac{M}{K_b}, \quad (6.99)$$

where  $K_a$  is a non-negative integer and  $K_b$  is a positive integer, is proposed.

If only the upper branch in the original FRM structure is used as the prototype filter for the CMT, the transfer function for the analysis filter becomes

$$H_m(z) = \sum_{n=0}^N c_{m,n} \left( f^L * g_1 \right) (n) z^{-n}, \quad (6.100)$$

where  $c_{m,n} = 2 \cos \left[ \frac{(2m+1)(n-\frac{N}{2})}{2M} + (-1)^m \frac{\pi}{4} \right]$  for  $m = 0, 1, \dots, M-1$  and  $n = 0, 1, \dots, N-1$ ,

and the term  $(f^L * g_1)(n)$  denotes the convolution between the impulse responses of  $F(z^L)$  and  $G_1(z)$ . Thus,  $F(z^L)$  can be decomposed to  $Q = 2K_b$  polyphase components assuming that  $N_F = QK_c - 1$  with  $K_c$  being a positive integer, and  $G_1(z)$  can be decomposed to  $2M$  polyphase components assuming that  $N_1 = 2K_d M - 1$  with  $K_d$  being a positive integer. Under the relation of  $L$  and  $M$  in (6.99), and  $c_{m,(n+2kM)} = (-1)^k c_{m,n}$ , the overall polyphase representation of  $H_m(z)$  is given by

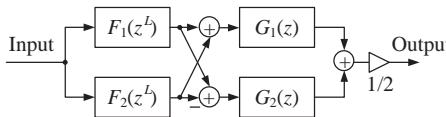

$$H_m(z) = \sum_{q=0}^{Q-1} \left[ z^{-Lq} E_F^q(-z^{LQ}) \times \sum_{p=0}^{2M-1} c_{m,\left(n+\frac{M}{K_b}q\right)} z^{-p} E_G^p(-z^{2M}) \right],$$

where  $E_F^q$  is the  $q$ th polyphase component of the prototype bandedge shaping filter  $F(z)$ , given by

$$E_F^q(z) = \sum_{k=0}^{K_c} (-1)^{K_a q} f(kQ + q) z^{-k}$$

and  $E_G^p(z)$  is the  $p$ th polyphase component of the masking filter  $G_1(z)$  given by

$$E_G^p(z) = \sum_{k=0}^{K_d-1} g_1(2kM + p) z^{-k}.$$

**FIGURE 6.80**

The overall structure of the recursive filter.

If both branches in the FRM design are used, this decomposition can be applied to the lower branch, and by enforcing both masking filters to have the same order  $N_1 = N_2$ , the responses of the two branches can be added together just before the modulation stage.

#### 1.06.8.5 FRM structure for recursive filter

While FRM structures were originally and mainly developed for the design of sharp filters with low computational complexity, a hybrid IIR and FIR filter structure was proposed for the design of high speed-recursive digital filters [83].

In the proposed structures, the bandedge shaping prototype filters are power complementary IIR filters, denoted as  $F(z)$  and  $F_c(z)$ , realized as a parallel connection of two allpass filters, and the masking filters are linear-phase FIR filters. The bandedge shaping prototype filters are expressed as

$$F(z) = \frac{F_1(z) + F_2(z)}{2}$$

and

$$F_c(z) = \frac{F_1(z) - F_2(z)}{2},$$

where  $F_1(z)$  and  $F_2(z)$  are stable allpass filters. When the magnitude responses of the power complementary IIR filter pair  $F(z)$  and  $F_c(z)$  are bounded by unity, the overall transfer function is expressible as

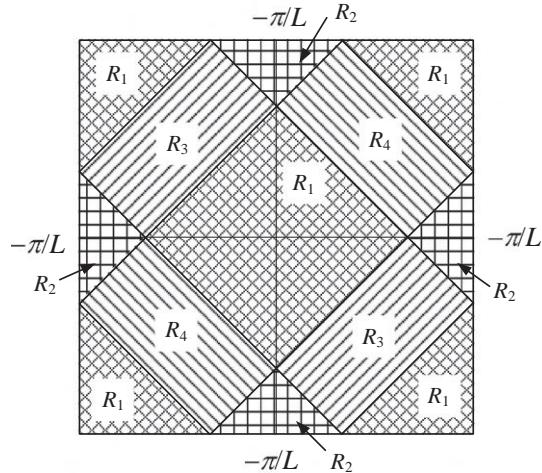

$$H(z) = \frac{F_1(z^L) + F_2(z^L)}{2} G_1(z) + \frac{F_1(z^L) - F_2(z^L)}{2} G_2(z),$$

where  $G_1(z)$  and  $G_2(z)$  are the linear-phase FIR masking filters. The structure of the overall filter is shown in Figure 6.80.

Since the maximum sample frequency of recursive filters is determined by the ratio of the number of delay elements and the operational latency in the critical loop of the filter realization, see (6.102), this structure introduced at least  $L$  delay elements in its critical loop, resulting in an  $L$ -fold increase of the maximal sample frequency.

#### 1.06.8.6 Two-dimensional FRM structure

The extension of the FRM structure to two-dimensional (2D) sharp filters is not straightforward. The main difficulty lies in the generation of complementary bandedge shaping filters, whose frequency responses of the compressed passbands should be separated by stopbands and able to be masked by the subsequent masking filters.

**FIGURE 6.81**

The four frequency regions for the complementary components of the 2D FRM filter.

A 2D diamond-shaped filter using FRM structure was proposed in [84]. The idea is to divide the frequency spectrum into four suitably chosen complementary components  $R_k$  for  $k = 1, 2, 3$ , and 4, as shown in Figure 6.81, in the 2D region  $[-\frac{\pi}{L}, \frac{\pi}{L}]^2$ , for a compression factor of  $L$ . These regions are also defined for the periodic repetitions of the 2D region  $[-\frac{\pi}{L}, \frac{\pi}{L}]^2$ .

These four complementary regions are obtained by four filters  $\hat{F}_k(z_1, z_2)$  for  $k = 1, 2, 3$ , and 4. To make the four filters complementary, an error filter, denoted as  $F_e(z_1, z_2)$ , is introduced, such that

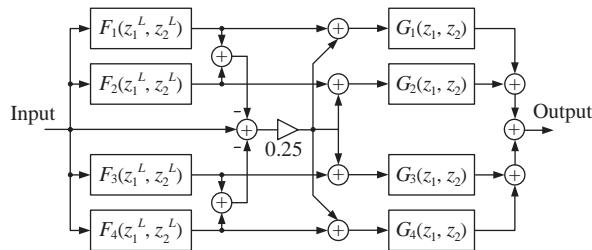

$$\sum_{k=1}^4 \hat{F}_k(z_1, z_2) + F_e(z_1, z_2) = 1. \quad (6.101)$$

Thus, the four bandedge shaping prototype filters, denoted as  $F_k(z_1, z_2)$ , are given by

$$F_k(z_1, z_2) = \hat{F}_k(z_1, z_2) + \frac{F_e(z_1, z_2)}{4}.$$

Each delay, in each dimension of the four bandedge shaping prototype filters, is replaced by  $L$  delays and four complementary bandedge shaping filters  $F_k(z_1^L, z_2^L)$  are obtained. The output of  $F_k(z_1^L, z_2^L)$  are then filtered by respective masking filters  $G_k(z_1, z_2)$ , and the resulting outputs are summed to form the final output. The generation of the complementary bandedge shaping filter and the overall 2D diamond-shaped FRM filter structure is shown in Figure 6.82.

Thus, based on the same principle of one-dimensional FRM filters, the specifications of the bandedge shaping prototype filters and masking filters can be derived for the design procedure.

**FIGURE 6.82**

The overall filter structure of the 2D diamond-shaped FRM filter.

### 1.06.8.7 Summary

As one of the most successful low computational complexity digital filter structures, basic FRM filter consists of an elegant filter network with two branches comprising three subfilters and realizes frequency responses owning sharp transition band. The price paid, for the high computational saving, is a small increase in the filter order. Further developments on the basic FRM structure have extended the technique to various areas of digital filters, including but not limited to recursive filters, multirate filters, filter banks, and 2D filters.

---

## 1.06.9 Computational properties of filter algorithms

In order to compare and evaluate different filter structures we need to discuss a few basic properties of algorithms and their implementation.

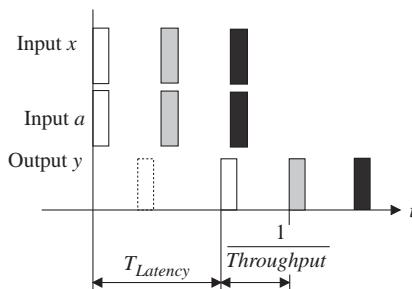

### 1.06.9.1 Latency and throughput

We define latency, as the time it takes to generate an output value from the corresponding input value, as illustrated in Figure 6.83, for an arithmetic operation. The throughput (samples/s) is defined as the reciprocal of the time between successive outputs. In sequential algorithms it is possible to increase the throughput of an algorithm—for example, by using pipelining [1].

### 1.06.9.2 Maximal sample rate

The maximal sample rate of an algorithm is determined only by its recursive loops [1, 85]. Nonrecursive parts of the signal-flow graph, e.g., input and output branches, generally do not limit the sample rate, but to achieve this limit, additional delay elements may have to be introduced into the nonrecursive branches [1]. The maximal sample frequency for an iterative recursive algorithm, described by a fully-specified signal-flow graph [1], is

$$f_{\max} = \min_i \left\{ \frac{N_i}{T_{\text{op}}} \right\}, \quad (6.102)$$

**FIGURE 6.83**

Latency and throughput.

where  $T_{op}$  is the total latency due to the arithmetic operations, and  $N_i$  is the number of delay elements in the directed loop  $i$ . We will later define the latency for different arithmetic operations. The loop with the lowest  $f_{max}$  is called the critical loop. The minimum sample period is also referred to as the iteration period bound. It is, of course, not possible to improve the iteration period bound for a given algorithm. However, a new algorithm with a higher bound can often be derived from the original algorithm using algorithm transformations [1, 86, 87]. We recognize from (6.102) that there are several possibilities to improve the bound:

- Reduce the operation latency,  $T_{op}$ , in the critical loop.
- Introduce additional delay elements into the loop, without changing the behavior.
- Remove superfluous arithmetic or logic operations from the loop.

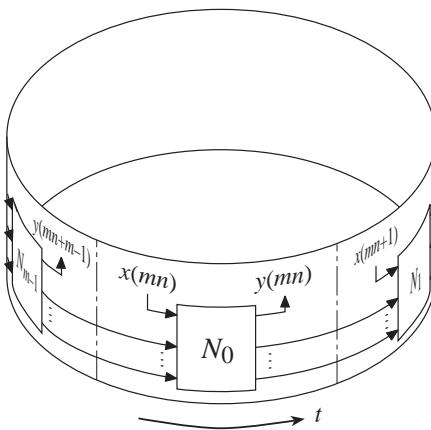

### 1.06.9.3 Cyclic scheduling

In order to achieve a maximally fast implementation that achieves the bound in (6.102), we must generally connect  $m$  computation graphs, that represents the operations within single sample interval [1], as illustrated in Figure 6.84.

This will result in a periodic scheduling formulation that allows a schedule period, that is  $m$  times longer than the sample interval. This cyclic formulation will under certain conditions result in a maximally fast, periodic schedule. Unfortunately, it is not possible to determine the best choice of  $m$  in the general case. In order to attain the minimum sample period, it is necessary to perform cyclic scheduling of the operations belonging to several successive sample intervals if

- The latency for a PE is longer than  $T_{min}$  or
- The critical loop(s) contains more than one delay element.

Generally, the critical loop should be at least as long as the longest latency for any of the PEs in the loop. Bit-serial and digit-serial operations with latencies longer than the minimal sample period can thereby

**FIGURE 6.84**

Cyclic scheduling.

be completed within the scheduling period. The minimum number of sample periods for the schedule is

$$m = \left\lceil \frac{\max_i (T_{\text{latency},i})}{T_{\min}} \right\rceil, \quad (6.103)$$

where  $T_{\text{latency},i}$  is the latency of operation  $i$ . From the cyclic scheduling formulation it is possible to find a resource-optimal schedule with a minimum number of concurrent operations.

### 1.06.10 Architecture

A major problem when implementing an algorithm is to decide upon a suitable hardware architecture. We may select to use one or several processing elements (PE) and one or several memories, or memory ports, and among a variety of communication networks between PEs and the memories [1]. Typically the design target is to minimize the implementation cost, e.g., chip area and power consumption, while meeting the throughput requirement. Normally, in digital signal processing applications there is no benefit in having a higher throughput than required.

We recommend that the arithmetic operations are scheduled cyclically to attain a maximally fast implementation as illustrated in Figure 6.84. A maximally fast schedule and the corresponding implementation is obtained by using an isomorphic mapping between the arithmetic operations and the processing elements [88–90]. This allows the hardware to operate with a low power supply voltage and low power consumption. Moreover, the communication network becomes simple and static. There exist graphic based methods to determine the number of independent memories or memory ports that are required [1]. Recently, it has been shown that a maximally fast implementation is obtainable using a numerically equivalent state-space representation and distributed arithmetic [91].

## 1.06.11 Arithmetic operations

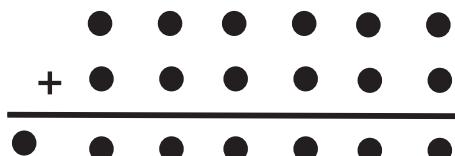

Here we are mainly interested in the arithmetic operations: addition, subtraction, and multiplications as well as sum-of-products. There exist many alternative arithmetic algorithms to perform these operations. Consider, for example, addition. Addition of two numbers, independently of their sign, can be performed using the same circuit, if two's-complement representation is used. Moreover changing the circuit for addition into a subtractor requires only that the bits of one of the inputs are inverted. An advantage of the two's-complement number representation is that several numbers can be added, with possible intermediate overflows, if we can guarantee that the result is within the correct number range. This situation occurs frequently in digital filter algorithms. A drawback is, however, that the carry propagation limits the latency. Several techniques to speed-up the computation of the carries as well as carry-free number representations have been proposed [3].

### 1.06.11.1 Addition and subtraction

The operation of adding two or more numbers is in many ways the most fundamental arithmetic operation, since most other operations in one way or another, are based on addition. The operands of concern here are either two's-complement or unsigned representation. Most DSP applications use fractional arithmetic instead of integer arithmetic [1]. The sum of two  $W$ -bit numbers is a  $(W+1)$ -bit number while the product of two binary  $W$ -bit numbers is a  $2W$ -bit number. In many cases, and always in recursive algorithms, the resulting number needs to be quantized to a  $W$ -bit number. Hence, the question is which bits of the result are to be retained. In fractional arithmetic, two's-complement numbers are interpreted as being in the range  $[-1, 1]$ , i.e.,

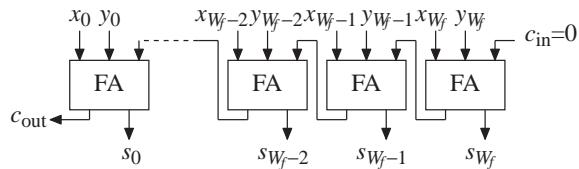

$$x = -x_0 + \sum_{i=1}^{W-1} x_i 2^{-i}. \quad (6.104)$$

Hence, the most significant part of a product is contained in the bits  $(x_0, x_1, \dots)$ . We use the graphic representation shown in Figure 6.85 to represent the operands and the sum bits with the most significant bit to the left.

**FIGURE 6.85**

Illustration of addition of two binary numbers.

**FIGURE 6.86**

Ripple-carry adder.

#### 1.06.11.1.1 Ripple-carry addition

A straightforward way to add two numbers is to sequentially add the two bits of the same significance and the carry from the previous stage using a full adder (FA) and propagate the carry bit to the next stage. This is called ripple-carry addition and is illustrated in Figure 6.86. Note that the operation propagate from right to the left and that only one FA perform have correct inputs at a give moment. Hence, the circuit performs addition sequentially, one bit at a time, even though it is referred to as a parallel adder. This type of adder can add both unsigned and two's-complement numbers.

The major drawback with the ripple-carry adder is that the worst-case delay is proportional to the wordlength. Also, typically the ripple-carry adder will produce many glitches since the full adders perform switching operations without having correct carries. This situation is improved if the delay for the carry bit is smaller than that of the sum bit [92].

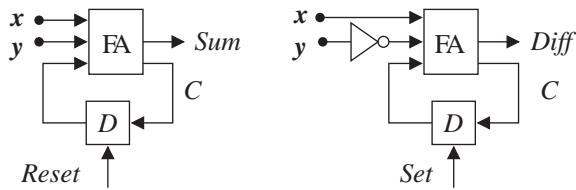

However, due to the simple design the energy per computation is still reasonable small [93]. Alternatively all pairs of two bits of the same significance can be added simultaneously and then the carries are added using some efficient scheme. There are many adder schemes proposed, for more details we refer to e.g., [93]. For carry-save addition we refer to [94, 95]. It is also possible to perform addition in constant time using redundant number systems such as signed-digit or carry-save representations. An alternative is to use residue number systems (RNS), which breaks the carry-chain into several shorter ones [96].

#### 1.06.11.1.2 Bit-serial addition and subtraction

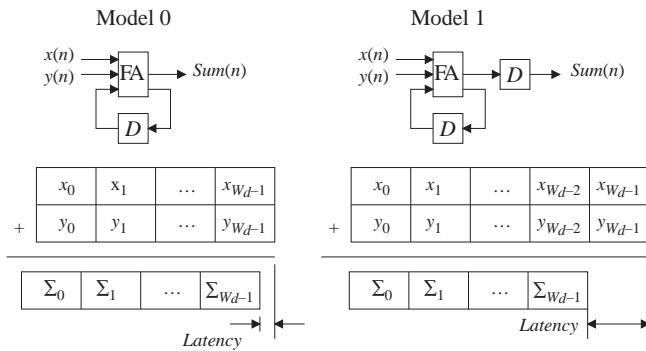

In bit-serial arithmetic the inputs  $x$  and  $y$  are normally processed with the least-significant bit first. Bit-serial numbers in two's-complement representation can be added or subtracted with the circuits shown in Figure 6.87.

Since the carries are saved from one bit position to the next, the circuits are called carry-save adder and carry-save subtractor, respectively. At the start of the addition the D flip-flop is reset (set) for the adder (subtractor), respectively.

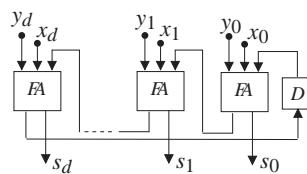

Figure 6.90 shows two latency models for bit-serial adders. The left most is suitable for static CMOS and the right most for dynamic (clocked) logic styles. The time to add two  $W$ -bit numbers is  $W$  or  $W + 1$  clock cycles. Note that the first bit of the sum, which is delayed by the latency given in Figure 6.90, can directly be feed to any subsequent bit-serial processing element (PE). Thus, the throughput of a complex computation may not necessarily be determined by the long addition time [1] (see Figure 6.88).

**FIGURE 6.87**

Bit-serial adder and subtracter.

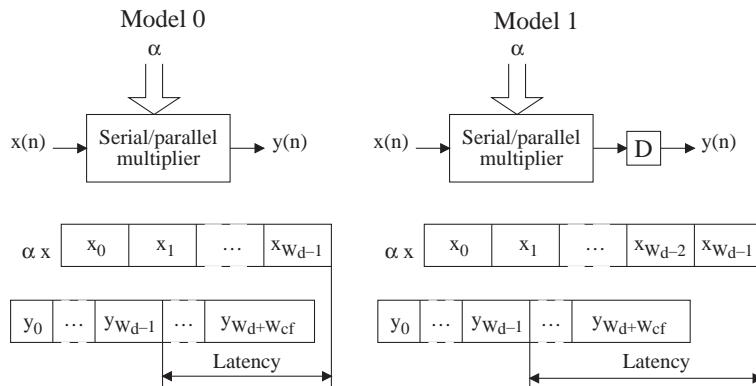

**FIGURE 6.88**

Latency models for a bit-serial adder.

**FIGURE 6.89**

Digit-serial adder with digit-size  $d$ .

Comparing the ripple-carry adder and the bit-serial adder, we note that both operate sequentially with one bit addition at a time. In the ripple-carry adder, each bit addition is mapped to its private FA, while in the bit-serial adder, all bit additions are mapped to a time-multiplexed FA. Hence, the difference in throughput is mainly due to the time lost in the D flip-flop. The chip area for bit-serial circuits is small and consequently the wiring is also small.

**FIGURE 6.90**

Latency models for a serial/parallel multiplier.

#### 1.06.11.1.3 Digit-serial addition and subtraction

From speed and power consumption points of view it may sometimes be advantageous to process several bits at a time, so-called digit-serial processing [97–103]. The number of bits processed in a clock cycle is referred to as the digit size. Figure 6.89 shows a  $d$ -bit digital-serial adder.

The flip-flop transmit the carry between successive digits. In case of subtraction of a two's-complement number, the negative value is instead added by inverting the bits and setting the carry flip-flop. Most of the principles for bit-serial arithmetic can easily be extended to digit-serial arithmetic. An advantage of bit-serial and digit-serial arithmetic is that less chip area is required and therefore the equivalent switched capacitance and leakage current is low [104]. The difference in throughput between a conventional word level and a digit-serial implementation is not great [105]. Both bit-serial and digit-serial are suitable for implementations in FPGA circuits.

#### 1.06.11.2 Multiplication

Bit-parallel multiplication of two numbers can be divided into two main steps:

- partial product generation that determines the bits to be added, and
- accumulation of the partial products.

Two main approaches to perform the accumulation have been proposed, namely array and tree type accumulation [3]. Bit-serial and digit-serial multiplications are usually based on a shift-and-add approach [1, 106]. Here, however, we will focus on implementation techniques that use addition and subtractions as the generic arithmetic operations.

To identify the critical loop in the filter, the total latency of the operations inside the loops must be determined. The total latency of several sequential arithmetic operations depend on how they are realized at the logic level, because the clock frequency is determined by the longest propagation path between any two registers. The propagation paths do not only depend on the internal circuitry in an

arithmetic unit; they also depend on the paths between units. Hence, it may be efficient to use pipelining inside the critical loop in order to avoid long propagation paths between arithmetic units.

Two latency models for a serial/parallel multiplier are shown in Figure 6.90. Denoting the number of fractional bits of the coefficient by  $W_{cf}$ , the latencies are  $W_{cf}$  for latency model 0 and  $W_{cf} + 1$  for latency model 1. The corresponding latency models for digit-serial arithmetic are defined in the same manner.

In model 0, which corresponds to a static CMOS logic style without pipelining of the gates, the latency is equal to the gate delay of a full adder. In model 1, which corresponds to a dynamic CMOS logic style, or a static CMOS logic style with pipelining at the gate level, the full adder followed by a D flip-flop making the latency equal to one clock cycle. Model 1 generally results in faster bit-serial implementations, due to the shorter logic paths between the flip-flops in successive operations.

### 1.06.11.2.1 Example 6

Consider a lattice wave digital filter. The critical loop in a first-order allpass section is indicated in Figure 6.91 [89, 90].

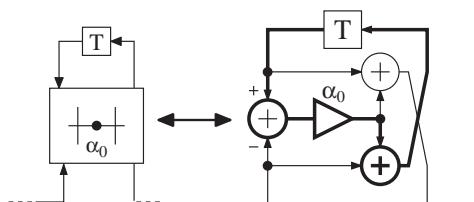

This loop containing two additions, one multiplication with  $\alpha_0$ , and one delay element has the minimal sample period given by

$$T_{\min 1} = \frac{T_{\alpha_0} + 2T_{\text{add}}}{1}. \quad (6.105)$$

In Figure 6.92 the critical loop in a second-order allpass section is indicated. For this loop consisting of four additions, two multiplications, and one delay element, the corresponding minimal sample period becomes

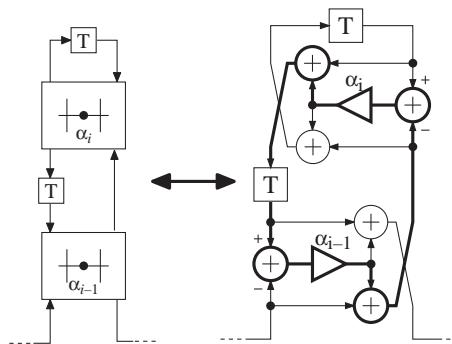

$$T_{\min 2} = \frac{T_{\alpha_i} + T_{\alpha_{i-1}} + 4T_{\text{add}}}{1}. \quad (6.106)$$

The minimal sample period of the filter is then bounded by the section with the lowest throughput, i.e., the loop  $i$  that yields  $T_{\min}$ , since each section has to operate with the same throughput. Figure 6.93 shows the scheduling of the operations belonging to  $m$  sample periods for a first-order allpass section. The shaded areas indicate execution time for the operations and darker shaded areas indicate their latency. Scheduling of second-order allpass sections can be found in [1]. Since a bit-serial processing element only processes 1 bit in each clock cycle, a complete arithmetic operation requires at least  $W_d$  clock cycles. Therefore, if the minimal sample period of  $T_{\min}$  clock cycles, where  $T_{\min} < W_d$ , operations

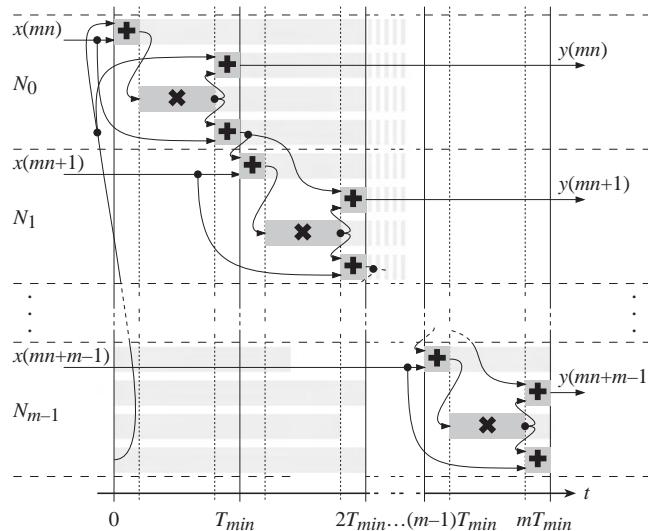

**FIGURE 6.91**

First-order allpass section.

**FIGURE 6.92**

The critical loop in a second-order allpass section.

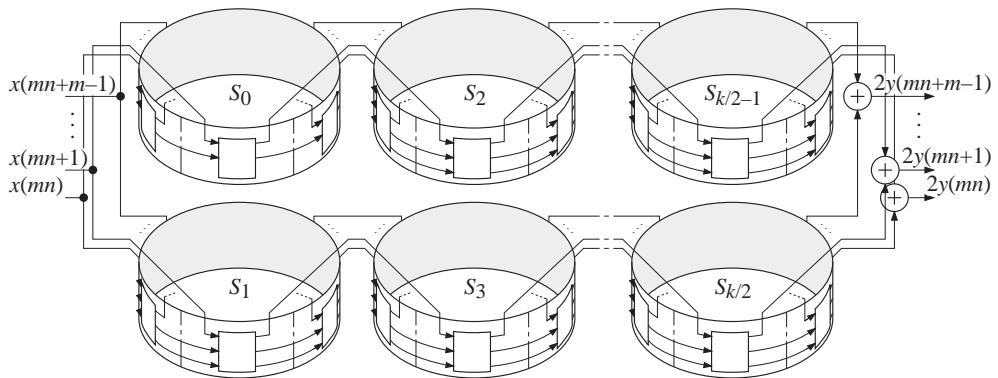

**FIGURE 6.93**

Maximally fast schedule for a first-order allpass section.

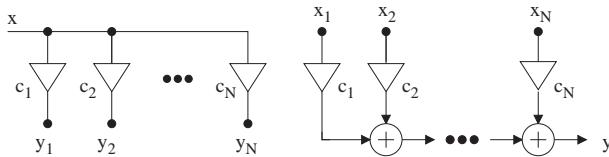

belonging to  $m$  sample periods need to be included in the schedule. It can be shown that  $m$  must be selected as

$$m \geq \left\lceil \frac{W_{cf} + W_d + m_{n0}}{T_{min}} \right\rceil, \quad (6.107)$$

where  $m_{n0}$  is 0 for model 0 and 1 for model 1, respectively in order to allow an arithmetic operation requiring  $W_{cf} + W_d + m_{n0}$  clock cycles to be completed within the scheduling period. Thus, the

**FIGURE 6.94**

Complete lattice wave digital filter.

**FIGURE 6.95**

Substructures suitable for multiple-constant multiplication.

scheduling period for a maximally fast schedule becomes  $mT_{\min}$ . The implementation of the complete filter is illustrated in Figure 6.94.

## 1.06.12 Sum-of-products (SOP)

In this section we discuss the two main techniques to simplify the hardware implementation of sum-of-products and their transpose. Note that the arithmetic networks shown in Figure 6.84 consists of a set of sum-of-products of the type shown in Figure 6.95. Consider the sum-of-products

$$y = \sum_{k=1}^N a_k x_k. \quad (6.108)$$

Typically, the coefficients,  $a_k$ , are fixed and  $x_k$  are variable, but there are several common cases where both  $a_k$  and  $x_k$  are variable, for example, computation of correlation, which require a general multiplier.

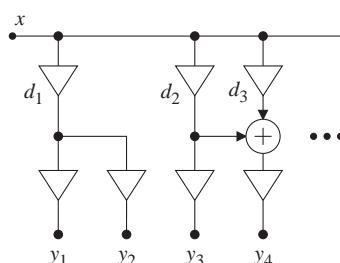

Distributed arithmetic is an efficient procedure for computing sum-of-products between a fixed and a variable data vector. The basic principle is owed to Croisier et al. [107]. Distributed arithmetic is suitable for implementation of relative short sum-of-products, discrete cosine transforms (DCT), as well as complex multiplications [1].

### 1.06.12.1 Multiple-constant multiplication (MCM)

Multiple-constant multiplication techniques [1, 3] are efficient methods to simplify multipliers with fixed coefficients and thereby reduce the power consumption. Single multipliers and substructures of the type shown in Figure 6.95 can be simplified significantly by using multiple-constant multiplication techniques [4–7, 108, 109]. For the multiple-constant multiplication case several effective algorithms have been proposed that avoids the problem of number representation dependency [110, 111]. Theoretical lower bounds for related problems have been presented in [11]. Moreover, using linear programming, the filter coefficient optimization and the MCM implementation can be jointly addressed [112, 113].

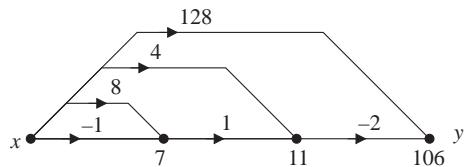

Figure 6.96 shows a typical example of an MCM network. The basic idea is to reduce the number of basic operations (i.e., add/sub-and-shift operations) by factoring out common factors in the coefficients  $c_i$ . By first generating a set of common subexpressions,  $d_1, d_2, d_3$ , that in the next step are multiplied with simple coefficients, or added/subtracted, to generate new subexpressions, and so on [8, 95]. A main drawback of these techniques is that they are highly specialized for a particular SOP and can therefore not be multiplexed to perform other SOPs. For multiple-constant multiplication, with many coefficients (for example for long FIR filters) the average increase of the number of adders/subtractors, approaches one, for an increase of the length of the filter by one. This is due to the fact that most subexpressions have already been generated and only a single addition/subtraction is needed to generate another coefficient. The problem of finding optimal solutions to the multiple-constant multiplication problem is NP complete. Several heuristic algorithms have therefore been derived, e.g., [4–6, 114, 115].

Figure 6.97 shows a graph that simultaneously realize the multiplication with 7, 11, and 106. Only three adder/subtractors and some shift operations are required. These techniques are efficient for implementing bit-parallel, digit-serial as well as bit-serial processing elements [1].

**FIGURE 6.96**

MCM network.

**FIGURE 6.97**

MCM example.

An implementation according to Figure 6.84 will consist of a set of MCM networks where the input to a network is taken from a register and the different subexpressions are SOP to be stored into other registers.

### 1.06.12.2 Distributed arithmetic

Consider the sum-of-products in (6.108) and assuming that the coefficients,  $a_k, k = 1, 2, \dots, N$  are fixed. Two's-complement representation is used for both coefficients and data. The inputs are scaled so that  $|x_k| \leq 1$ . The sum-of-products can be rewritten

$$y = \sum_{k=1}^N a_k \left( -x_{k0} + \sum_{i=1}^{W_d-1} x_{ki} 2^{-i} \right), \quad (6.109)$$

where  $x_{ki}$  is the  $i$ th bit in  $x_k$ . By interchanging the order of the two summations we get

$$y = - \sum_{k=1}^N a_k x_{k0} + \sum_{i=1}^{W_d-1} \sum_{k=1}^N (a_k x_{ki}) 2^{-i} \quad (6.110)$$

which can be written

$$y = -F_0(x_{10}, x_{20}, \dots, x_{N0}) + \sum_{i=1}^{W_d-1} F_i(x_{1i}, x_{2i}, \dots, x_{Ni}) 2^{-i}, \quad (6.111)$$

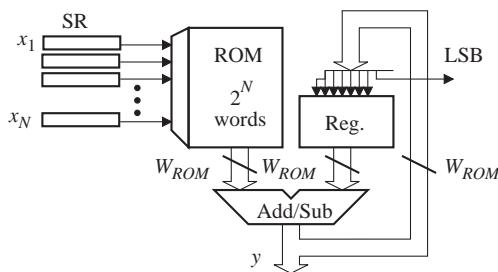

where

$$F_i(x_{1i}, x_{2i}, \dots, x_{Ni}) = \sum_{k=1}^N a_k x_{ki}. \quad (6.112)$$

$F$  is a function of  $N$  binary variables, the  $k$ th variable being the  $i$ th bit in the data  $x_k$ . Since  $F_i$  can take on only a finite number of values,  $2^N$ , it can be computed and stored in a ROM (Read-Only Memory). Equation (6.111) can, using Horner's method for evaluating a polynomial for  $x = 0.5$ , be rewritten as

$$y = (((((0 + F_{W_d-1})2^{-1} + \dots + F_2)2^{-1} + F_1)2^{-1} - F_0)). \quad (6.113)$$

Figure 6.98 shows a block diagram for computing a sum-of-products according to (6.113).

**FIGURE 6.98**

Block diagram for distributed arithmetic.

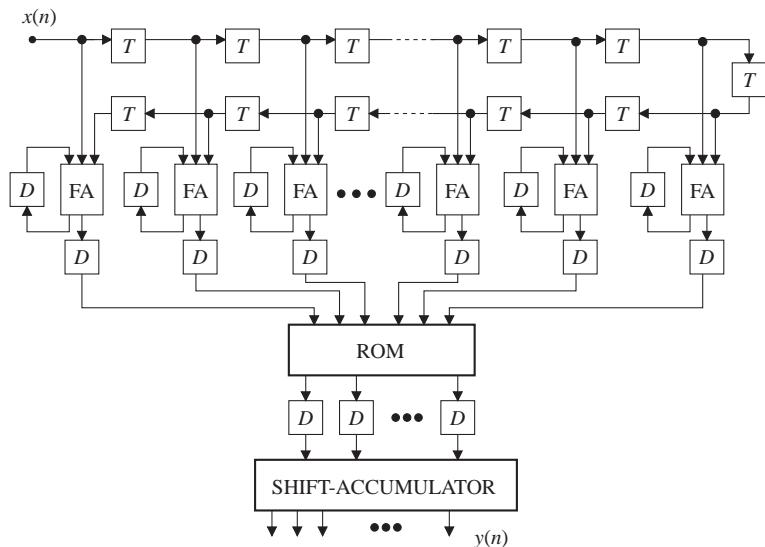

Inputs,  $x_1, x_2, \dots, x_N$  are shifted bit-serially out from the shift registers with the least-significant bit first. The bits  $x_{ki}$  are used as an address to the ROM storing the look-up table. Computation of the sum-of-products starts by adding  $F_{W_d-1}$  to the initially cleared accumulator register, REG. In the next clock cycle, outputs from the shift registers address  $F_{W_d-2}$ , which is added to the value in the accumulator register. The result is divided by 2 and stored back into REG. After  $W_d - 1$  clock cycles,  $F_0$  is subtracted from the value in the accumulator register. The computation time is  $W_d$  clock cycles. The required wordlength in the ROM,  $W_{ROM}$ , depends on the  $F_{\text{imax}}$  with the largest magnitude and the coefficient wordlength,  $W_c$ , and  $W_{ROM} = \lceil W_c + \log_2(N) \rceil$ .

The hardware cost is similar to a multiplier. In fact, most multiplier structures, e.g., serial/parallel, array, and three structures multipliers, can be used for distributed arithmetic. Distributed arithmetic can be used to implement first- and second-order direct form I sections, FIR filters, as well as wave digital filters [20, 107, 116–119].

#### 1.06.12.2.1 Implementation of FIR filters using distributed arithmetic

Figure 6.99 shows an implementation of an eleventh-order linear-phase FIR filter.  $N/2$  bit-serial adders (subtractors) are used to sum the symmetrically placed values in the delay line. This reduces the number of terms in the sum-of-products. Only 64 words are required whereas  $2^{12} = 4096$  words are required for the general case, e.g., a nonlinear-phase FIR filter. For higher-order FIR filters the reduction in the number of terms by 50% is significant. Further, the logic circuitry has been pipelined by introducing  $D$  flip-flops between the adders (subtractors) and the ROM, and between the ROM and the shift-and-add accumulator.

The number of words in the ROM is  $2^N$  where  $N$  is the number of terms in the sum-of-products. The chip area for the ROM is small for sum-of-products with up to 5–6 terms. The basic approach is useful for up to 10–11 terms. However, sum-of-products containing many terms, can be partitioned into a number of smaller sum-of-products, which can be computed and summed by using either distributed arithmetic or an adder tree. A complete sum-of-products PE and several similar types of PEs, for example adaptors and butterflies, can be based on distributed arithmetic. The main parts of a sum-of-products PE are the shift-accumulator, the coefficient ROM with decoder, and the control circuits. Overflow and quantization circuitry are also necessary, but it is often advantageous to move parts of this circuitry to the serial/parallel converters used in the interconnection network [1].

**FIGURE 6.99**

Eleventh-order linear-phase FIR filter.

Distributed arithmetic can, of course, be implemented in parallel form, i.e., by allocating a ROM to each of the terms in (6.113) and use an adder tree for the accumulation.

### 1.06.12.2 Memory reduction techniques

The amount of memory required becomes very large for long sum-of-products. There are mainly two ways to reduce the memory requirements. Namely, partitioning and coding of input signals. The two methods can be applied at the same time to obtain a very small amount of memory.

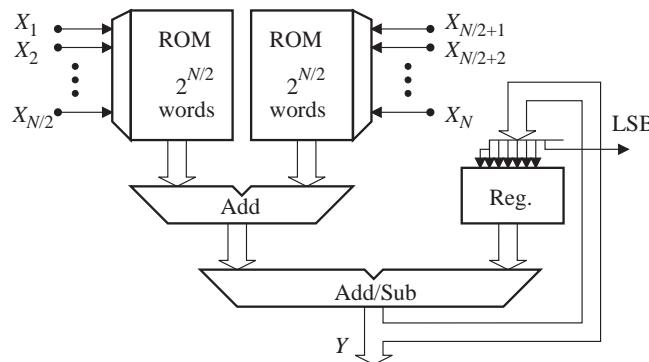

One way to reduce the overall memory requirement is to partition the memory into smaller pieces that are added before the shift-accumulator as shown in Figure 6.100.

The amount of memory is reduced from  $2^N$  words to  $2 \cdot 2^{\frac{N}{2}}$  words if the original memory is partitioned into two parts. For example, for  $N = 10$  we get  $2^{10} = 1024$  words to  $2 \cdot 2^5 = 64$  words. Hence, this approach reduces the memory significantly at the cost of an additional adder. In addition, the partitioning may in some case be done so that long and short values are stored in different partitions. Notice, depending on the values in the ROM, it is often favorable from both speed and area points of view to implement a ROM by logic gates. Large ROMs tend to be slow.

The second approach is based on a special coding of the inputs,  $x_i$ , which result in a symmetric ROM content [1, 107]. Memory size can be halved by using the ingenious scheme [107] based on the identity

$$x = \frac{1}{2}(x - (-x)). \quad (6.114)$$

This approach is also used for implementation of a complex multiplier using only two shift-accumulators and a common ROM [1].

**FIGURE 6.100**

Reducing the memory by partitioning.

### 1.06.13 Power reduction techniques

Many approaches to reduce the power consumption are based on various techniques to decrease the arithmetic workload. This can be done at the algorithmic level by using efficient, low-sensitivity structures that allows few and simple coefficients, and at the hardware level by using simplified multiplier realizations. Usually the power consumption, due to the memory, communication, and control, is neglected in these techniques, although their contribution may be significant. Polyphase structures and frequency masking techniques are commonly used to reduce the arithmetic workload.

Another approach is based on power supply voltage scaling where the implementation is operated with a low supply voltage. Pipelining and interleaving are not applicable to recursive algorithms. However, pipelining inside recursive loops can be performed at the logic level. It is therefore important to exploit all parallelism of the recursive algorithm in order to obtain excess speed that allows a reduction in the power supply voltage.

We propose the following strategy to design recursive digital filters with a low power consumption:

- Select an inherently fast and low-sensitivity filter algorithm, e.g., ladder or lattice wave digital filters, possibly in combination with frequency masking techniques.
- Use an approximation with a diminishing ripple, which reduces the passband sensitivity in ladder WDFs, and use discrete optimization techniques to reduce the operation latencies in the critical loop.
- Use pipelining to split the nonrecursive parts into smaller pieces so that  $T_{\min}$  can be achieved.
- Find a maximally fast and resource minimal schedule.
- Use an isomorphic mapping to an optimal hardware structure with bit- or digit-serial PEs.
- Use CMOS logic circuits that yield bit- or digit-serial PEs with a low power consumption, especially for the D flip-flops in the bit-serial case.
- Convert any excess circuit speed to a reduced power consumption by reducing the power supply voltage.

# Multirate Signal Processing for Software Radio Architectures

7

**Fred Harris, Elettra Venosa, and Xiaofei Chen***San Diego State University, Department of Electrical and Computer Engineering,  
San Diego, CA, USA*

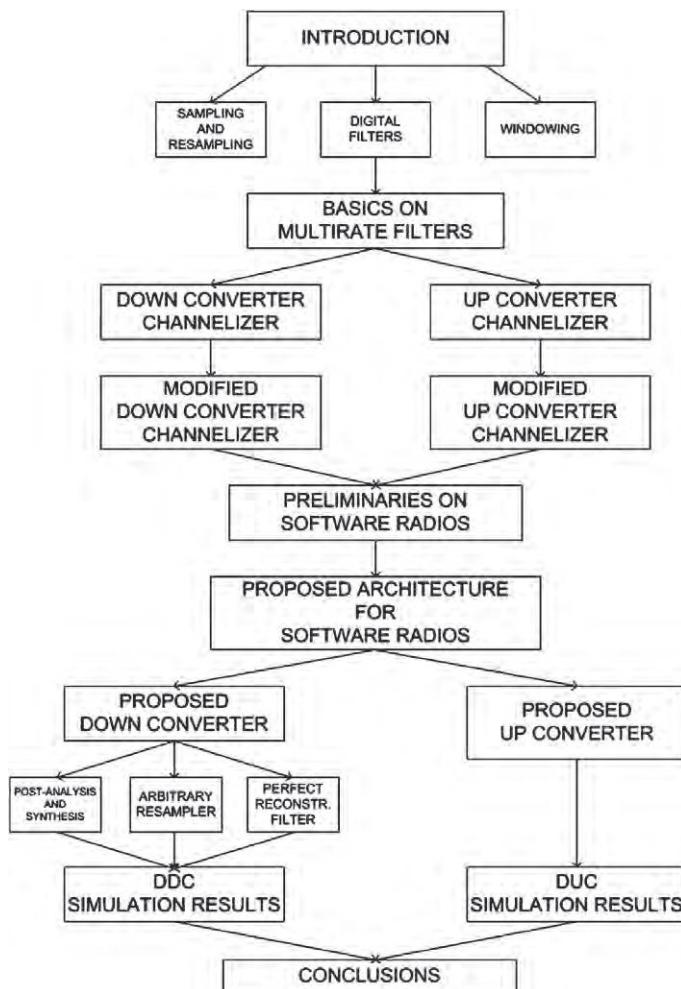

After the introductory sections on resampling theory and basics of digital filters, the architectures of up and down converter channelizers are presented. Those paragraphs are followed by the main core of this chapter in which the authors present novel digital up converter (DUC) and digital down converter (DDC) architectures for software defined radios (SDRs) which are based on variations of standard polyphase channelizers.

The proposed DUC is able to simultaneously up convert multiple signals, having arbitrary bandwidths, to arbitrarily located center frequencies. On the other side of the communication chain, the proposed DDC is able to simultaneously down convert multiple received signals with arbitrary bandwidth and arbitrarily located in the frequency domain. Both the proposed structures avoid the digital data section replication, which is necessary in the current digital transmitters and receivers, when multiple signals have to be handled. Due to the inverse discrete Fourier transform (IDFT), performed by using inverse fast Fourier transform (IFFT) algorithm, embedded in the channelizers, the proposed architectures are very efficient in terms of total workload.

This chapter is structured into two main parts which are composed, in total, of 10 sections. Its structure is described in Figure 7.1. The first part provides preliminary concepts on the sampling process, resampling process of a digital signal, digital filters, multirate structures, standard  $M$ -path polyphase up and down converter channelizers as well as their modified versions that represent the core of the structures we present in the second part of this document. These are well known topics in the digital signal processing (DSP) area and they represent the necessary background for people who want to start learning about software radios. The second part of this chapter goes through new frontiers of the research presenting the novel transmitting and receiving designs for software radios and demonstrating, while explaining the way in which they work, the reasons that make them the perfect candidates for the upcoming cognitive radios.

## 1.07.1 Introduction

Signal processing is the art of representing, manipulating, and transforming wave shapes and the information content that they carry by means of hardware and/or software devices. Until 1960s almost entirely continuous time, analog technology was used for performing signal processing. The evolution of digital systems along with the development of important algorithms such as the well known fast

**FIGURE 7.1**

Structure of the chapter.

Fourier transform (FFT), by Cooley and Tukey in 1965, caused a major shift to digital technologies giving rise to new digital signal processing architectures and techniques. The key difference between analog processing techniques and digital processing techniques is that while the first one processes analog signals, which are continuous functions of time; the second one processes sequences of values. The sequences of values, called digital signals, are series of quantized samples (discrete time signal values) of analog signals.

The link between the analog signals and their sampled versions is provided by the sampling process. When sampling is properly applied it is possible to reconstruct the continuous time signal from

its samples preserving its information content. Thus the selection of the sampling rate is crucial: an insufficient sampling frequency causes, surely, irrecoverable loss of information, while a more than necessary sampling rate causes useless overload on the digital systems.

The string of words multirate digital signal processing indicates the operation of changing the sample rate of digital signals, one or multiple times, while processing them. The sampling rate changes can occur at a single or multiple locations in the processing architecture. When the multirate processing applied to the digital signal is a filtering then the digital filter is named multirate filter; a multirate filter is a digital filter that operates with one or more sample rate changes embedded in the signal processing architecture. The opportunity of selecting the most appropriate signal sampling rate at different stages of the processing architecture, rather than having a single (higher) sampling rate, enhances the performance of the system while reducing its implementation costs. However, the analysis and design of multirate systems could result complicated because of the fact that they are time-varying systems. It is interesting to know that the first multirate filters and systems were developed in the context of control systems. The pioneer papers on this topic were published in the second half of 1950s [1–3]. Soon the idea spilled in the areas of speech, audio, image processing [4,5], and communication systems [6]. Today, multirate structures seem to be the optimum candidates for cognitive and software defined radio [7–11] which represents the frontier of innovation for the upcoming communication systems.

One of the well known techniques that find its most efficient application when embedded in multirate structures is the polyphase decomposition of a prototype filter. The polyphase networks, of generic order  $M$ , originated in the late 1970s from the works by Bellanger et al. [12,13]. The term polyphase is the aggregation of two words: poly, that derives from the ancient greek word polys, which means many, and phase. When applied to an  $M$ -path partitioned filter these two words underline the fact that, on each path, each aliased filter spectral component, experiences a unique phase rotation due to both their center frequencies and the time delays, which are different in each path because of the way in which the filter has been partitioned. When all the paths are summed together the undesired spectral components, having phases with opposite polarity, cancel each other while only the desired components, which experience the same phase on all the arms of the partitions, constructively add up. By applying appropriate phase rotators to each path we can arbitrarily change the phases of the spectral components selecting the spectral component that survives as a consequence of the summation. It is interesting to know that the first applications of the polyphase networks were in the areas of real-time implementation of decimation and interpolation filters, fractional sampling rate changing devices, uniform DFT filter banks as well as perfect reconstruction analysis/synthesis systems. Today polyphase filter banks, embedded in multirate structures, are used in many modern DSP applications as well as in communication systems where they represent, according to the author's belief, one of the most efficient options for designing software-based radio.

The processing architecture that represents the starting point for the derivation of the standard polyphase down converter channelizer is the single channel digital down converter. In a digital radio receiver this engine performs the operations of filtering, frequency translation and resampling on the intermediate frequency (IF) signals. The resampling is a down sampling operation for making the signal sampling rate commensurate to its new reduced bandwidth. When the output sampling rate is selected to be an integer multiple of the signal's center frequency, the signal spectrum is shifted, by aliasing, to base-band and the complex heterodyne defaults to unity value disappearing from the processing path. The two remaining operations of filtering and down sampling are usually performed in a single processing architecture (multirate filter). After exchanging the positions of the filter and resampler, by

applying polyphase decomposition, we achieve the standard  $M$ -path polyphase down converter channelizer which shifts a single narrowband channel to base-band while reducing its sampling rate. By following a similar procedure the standard up converter channelizer can also be obtained. It performs the operation of up converting while interpolating a single narrowband channel.

When the polyphase channelizer is used in this fashion the complex phase rotators can be applied to each arm to select, by coherent summation, a desired channel arbitrarily located in the frequency domain. Moreover, the most interesting and efficient application of this engine is in the multichannel scenario. When the inverse discrete Fourier transform block is embedded, the polyphase channelizer acquires the capability to simultaneously up and down convert, by aliasing, multiple, equally spaced, narrowband channels having equal bandwidths. Due to its computational efficiency, the polyphase channelizer, and its modified versions, represents the best candidate for building up new flexible multichannel digital radio architectures [14] like software defined radio promises to be.

Software defined radio represents one of the most important emerging technologies for the future of wireless communication services. By moving radio functionality into software, it promises to give flexible radio systems that are multi-service, multi-standard, multi-band, reconfigurable, and reprogrammable by software. The goal of software defined radio is to solve the issue of optimizing the use of the radio spectrum that is becoming more and more pressing because of the growing deployment of new wireless devices and applications [15–18].

In the second part of this chapter we address the issue of designing software radio architectures for both the transmitter and the receiver. The novel structures are based on modified versions of the standard polyphase channelizer, which provides the system with the capability to optimally adapt its operating parameters according to the surrounding radio environment [7, 19–21]. This implies, on the transmitter side, the capability of the radio to detect the available spectral holes [22, 23] in the spanned frequency range and to dynamically use them for sending signals having different bandwidths at randomly located center frequencies. The signals could be originated from different information sources or they could be spectral partitions of one signal, fragmented because of the unavailability of free space in the radio spectrum or for protecting it from unknown and undesired detections.

The core of the proposed transmitter is a synthesis channelizer [24]. It is a variant of the standard  $M$ -path polyphase up converter channelizer [6, 8] that is able to perform 2-to- $M$  up sampling while shifting, by aliasing, all the base-band channels to the desired center frequencies. Input signals with bandwidths wider than the synthesis channelizer bandwidth are pre-processed through small down converter channelizers that disassemble their bandwidths into reduced bandwidth sub-channels. The proposed transmitter avoids the need to replicate the sampled data section when multiple signals have to be simultaneously transmitted and it also allows partitioning of the signal spectra, when necessary, before transmitting them. Those spectral fragments will be reassembled in the receiver after being shifted to base-band without any loss of energy because perfect reconstruction filters are used as low-pass prototype in the channelizer polyphase decompositions.

On the other side of the communication chain, a cognitive receiver has to be able to simultaneously detect multiple signals, recognize, when necessary, all their spectral partitions, filter, down convert and recompose them without energy losses [7] independently of their bandwidths or center frequencies. An analysis channelizer is the key element of the proposed receiver [7]. This engine is able to perform  $M$ -to-2 down sampling while simultaneously demodulating, by aliasing, all the received signal spectra having

arbitrary bandwidths residing at arbitrary center frequencies [9]. Post-processing up converter channelizers are used for reassembling, from the analysis channelizer base-line channels, signal bandwidths wider than the analysis channelizer channel bandwidth.

In the transmitter complex frequency rotators apply the appropriate frequency offsets for arbitrary center frequency positioning of the spectra. When the frequency rotators are placed in the proposed receiver, they are responsible for perfect DC alignment of the down converted signals.

This chapter is composed of 10 main sections. The first four sections are dedicated to the basics of digital signal processing, multirate signal processing, and polyphase channelizers. These sections contain preliminary concepts necessary for completely understanding the last sections of this work in which actual research issues on software radio (SR) architecture design are discussed and innovative results are presented. In particular, Section 1.07.2 recalls basic concepts on the resampling process of a discrete time signal as opposed to the sampling process of an analog, continuous time, signal. Section 1.07.3 introduces the readers to digital filters providing preliminaries on their design techniques. Section 1.07.5 presents the standard single path architectures for down sampling and up sampling digital signals. Section 1.07.6 introduces the standard version of the  $M$ -path polyphase down and up converter channelizers. Both of them are derived, step by step, by the single path structures that represent the current state of the technology. In Section 1.07.7 we present the modified versions of these engines. These are the structures that give form to the proposed digital down and up converters for SDRs which are presented in Section 1.07.9 which also provides the simulation results. Section 1.07.8 introduces the readers to the concept of software radio while Section 1.07.10 gives concluding remarks along with suggestions for future research works in this same area.

## 1.07.2 The Sampling process and the “Resampling” process

In the previous section we mentioned that the sampling process is the link between the continuous time world and the discrete time world. By sampling a continuous time signal we achieve its discrete time representation. When sampling frequency is properly selected the sampling process becomes invertible and it is possible to re-shift from the discrete time representation to the continuous time representation of a signal maintaining its information content during the process.

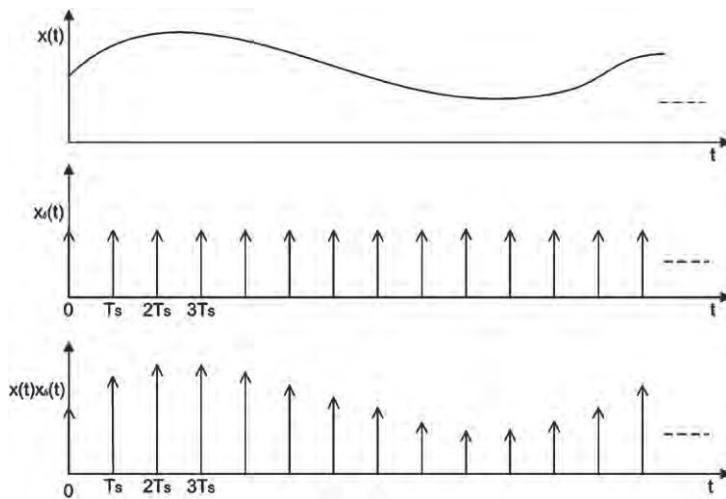

It is well known that, when the signal is bandlimited and has no frequency components above  $f_{\text{MAX}}$ , it can be uniquely described by its samples taken uniformly at frequency

$$f_s \geq 2f_{\text{MAX}}. \quad (7.1)$$

Equation (7.1) is known as Nyquist sampling criterion (or uniform sampling theorem) and the sampling frequency  $f_s = 2f_{\text{MAX}}$  is called the Nyquist sampling rate. This theorem represents a theoretically sufficient condition for reconstructing the analog signal from its uniformly spaced samples.

Even though sampling is practically implemented in a different way, it is convenient, in order to facilitate the learning process, to represent it as a product of the analog waveform,  $x(t)$ , with a periodic train of unit impulse functions defined as

$$x_\delta(t) = \sum_{n=-\infty}^{\infty} \delta(t - nT_s),$$

**FIGURE 7.2**

Sampling process as a product of the analog waveform,  $x(t)$ , with a periodic train of unit impulse functions  $x_\delta(t)$ .

where  $T_s = 1/f_s$  is the sampling period. By using the shifting property of the impulse function we obtain

$$x_s(t) = x(t)x_\delta(t) = x(t) \sum_{n=-\infty}^{\infty} \delta(t - nT_s) = \sum_{n=-\infty}^{\infty} x(nT_s)\delta(t - nT_s). \quad (7.2)$$

A pictorial description of Eq. (7.2) is given in Figure 7.2.

For facilitating the readers' understanding of the uniform sampling effects on the bandlimited continuous time signal,  $x(t)$ , we shift from time domain to the frequency domain where we are allowed to use the properties of the Fourier transform. The product of two functions in time domain becomes the convolution of their Fourier transforms in the frequency domain. Thus, if  $X(f)$  is the Fourier transform of  $x(t)$  and  $X_\delta(f)$  is the Fourier transform of  $x_\delta(t)$ , then the Fourier transform of  $x_s(t)$  is

$$X_s(f) = X(f) * X_\delta(f),$$

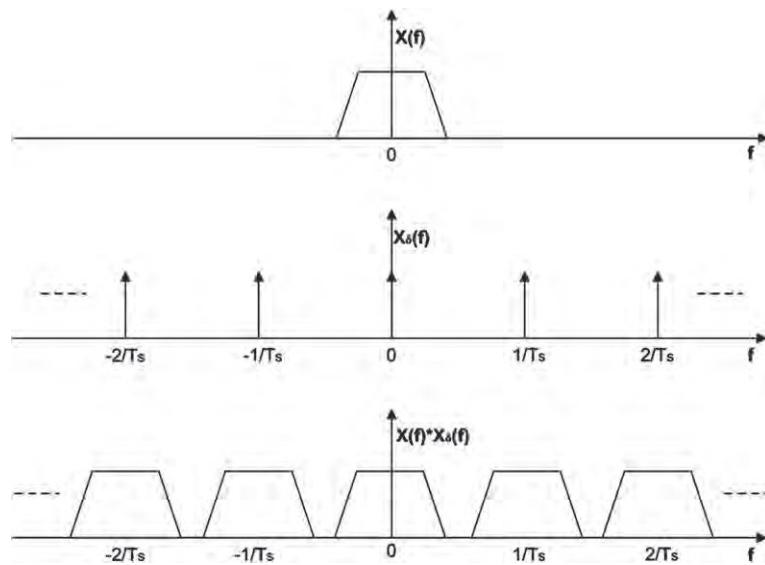

where  $*$  indicates linear convolution and

$$X_\delta(f) = \frac{1}{T_s} \sum_{k=-\infty}^{\infty} \delta(f - kf_s).$$

Note that the Fourier transform of a impulse train is another impulse train with the values of the periods reciprocally related to each other. Then in the frequency domain Eq. (7.2) becomes

$$X_s(f) = X(f) * X_\delta(f) = X(f) * \frac{1}{T_s} \sum_{k=-\infty}^{\infty} \delta(f - kf_s) = \frac{1}{T_s} \sum_{k=-\infty}^{\infty} X(f - kf_s), \quad (7.3)$$

whose pictorial view is shown in Figure 7.3.

**FIGURE 7.3**

Sampling process in the frequency domain.

From Eq. (7.3) we conclude that the spectrum of the sampled signal, in the original signal bandwidth ( $[-f_s/2, f_s/2]$ ), is the same as the continuous time one (except for a scale factor,  $\frac{1}{T_s}$ ) however, as a consequence of the sampling process, this spectrum periodically repeats itself with a period of  $f_s = \frac{1}{T_s}$ . We can easily recognize that it should be possible to recover the original spectrum (associated to the spectral replica which resides in  $[-f_s/2, f_s/2]$ ), by filtering the periodically sampled signal spectrum with an appropriate low-pass filter.

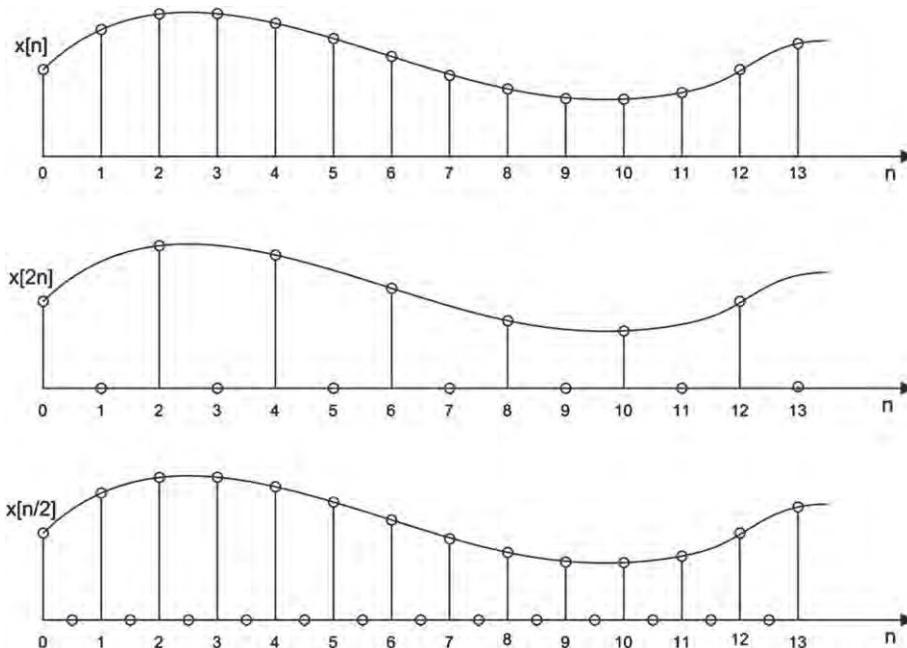

Notice, from Eq. (7.3) that the spacing,  $f_s$ , between the signal replicas is the reciprocal of the sampling period  $T_s$ . A small sampling period corresponds to a large space between the spectral replicas.

A fundamental observation, regarding the selection of the uniform sampling frequency, needs to be done at this point: when the sampling rate is selected to be less than the maximum frequency component of the bandlimited signal ( $f_s < 2f_{MAX}$ ) the periodic spectral replicas overlap each other. The amount of the overlap depends of the selected sampling frequency. Smaller the sampling frequency, larger the amount of overlap experienced by the replicas. This phenomenon is well known as aliasing. When aliasing occurs it is impossible to recover the analog signal from its samples. When  $f_s = 2f_{MAX}$  the spectral replicas touch each other without overlapping and it is theoretically (but not practically) possible to recover the analog signal from its samples; however a filter with infinite number of taps would be required. As a matter of practical consideration, we need to specify here that the signals (and filters) of interest are never perfectly bandlimited and some amount of aliasing always occurs as effect of sampling however some techniques can be used to limit the phenomena making it less harmful.

After the sampling has been applied the amplitude of each sample is one from an infinite set of possible values. This is the reason for which the samples are not compatible with a digital system yet. A digital

system can, in fact, only deal with a finite number of values. The digital samples need to be quantized before being sent to the digital data system. The quantization process limits the amplitude of the samples to a finite set of values. After the quantization process the signal can still be recovered, however some additional imprecision is added to it. The amount of imprecision depends of the quantization levels used in the process and it has the same effect on the signal as white noise. This is the reason for which it is referred to as quantization noise. The sampling of a continuous time signal and the quantization of its discrete time samples are both performed with devices called analog-to-digital converters (ADCs).

The selection of the appropriate sampling rate is a fundamental issue faced when designing digital communication systems. In order to preserve the signal, the Nyquist criterion must be always satisfied. Also, it is not difficult to find tasks for which, at some points in the digital data section of the transmitter and the receiver, it is recommended to have more than two samples per signal bandwidth. On the other hand, large sample rates cause an increase in the total workload of the system. Thus the appropriate sampling rate must be selected according to both the necessities: to have the required number of samples and to minimize the total workload. Most likely the optimum sampling frequency changes at different points in the digital architecture. It would be a huge advantage to have the option of changing the signal sampling rate at different parts in the systems while processing it, thus optimizing the number of samples as a function of the requirements. The process of changing the sampling rate of a digital signal is referred to as resampling process. The resampling process is the key concept in multirate signal processing.

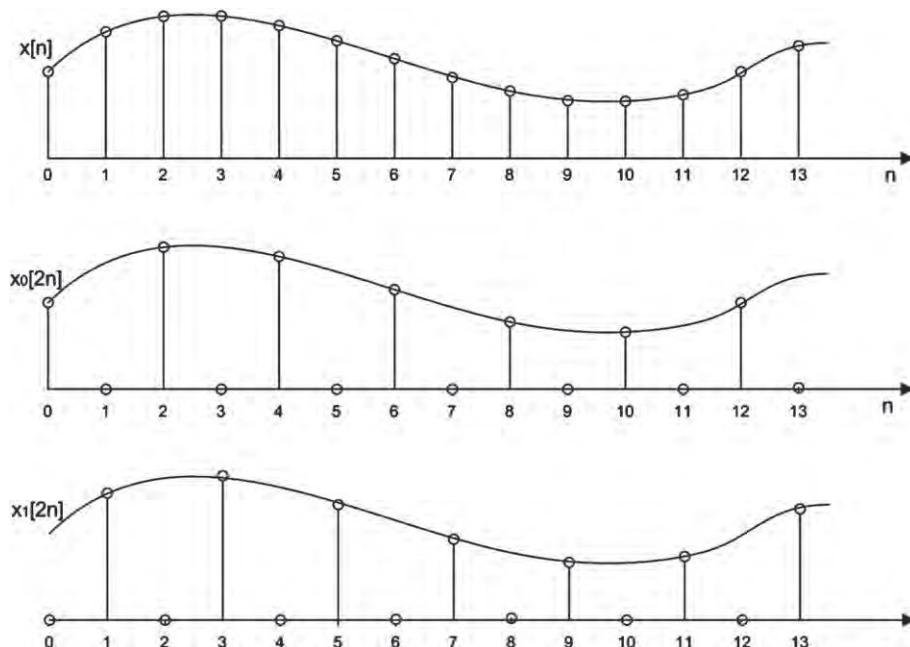

**FIGURE 7.4**

Resampling by zeroing sample values and by inserting zero valued samples.

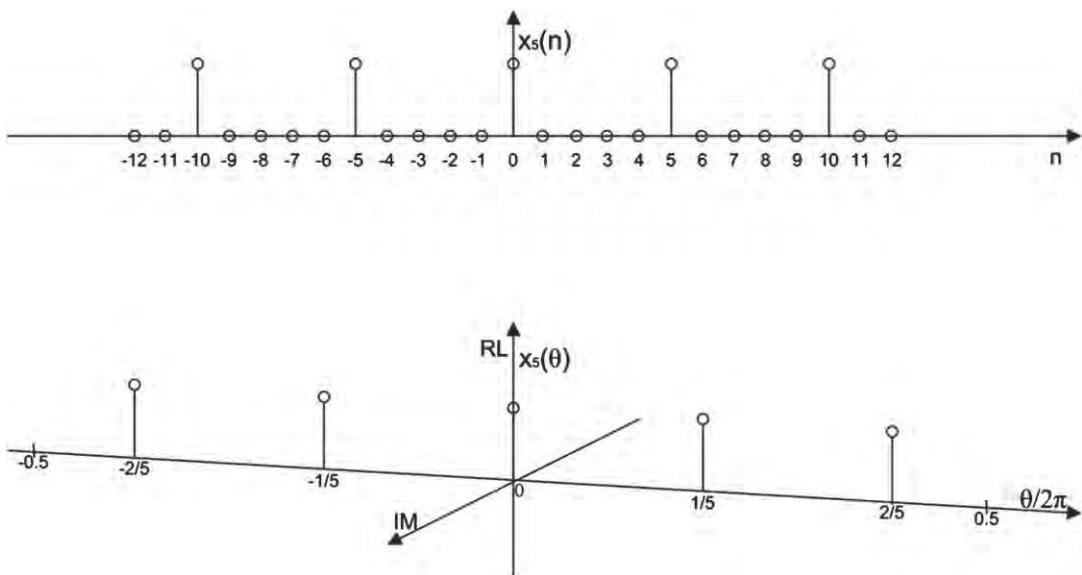

After the brief previous discussion about the sampling process of a continuous time signal, we address now the process of resampling an already sampled signal. Notice that when a continuous time signal is sampled there are no restrictions on the sample rate or the phase of the sample clock relative to the time base of the continuous time signal. On the other hand, when we resample an already sampled signal, the output sample locations are intimately related to the input sample positions. A resampled time series contains samples of the original input time series separated by a set of zero valued samples. The zero valued time samples can be the result of setting a subset of input sample values to zero or the result of inserting zeros between existing input sample values. Both options are shown in Figure 7.4. In the first example shown in this figure, the input sequence is resampled 2-to-1, keeping every second input sample starting at sample index 0 while zeroing the interim samples. In the second example, the input sequence is resampled 1-to-2, keeping every input sample but inserting a zero valued sample between each input samples. These two processes are called down sampling and up sampling respectively.

The non-zero valued samples of two sequences having the same sample rate can occur at different time indices (i.e., the same sequence can have different initial time offset) as in Figure 7.5 in which the two 2-to-1 down sampled sequences,  $s_2(n)$  and  $s_2(n - 1)$ , have different starting time index, 0 and 1, which gives equal magnitude spectral components with different phase profiles. This is explicitly shown in Figures 7.6 and 7.7, in which the time domain and the frequency domain views of the resampled sequences  $s_5(n)$  and  $s_5(n - 1)$  are depicted respectively. Remember, in fact, the time shifting property of

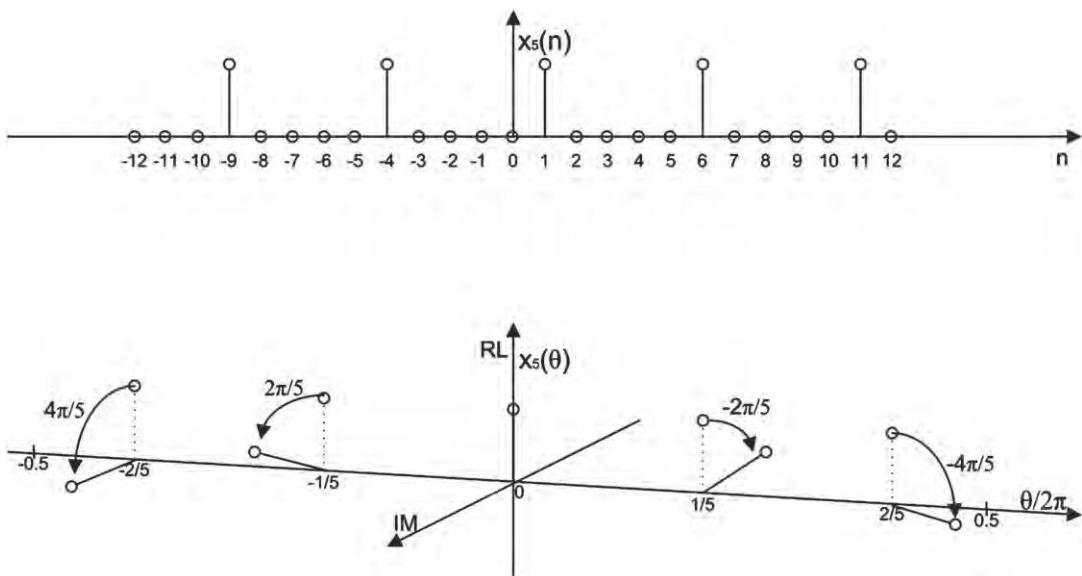

**FIGURE 7.5**

Two examples of 2-to-1 down sampling of a time series with different time offsets.

**FIGURE 7.6**

**FIGURE 7.7**

Sampling sequence  $s_5(n - 1)$  in time and frequency domain.

the discrete Fourier transform (DFT) for which a shift in time domain is equivalent to a linear phase shift in the frequency domain. The different phase profiles play a central role in multirate signal processing.

The  $M$  zero valued samples inserted between the signal samples create  $M$  periodic replicas of the original spectrum at the frequency locations  $k/M$ , with  $k = 0, \dots, M-1$  in the normalized domain. This observation suggests that resampling can be used to affect translation of spectral bands, up and down conversion, without the use of sample data heterodynes.

In the following paragraphs we clarify this concept showing how to embed the spectral translation of narrowband signals in resampling filters and describe the process as aliasing.

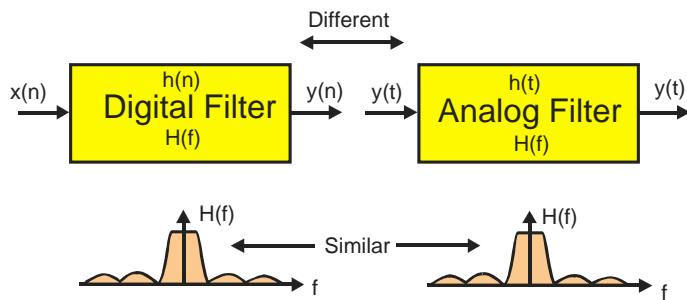

A final comment about the resampling process is that it can be applied to a time series or to the impulse response of a filter, which, of course, is simply another time series. When the resampling process is applied to a filter, the architecture of the filter changes considerably and the filter is called multirate filter.

### 1.07.3 Digital filters

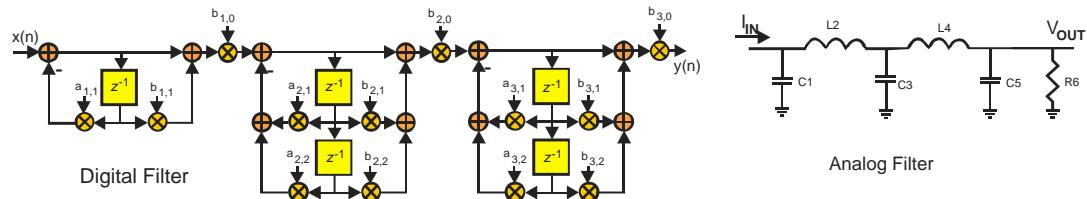

Filtering is the practice of processing signals which results in some changes of their spectral contents. Usually the change implies a reduction or filtering out some undesired input spectral components. A filter allows certain frequencies to pass while attenuating others. While analog filters operate on continuous-time signals, digital filters operate on sequences of discrete sampled value (see Figure 7.8) although digital filters perform many of the same functions as analog filters, they are different!

The two classes of filters share many of the same or analogous properties. In the standard order of our educational process we first learn about analog filters and later learn about digital filters. To ease the entry into the digital domain we emphasize the similarities of the two classes of filters. This order is due to fact that an analog filter is less abstract than a digital filter. We can touch the components of an analog filter; capacitors, inductors, resistors, operational amplifiers and wires. On the other hand a digital filter doesn't have the same physical form because a digital filter is merely a set of instructions that perform arithmetic operations on an array of numbers. The operations can be weighted sums or inner products (see Figure 7.9). It is convenient to visualize the array as a list of uniformly spaced sample values of an analog waveform. The instructions to perform these operations can reside as software in a computer or microprocessor or as firmware in a dedicated collection of interconnected hardware elements.

Let us examine the similarities that are emphasized when we learn about digital filters with some level of prior familiarity with analog filters and the tools to describe them. Many analog filters are formed by interconnections of lumped linear components modeled as ideal capacitors, inductors, and resistors while others are formed by interconnections of resistors, capacitors, and operational amplifiers. Sampled data filters are formed by interconnections of registers, adders, and multipliers. Most analog filters are designed to satisfy relationships defined by linear time invariant differential equations. The differential equations are recursive which means the initial condition time domain response, called the homogeneous or undriven response, is a weighted sum of exponentially decaying sinusoids. Most sampled data filters are designed to satisfy relationships defined by linear time invariant difference equations. Here we find the first major distinction between the analog and digital filters: the difference equations for the sampled data filters can be recursive or non recursive. When the difference equations are selected to be recursive the initial condition response is, as it was for the analog filter, samples of a

**FIGURE 7.8**

Digital and analog filters are different even though they perform similar tasks.

**FIGURE 7.9**

Digital filter: registers, adders, and multipliers. Analog filter, capacitor, inductors, and resistors.

weighted sum of exponentially decaying sinusoids. On the other hand, when the difference equation is non recursive the initial condition response is anything the designer wants it to be and is limited only by her imagination but is usually designed to satisfy some frequency domain specifications.

When we compare the two filter classes, analog and digital, we call attention to the similarities of the tools we use to describe, analyze, and design them. They are described by differential and difference equations which are weighted sums of signal derivates or weighted sums of delayed sequences. They both have linear operators or transforms, the Laplace transform  $L\{h(t)\} = H(s)$ , and the  $z$  transform  $z\{h(n)\} = H(z)$ , that offer us insight into the internal structure of the differential or difference equations (see Figure 7.10). They both have operator descriptions that perform the equivalent functions. These are the integral operator, denoted by  $s^{-1}$ , and the delay operator, denoted by  $z^{-1}$ , in which reside the system memories or state of the analog and digital filters respectively. Both systems have transfer functions  $H(s)$  and  $H(z)$ , ratios of polynomials in the operator variable  $s$  and  $z$ . The roots of the denominator polynomial, the operator version of the characteristic equation, are the filter poles. These poles describe the filter modes, the exponentially damped sinusoids, of the recursive structure. The roots of numerator polynomial are the filter zeros. The zeros describe how the filter internal mode responses are connected to the filter input and output ports. They tell us the amplitude of each response component, (called residues to impress us) in the output signal's initial condition response. The transforms of the two filter

$$\begin{aligned}
 H(z) &= \sum_{n=0}^{\infty} h(n)z^{-n} & H(s) &= \int_0^{\infty} h(t) e^{-st} dt \\
 H(z) &= b_0 \frac{z^3 + b_1 z^2 + b_2 z^1 + b_3}{z^3 + a_1 z^2 + a_2 z^1 + a_3} & H(s) &= b_0 \frac{s^3 + b_1 s^2 + b_2 s^1 + b_3}{s^3 + a_1 s^2 + a_2 s^1 + a_3} \\
 H(z) &= b_0 \frac{(z - z_1)(z - z_2)(z - z_3)}{(z - p_1)(z - p_2)(z - p_3)} & H(s) &= b_0 \frac{(s - z_1)(s - z_2)(s - z_3)}{(s - p_1)(s - p_2)(s - p_3)} \\
 H(z) &= c_0 + c_1 \frac{z}{z - p_1} + c_2 \frac{z}{z - p_2} + c_3 \frac{z}{z - p_3} & H(s) &= c_0 + c_1 \frac{p_1}{s - p_1} + c_2 \frac{p_2}{s - p_2} + c_3 \frac{p_3}{s - p_3} \\
 h(n) &= c_0 + c_1 p_1^n + c_2 p_2^n + c_3 p_3^n & h(t) &= c_0 \delta(t) + c_1 e^{-p_1 t} + c_2 e^{-p_2 t} + c_3 e^{-p_3 t}
 \end{aligned}$$

**FIGURE 7.10**

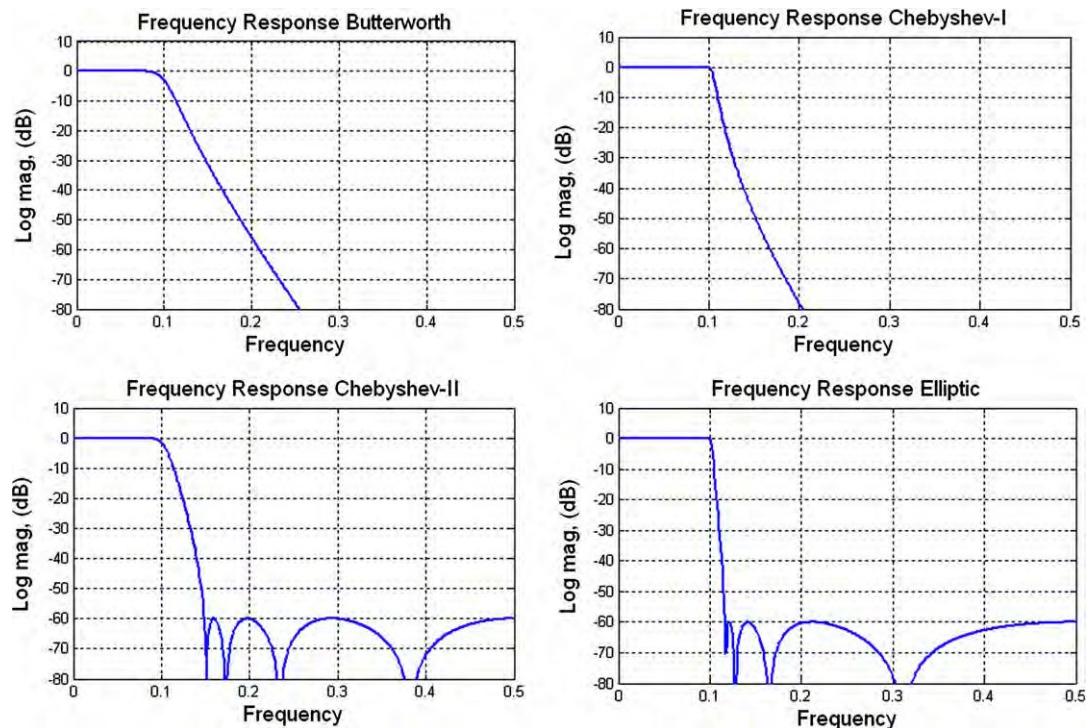

Similarity of system equations for digital and analog filters.

classes have companion transforms the Fourier transform  $H(\omega)$  and the sampled data Fourier series  $H(\theta)$  which describe, when they exist, the frequency domain behavior, sinusoidal steady state gain and phase, of the filters. It is remarkable how many similarities there are in the structure, the tools, and the time and frequency responses of the two types of filters. It is no wonder we emphasize their similarities.

We spend a great deal of effort examining recursive digital filters because of the close relationships with their analog counterparts. There are digital filters that are mappings of the traditional analog filters. These include maximally flat Butterworth filters, equal ripple pass-band Tchebychev-I filters, equal ripple stop-band Tchebychev-II filters, and both equal ripple pass-band and equal ripple stop-band Elliptic filters. The spectra of these infinite impulse response (IIR) filters are shown in Figure 7.11. All DSP filter design programs offer the DSP equivalents of their analog recursive filter counterparts.

In retrospect, emphasizing similarities between the analog filter and the equivalent digital was a poor decision. We make this claim for a number of reasons. The first is there are limited counterparts in the analog domain to the non-recursive filter of the digital domain. This is because the primary element of the non recursive filter is the pure delay, represented by the delay operator  $z^{-1}$ . We cannot form a pure delay response, represented by the analog delay operator  $e^{-sT}$ , in the analog domain as the solution of a linear differential equation. To obtain pure delay, we require a partial differential equation which offers the wave equation whose solution is a propagating wave which we use to convert distance to time delay. The propagation velocity of electromagnetic waves is too high to be of practical use in most analog filter designs but the velocity of sound waves in crystal structures enables an important class of analog filters known as acoustic surface wave (SAW) devices. Your cell phone contains one or more such filters. In general, most of us have limited familiarity with non-recursive analog filters so our first introduction to the properties and design techniques for finite duration impulse response (FIR) filters occurs in our DSP classes.

The second reason for not emphasizing the similarities between analog and digital filters is that we start believing the statement that “a digital filter is the same as an analog filter” and that all the properties of one are embedded in the other. That seemed like an ok perspective the first 10 or 20 times we heard that claim. The problem is, it is not true! The digital filter has a resource the analog filter does not have! The digital filter can perform tasks the analog filter cannot do! What is that resource? It is the sampling clock! We can do applied magic in the sampled data domain by manipulating the sample clock. There

**FIGURE 7.11**

Frequency response of digital IIR filter realizations of standard analog filters.

is no equivalent magic available in the analog filter domain! Analog designers shake their heads in disbelief when they see what a multirate filter can do. Actually digital designers also shake their heads in disbelief when they learn that manipulating the clock can accomplish such amazing things.

We might ask how can the sampling clock affect the performance or more so, enhance the capabilities of a digital filter? Great question! The answer my friend is written in the way we define frequency of a sampled data signal. Let us review how frequency as we understand it in the analog world is converted to frequency in the digital world. We now present a concise review of complex and real sinusoids with careful attention paid to their arguments.

The exponential function  $e^x$  has the interesting property that it satisfies the differential equation shown in Eq. (7.4). This means the exponential function replicates under the differential operator, an important property inherited by real and complex sinusoids. It is easy to verify that the Taylor series shown in Eq. (7.5) satisfies Eq. (7.4). When we replace the argument “ $x$ ” of Eq. (7.5) with the argument “ $j\theta$ ” we obtain the series shown in Eq. (7.6) and when we gather the terms corresponding to the even and odd powers respectively of the argument “ $j\theta$ ” we obtain the partitioned series shown in Eq. (7.7). We recognize that the two Taylor series of the partitioned Eq. (7.7) are the Taylor series of the cosine and sine which we show explicitly in Eq. (7.8). We note that the argument of both the real exponential and of

the complex exponential must be dimensionless otherwise we would not be able to sum the successive powers of the series. We also note that the units of the argument “ $\theta$ ” are radians, a dimensionless unit formed by the ratio of arc length on a circle normalized by the radius of the circle. When we replace the “ $\theta$ ” argument of Eq. (7.8) with a time varying angle “ $\theta(t)$ ” we obtain the time function shown in Eq. (7.9). The simplest time varying angle is one the changes linearly with time,  $\theta(t) = \omega_c t$ , which when substituted in Eq. (7.9) we have Eq. (7.10). All of this discussion leads us to the next statement. Since the argument of a sinusoid has the dimensionless units radians and the units of “ $t$ ” has units of seconds, then the units of  $\omega_c$  must be rad/s, a velocity. In other words, the frequency  $\omega_c$  is the time derivative of the linearly increasing phase angle  $\omega_c t$

$$\frac{d}{dx} f(x) = f(x), \quad (7.4)$$

$$e^x = \sum_{k=0}^{\infty} \frac{x^k}{k!} = 1 + x + \frac{x^2}{2} + \frac{x^3}{6} + \frac{x^4}{24} + \frac{x^5}{120} + \dots, \quad (7.5)$$

$$e^{j\theta} = \sum_{k=0}^{\infty} \frac{(j\theta)^k}{k!} = 1 + j\theta + \frac{(j\theta)^2}{2} + \frac{(j\theta)^3}{6} + \frac{(j\theta)^4}{24} + \dots, \quad (7.6)$$

$$e^{j\theta} = \left[ 1 - \frac{\theta^2}{2} + \frac{\theta^4}{24} - \frac{\theta^6}{720} + \dots \right] + j \left[ \theta - \frac{\theta^3}{6} + \frac{\theta^5}{120} - \frac{\theta^7}{5040} + \dots \right], \quad (7.7)$$

$$e^{j\theta} = \cos(\theta) + j \sin(\theta), \quad (7.8)$$

$$s(t) = e^{j\theta(t)} = \cos(\theta(t)) + j \sin(\theta(t)), \quad (7.9)$$

$$s(t) = e^{j\omega_c t} = \cos(\omega_c t) + j \sin(\omega_c t). \quad (7.10)$$

We now examine the phase argument of the sampled data sinusoid. The successive samples of a sampled complex sinusoid are formed as shown in Eq. (7.11) by replacing the continuous argument  $t$  with the sample time positions  $nT$  as was done in Eq. (7.12). We now note that while the argument of the sampled data sinusoid is dimensionless, the independent variable is no longer “ $t$ ” with units of seconds but rather “ $n$ ” with units of sample. This is consistent with the dimension of “ $T$ ” which of course is s/sample. Consequently the product  $\omega_c T$  has units of (rad/s) · (s/smpl) or rad/smpl, thus digital frequency is rad/smpl or emphatically the angle change per sample! A more useful version of Eq. (7.12) is obtained by replacing  $\omega_c$  with  $2\pi f_c$  as done in Eq. (7.13) and then replace  $T$  with  $1/f_s$  as was done in Eq. (7.14). We finally replace  $2\pi f_c / f_s$  with  $\theta_c$  as was done in Eq. (7.15). Here we clearly see that the parameter  $\theta_c$  has units of rad/smpl, which described the fraction of the circle the argument traverses per successive sample

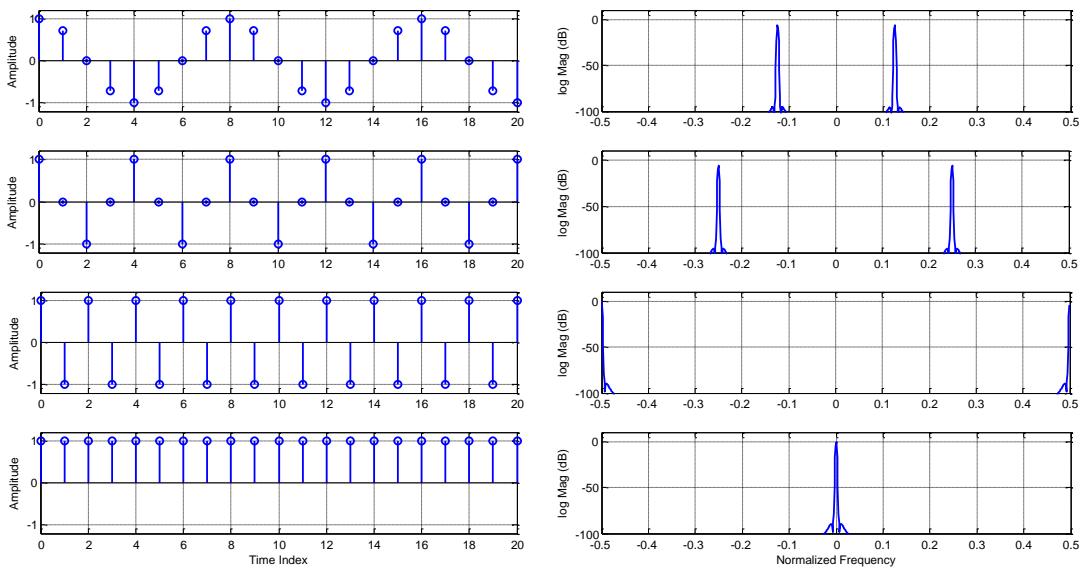

$$s(n) = s(t)|_{t=nT} = \cos(\omega_c t)|_{t=nT} + j \sin(\omega_c t)|_{t=nT}, \quad (7.11)$$

$$s(n) = \cos(\omega_c nT) + j \sin(\omega_c nT), \quad (7.12)$$

$$s(n) = \cos(2\pi f_c nT) + j \sin(2\pi f_c nT), \quad (7.13)$$

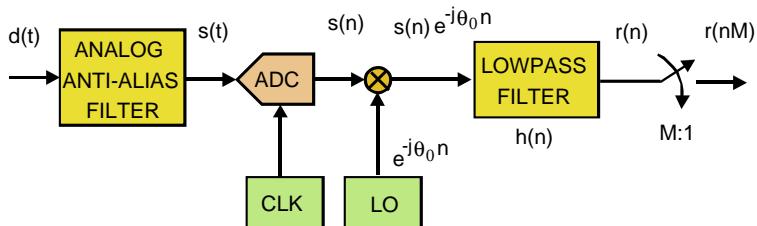

$$s(n) = \cos\left(2\pi \frac{f_c}{f_s} n\right) + j \sin\left(2\pi \frac{f_c}{f_s} n\right), \quad (7.14)$$

$$s(n) = \cos(\theta_c n) + j \sin(\theta_c n). \quad (7.15)$$

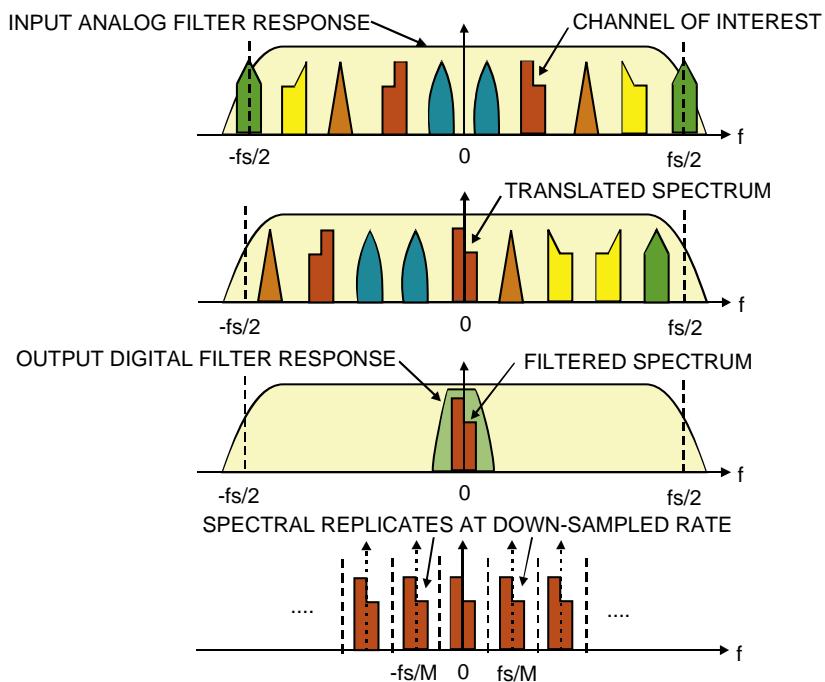

**FIGURE 7.12**

Time series and spectra of sinusoid aliased to new digital frequencies as a result of down-sampling.

Now suppose we have a sampled sinusoid with sample rate 8-times the sinusoid's center frequency so that there are 8-samples per cycle. This is equivalent to the sampled sinusoid having a digital frequency of  $2\pi/8$  rad/smpl. We can visualize a spinning phasor rotating 1/8th of the way around the unit circle per sample. Figure 7.12 subplots 1 and 2 show 21 samples of this sinusoid and its spectrum. Note the pair of spectral lines located at  $\pm 0.125$  on the normalized frequency axis. We can reduce the sample rate of this time series by taking every other sample. The spinning rate for this new sequence is  $2 \cdot 2\pi/8$  or  $2\pi/4$ . The down sampled sequence has doubled its digital frequency. The newly sampled sequence and its spectrum are shown in Figure 7.12 subplots 3 and 4. Note the pair of spectral lines are now located at  $\pm 0.25$  on the normalized frequency axis. We can further reduce the sample rate of by again taking every other sample (or every 4th sample of the original sequence). The spinning rate for this new sequence is  $4 \cdot 2\pi/8$  or  $2\pi/2$ . The down sampled sequence has again doubled its digital frequency. The newly sampled sequence and its spectrum are shown in Figure 7.12 subplots 5 and 6. Note the pair of spectral lines are now located at  $\pm 0.5$  on the normalized frequency axis. We once again reduce the sample rate of by taking every other sample (or every 8th sample of the original sequence). The spinning rate for this new sequence is  $8 \cdot 2\pi/8$  or  $2\pi$ , but since a  $2\pi$  rotation is equivalent to no rotation, the spinning phasor appears to be stationary or rotating at 0 rad/smpl. The newly sampled sequence and its spectrum are shown in Figure 7.12 subplots 7 and 8. Note the pair of spectral lines are now located at  $\pm 1$  which is equivalent to 0 on the normalized frequency axis. Frequency shifts due to sample rate changes are attributed to aliasing. Aliasing enables us to move spectrum from one frequency location to another location without the need for the complex mixers we normally use in a digital down converter to move a spectral span to base-band.

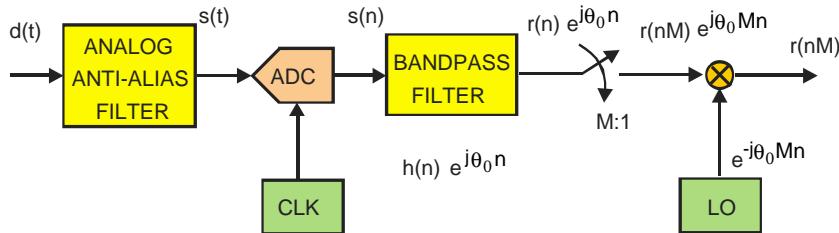

**FIGURE 7.13**

Building blocks of conventional digital down converter.

**FIGURE 7.14**

Spectra at consecutive points in conventional digital down converter.

Speaking of the standard digital down converter Figure 7.13 presents the primary signal flow blocks based on the DSP emulation of the conventional analog receiver. Figure 7.14 shows the spectra that will be observed at successive output ports of the DDC. We can follow the signal transformations of the DDC by following the spectra in the following description. The top figure shows the spectrum at the output of the analog to digital converter. The second figure shows the spectrum at the output of the quadrature mixer. Here we see the input spectrum has been shifted so that the selected channel band resides at zero

**FIGURE 7.15**

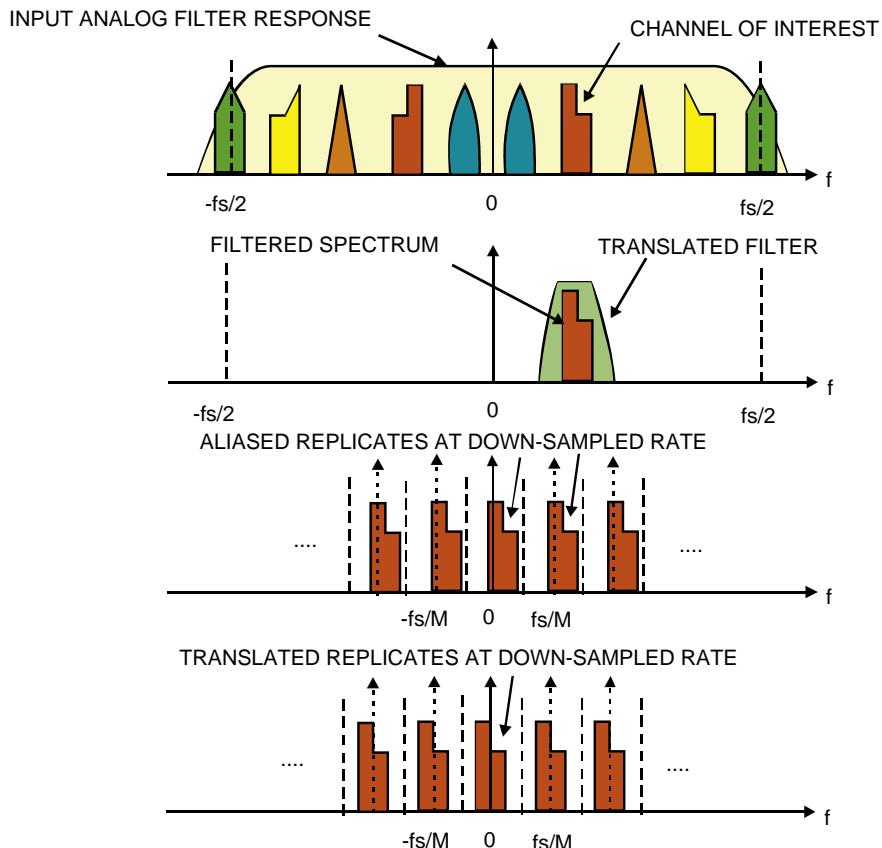

Building blocks of aliasing digital down converter with  $M$ -to-1 down sampler following filter.

frequency. The third figure shows the output of the low-pass filter pair. Here we see that a significant fraction of the input bandwidth has been rejected by the stop band of the low pass filter. Finally, the last figure shows the spectrum after the  $M$ -to-1 down sampling that reduced the sample rate in proportion to the reduction in bandwidth performed by the filter. We will always reduce sample rate if we are reducing bandwidth. We have no performance advantage for over satisfying the Nyquist criterion, but incur significant penalties by operating the DSP processors at higher than necessary sample rates.

Figure 7.15 presents the primary signal flow blocks based on aliasing the selected band pass span to base-band by reducing the output sample rate of the band pass filter. Figure 7.16 shows the spectra that will be observed at successive output ports of the aliasing DDC. We can follow the signal transformations of the aliasing DDC by following the spectra in the following description. The top figure shows the spectrum at the output of the analog to digital converter. The second figure shows the spectrum of the complex band pass filter and the output spectrum from this filter. The band pass filter is formed by up-converting, by a complex heterodyne, the coefficients of the prototype low pass filter. We note that this filter does not have a mirror image. Analog designers sigh when they see this digital option. The third figure shows the output of the band pass filter pair following the  $M$ -to-1 down sampling. If the center frequency of the band is a multiple of the output sample rate the aliased band resides at base band. For the example shown here the center frequency was  $\Delta f$  above  $k f_s/M$  and since all multiples of  $f_s/M$  alias to base-band, our selected band has aliased to  $\Delta f$  above zero frequency. Finally, the last figure shows the spectrum after the output heterodyne from  $\Delta f$  to base-band. Note that the heterodyne is applied at the low output rate rather than at the input at the high input rate as was done in Figure 7.13.

Our last section of this preface deals with the equivalency of cascade operators. Here is the core idea. Suppose we have a cascade of two filters, say a low pass filter followed by a derivative filter as shown in Figure 7.17. The filters are linear operators that commute and are distributive. We could reorder the two filters and have the same output from their cascade or we could apply the derivative filter operator to the low pass filter to form a composite filter and obtain the same output as from the cascade. This equivalency is shown in Figure 7.18. The important idea here is that we can filter the input signal and then apply an operator to the filter output or we can apply the operator to the filter and have the altered filter perform both operators to the input signal simultaneously.

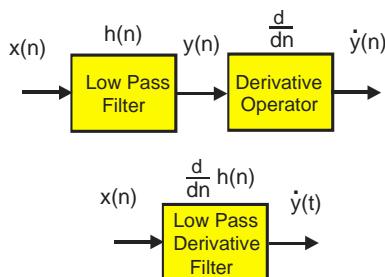

Here comes the punch-line! Let us examine the aliasing digital down converter of Figure 7.15 which contains a band pass filter followed by an  $M$ -to-1 resampler. This section is redrawn in the upper half of Figure 7.19. If we think about it, this almost silly: Here we compute one output sample for each input sample and then discard  $M-1$  of these samples in the  $M$ -to-1 down sampler. Following the lead of the

**FIGURE 7.16**

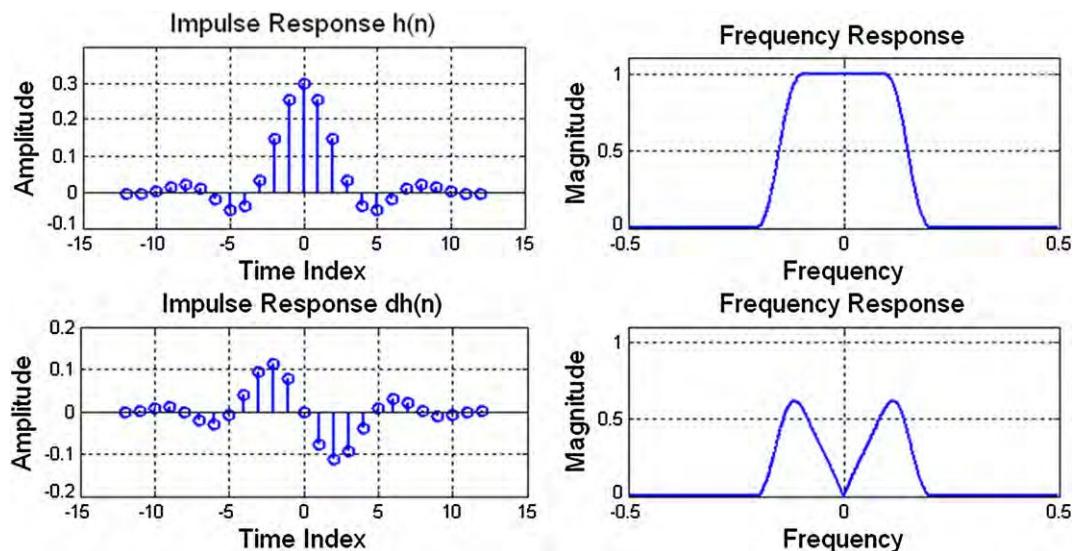

Spectra at consecutive points in aliasing digital down converter with down sampling following filter.

cascade linear operators, the filter and resampler, being equivalent to a composite filter containing the resampler applied to the filter we replace the pair of operators with the composite operator as shown in the lower half of Figure 7.19.

Embedding the  $M$ -to-1 resampler in the band pass filter is accomplished by the block diagram shown in Figure 7.20. This filter accepts  $M$  inputs, one for each path, and computes 1 output. Thus we do not waste operations computing output sample scheduled to be discarded. An interesting note here is that the complex rotators applied to the prototype low pass filter in Figure 7.15 have been factored out of each arm and are applied once at the output of each path. This means that if the input data is real, the samples are not made complex till they leave the filter. This represents a 2-to-1 savings over the architecture of Figure 7.13 in which the samples are made complex on the way into the filter which means there are 2 filters, one for each path of the complex heterodyne. The alias based DDS with

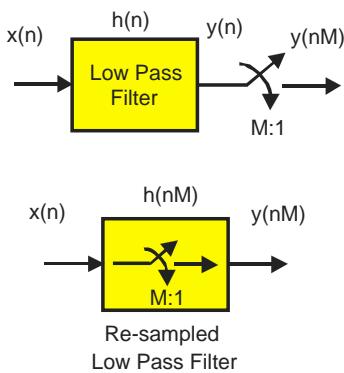

**FIGURE 7.17**

A cascade of two filters is same as a single filter formed by a composite filter.

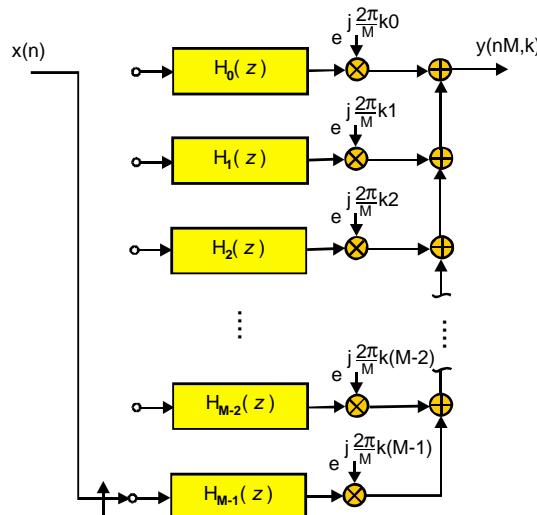

**FIGURE 7.18**

Spectrum of cascade filters is same as spectrum of single filter containing combined responses.

resampler embedded in the filter is not a bad architecture! It computes output samples at the output rate and it only uses one partitioned filter rather than 2. Not bad is understatement! The cherry on top of this dessert is the rotator vector applied to the output of the path filters. This rotator can extract any band from the aliased frequency spans that have aliased to base-band by the resampling operator. If it can extract any band then we have the option of extracting more than one band, and in fact we can extract every band from the output of the partitioned filter. That's amazing! This filter can service more than one output channel simultaneously; all it needs is additional rotator vectors. As we will see shortly, the single filter structure can service all the channels that alias to base-band and the most efficient bank of

**FIGURE 7.19**

Cascade of filter and  $M$ -to-1 resampler equivalent to  $M$ -to-1 resample filter.

**FIGURE 7.20**

$M$ -path  $M$ -to-1 resample band pass filter performs aliased digital down converter.

rotators is implemented by an  $M$ -point IFFT. More to come! Be sure to read on! We have only scratched the surface and the body of material related to multirate filters if filled with many wonderful properties and applications.

### 1.07.4 Windowing

As specified in the previous section, digital filters can be classified in many ways, starting with the most general frequency domain characteristics such as low pass, high pass, band pass, band stop and finishing with, secondary characteristics such as uniform and non-uniform group delay. We now also know that an important classification is based on the filter's architectural structure with a primary consideration being that of finite impulse response and infinite impulse response filter. Further sub-classifications, such as canonic forms, cascade forms, lattice forms are primarily driven by consideration of sensitivity to finite arithmetic, memory requirements, ability to pipeline arithmetic, and hardware constraints.

The choice to perform a given filtering task with a recursive or a non-recursive filter is driven by a number of system considerations, including processing resources, clock speed, and various filter specifications. Performance specifications, which include operating sample rate, pass band and stop band edges, pass band ripple, and out-of-band attenuation, all interact to determine the complexity required of the digital filter.

In filters with infinite impulse response each output sample depends on previous input samples and on previous filter output samples. That is the reason for which their practical implementation always requires a feedback loop. Thus, like all feedback based architectures, IIR filters are sensitive to input perturbations that could cause instability and infinite oscillations at the output. However infinite impulse response filters are usually very efficient and require far few multiplications than an FIR filter per output sample. Notice that an IIR filter could have an infinite sequence of output samples even if the input samples become all zeros. It is this characteristic which gives them their name.

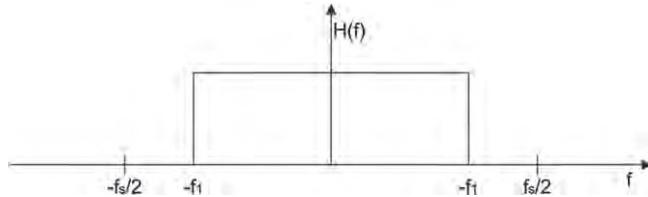

Finite impulse response filters use only current and past input samples and none of the filter's previous output samples to obtain a current output sample value (remember that they are also sometimes referred to as non-recursive filters). Given a finite duration of the input signal, the FIR filter will always have a finite duration of non-zero output samples and this is the characteristic which gives them their name.

The procedure by which the FIR filters calculate the output samples is the convolution of the input sequence with the filter impulse response which is shown in Eq. (7.16)

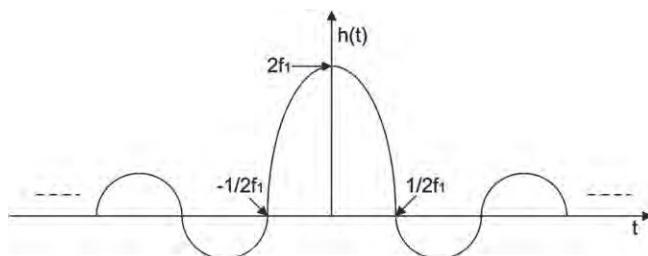

$$y(n) = \sum_{k=0}^{M-1} h(k)x(n-k), \quad (7.16)$$

where  $x(n)$  is the input sequence,  $h(n)$  is the filter impulse response and  $M$  is the number of filter taps. The convolution is nothing but a series of multiplications followed by the addition of the products while the impulse response of a filter is nothing but what the name tells us: it is the time domain view of the filter's output values when the input is an impulse (a single unity-valued sample preceded and followed by zero-valued samples).

In the following paragraphs we introduce the basic window design method for FIR filters. Because low pass filtering is the most common filtering task, we will introduce the window design method for low pass FIR filters. However the relationships between filter length and filter specifications and the interactions between filter parameters remain valid for other filter types. Many other techniques can be also used to design FIR filters and, at the end of this section, we will introduce the Remez algorithm,

**FIGURE 7.21**

Frequency response of a prototype ideal low pass filter.

**FIGURE 7.22**

Impulse response of a prototype ideal low pass filter.

which is one of the most used filter design technique, as well as one of its modified versions which allows us to achieve  $1/f$  type of decay for the out of band side-lobes.

The frequency response of a prototype low pass filter is shown in Figure 7.21. The pass band is seen to be characterized by an ideal rectangle with unity gain between the frequencies  $\pm f_1$  Hz and zero gain elsewhere.

The attraction of the ideal low pass filter  $H(f)$  as a prototype is that, from its closed form inverse Fourier transform, we achieve the exact expression for its impulse response  $h(t)$  which is shown in Eq. (7.17)

$$h(t) = 2f_1 \frac{\sin(2\pi f_1 t)}{2\pi f_1 t}. \quad (7.17)$$

The argument of the  $\sin(x)/x$  function is always the product of  $2\pi$ , half the spectral support  $(2f_1)/2$ , and the independent variable  $t$ . The numerator is periodic and becomes zero when the argument is a multiple of  $\pi$ . The impulse response of the prototype filter is shown in Figure 7.22. The  $\sin(x)/x$  filter shown in Figure 7.22 is a continuous function which we have to sample to obtain the prototype sampled data impulse response. To preserve the filter gain during the sampling process we scale the sampled function by the sample rate  $1/f_s$ . The problem with the sample set of the prototype filter is that the number of samples is unbounded and the filter is non-causal. If we had a finite number of samples, we could delay the response to make it causal and solve the problem. Then our first task is to reduce the unbounded set of filter coefficients to a finite set. The process of pruning an infinite sequence to a finite sequence is called windowing. In this process, a new limited sequence is formed as the product

of the finite sequence  $w(n)$  and the infinite sequence as shown in Eq. (7.18) where the  $\cdot^*$  operator is the standard MATLAB point-by-point multiply

$$h_w(n) = w(n) \cdot^* h(n). \quad (7.18)$$

Applying the properties of the Fourier transforms we obtain the expression for the spectrum of the windowed impulse response which is the circular convolution of the Fourier transform of  $h(n)$  and  $w(n)$ .

The symmetric rectangle we selected as our window abruptly turns off the coefficient set at its boundaries. The sampled rectangle weighting function has a spectrum described by the Dirichlet kernel which is the periodic extension of the transform of a continuous time rectangle function. The convolution between the spectra of the prototype filter with the Dirichlet kernel forms the spectrum of the rectangle windowed filter coefficient set. The contribution to the corresponding output spectrum is seen to be the stop band ripple, the transition bandwidth, and the pass band ripple. The pass band and stop band ripples are due to the side-lobes of the Dirichlet kernel moving through the pass band of the prototype filter while the transition bandwidth is due to the main lobe of the kernel moving from the stop band to the pass band of the prototype. A property of the Fourier series is that their truncated version forms a new series exhibiting the minimum mean square (MMS) approximation to the original function. We thus note that the set of coefficients obtained by a rectangle window exhibits the minimum mean square approximation to the prototype frequency response. The problem with MMS approximations in numerical analysis is that there is no mechanism to control the location or value of the error maxima. The local maximum errors are attributed to the Gibbs phenomena, the failure of the series to converge in the neighborhood of a discontinuity. These errors can be objectionably large. A process must now be invoked to control the objectionably high side-lobe levels. We have two ways to approach the problem. First we can redefine the frequency response of the prototype filter so that the amplitude discontinuities are replaced with a specified tapering in the transition bandwidth. In this process, we trade-off the transition bandwidth for side-lobe control. Equivalently, knowing that the objectionable stop band side-lobes are caused by the side-lobes in the spectrum of the window, we can replace the rectangle window with other even symmetric functions with reduced amplitude side-lobe levels. The two techniques, side-lobe control and transition-bandwidth control are tightly coupled. The easiest way to visualize control of the side-lobes is by destructive cancellation between the spectral side-lobes of the Dirichlet kernel associated with the rectangle and the spectral side-lobes of translated and scaled versions of the same kernel. The cost we incur to obtain reduced side-lobe levels is an increase in main lobe bandwidth. Remembering that the window's two-sided main lobe width is an upper bound to the filter's transition bandwidth, we can estimate the transition bandwidth of a filter required to obtain a specified side-lobe level. The primary reason we examined windows and their spectral description as weighted Dirichlet kernels was to develop a sense of how we trade the main lobe width of the window for its side-lobe levels and in turn filter transition bandwidth and side-lobe levels. Some windows perform this trade-off of bandwidth for side-lobe level very efficiently while others do not.

The Kaiser-Bessel window is very effective while the triangle (or Fejer) window is not. The Kaiser-Bessel window is in fact a family of windows parameterized over the time-bandwidth product,  $\beta$ , of the window. The main lobe width increases with  $\beta$  while the peak side-lobe level decreases with  $\beta$ . The Kaiser-Bessel window is a standard option in filter design packages such as Matlab and QED-2000.

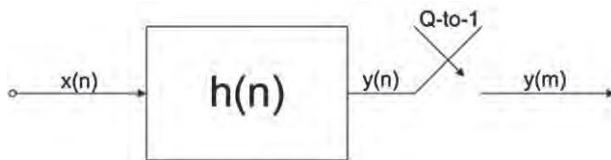

Other filter design techniques include the Remez algorithm [6], sometimes also referred to as the Parks-McClellan or P-M, the McClellan, Parks and Rabiner or MPR, the Equiripple, and the Multiple Exchange algorithm, which found large acceptance in practice. It is a very versatile algorithm capable

of designing FIR filters with various frequency responses, including multiple pass band and stop band frequency responses with independent control of ripple levels in the multiple bands. The desired pass band cut off frequencies, the frequencies where the attenuated bands begin and the desired pass band and stop band ripple are given as input parameters to the software which will generate  $N$  time domain filter coefficients.  $N$  is the minimum number of taps required for the desired filter response and it is selected by using the Harris approximation or the Hermann approximation (in Matlab). The problem with the Remez algorithm is that it shows equiripple side-lobes which is not a desirable characteristic. We would like to have a filter frequency response which has a  $1/f$  out-of-band decay rate rather than exhibit equiripple. The main reasons for desiring that characteristic are related to system performance. We often build systems comprising a digital filter and a resampling switch. Here the digital filter reduces the bandwidth and is followed by a resampling switch that reduces the output sample commensurate with the reduced output bandwidth. When the filter output is resampled, the low level energy residing in the out-of-band spectral region aliases back into the filter pass band. When the reduction in sample rate is large, there are multiple spectral regions that alias or fold into the pass band. For instance, in a 16-to-1 reduction in sample rate, there are 15 spectral regions that fold into the pass band. The energy in these bands is additive and if the spectral density in each band is equal, as it is in an equiripple design, the folded energy level is increased by a factor of  $\sqrt{15}$ . The second reason for which we may prefer FIR filters with  $1/f$  side-lobe attenuation as opposed to uniform side-lobes is finite arithmetic. A filter is defined by its coefficient set and an approximation to this filter is realized by a set of quantized coefficients. Given two filter sets  $h(n)$  and  $g(n)$ , the first with equiripple side-lobes, the second with  $1/f$  side-lobes, we form two new sets,  $h_Q(n)$  and  $g_Q(n)$ , by quantizing their coefficients. The quantization process is performed in two steps: first we rescale the filters by dividing with the peak coefficient. Second, we represent the coefficients with a fixed number of bits to obtain the quantized approximations. The zeros of an FIR filter residing on the unit circle perform the task of holding down the frequency response in the stop band. The interval between the zeros contains the spectral side-lobes. When the interval between adjacent zeros is reduced, the amplitude of the side-lobe between them is reduced and when the interval between adjacent zeros is increased the amplitude of the side-lobe between them is increased. The zeros of the filters are the roots of the polynomials  $H(z)$  and  $G(z)$ . The roots of the polynomials formed by the quantized set of coefficients differ from the roots of the non-quantized polynomials. For small changes in coefficient size, the roots exhibit small displacements along the unit circle from their nominal positions. The amplitude of some of the side-lobes must increase due to this root shift. In the equiripple design, the initial side-lobes exactly meet the designed side-lobe level with no margin for side-lobe increase due to root shift caused by coefficient quantization. On the other hand, the filter with  $1/f$  side-lobe levels has plenty of margin for side-lobe increase due to root shift caused by coefficient quantization.

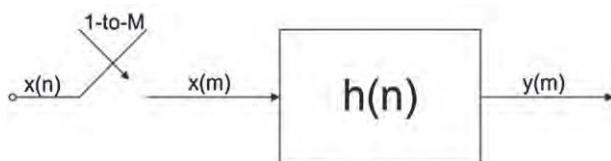

More details on the modified Remez algorithm can be found in [6].

## 1.07.5 Basics on multirate filters

Multirate filters are digital filters that contain a mechanism to increase or decrease the sample rate while processing input sampled signals. The simplest multirate filter performs integer up sampling of 1-to- $M$  or integer down sampling of  $Q$ -to-1. By extension, a multirate filter can employ both up sampling and down sampling in the same process to affect a rational ratio sample rate change of  $M$ -to- $Q$ . More sophisticated techniques exist to perform arbitrary and perhaps slowly time varying sample rate changes.

**FIGURE 7.23**

Down sampling process; filtering and sample rate reduction.

**FIGURE 7.24**

Up sampling process; sample rate increasing and filtering.

The integers  $M$  and  $Q$  may be selected to be the same so that there is no sample rate change between input and output but rather an arbitrary time shift or phase offset between input and output sample positions of the complex envelope. The sample rate change can occur at a single location in the processing chain or can be distributed over several subsections.

Conceptually, the process of down sampling can be visualized as a two-step progression indicated in Figure 7.23. There are three distinct signals associated with this procedure. The process starts with an input series  $x(n)$  that is processed by a filter  $h(n)$  to obtain the output sequence  $y(n)$  with reduced bandwidth. The sample rate of the output sequence is then reduced  $Q$ -to-1 to a rate commensurate with the reduced signal bandwidth. In reality the processes of bandwidth reduction and sample rate reduction are merged in a single process called multirate filter. The bandwidth reduction performed by the digital filter can be a low-pass or a band-pass process.

In a dual way, the process of up sampling can be visualized as a two-step process as indicated in Figure 7.24. Here too there are three distinct time series. The process starts by increasing the sample rate of an input series  $x(n)$  by resampling it 1-to- $M$ . The zero-packed time series with  $M$ -fold replication of the input spectrum is processed by a filter  $h(n)$  to reject the spectral replicas and output the sequence  $y(m)$  with the same spectrum as the input sequence but sampled at  $M$  times higher sample rate. In reality the processes of sample rate increase and selected bandwidth rejection are also merged in a single process again called multirate filtering.

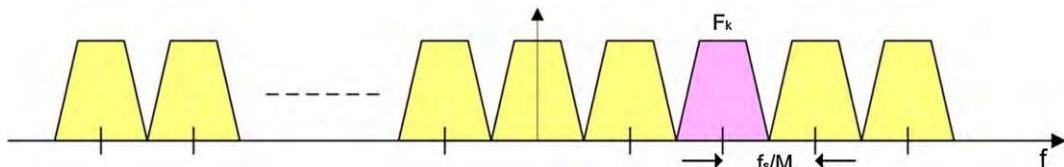

The presented structures are the most basic forms of multirate filters; in the following we present more complicated multirate architecture models. In particular we focus on the polyphase decomposition of a prototype filter which is very efficient when embedded in multirate structures. We also propose the derivation, step by step, of both the polyphase down converter and up converter channelizers. These are the two standard engines that we will modify for designing a novel polyphase channelizer that better fits the needs of the future software defined radio.

## 1.07.6 From single channel down converter to standard down converter channelizer

The derivation of the standard polyphase channelizer begins with the issue of down converting a single frequency band, or channel, located in a multi channel frequency division multiplexed (FDM) input signal whose spectrum is composed of a set of  $M$  equally spaced, equal bandwidth channels, as shown in Figure 7.25. Note that this signal has been band limited by analog filters and has been sampled at a sufficiently high sample rate to satisfy the Nyquist criterion for the full FDM bandwidth.

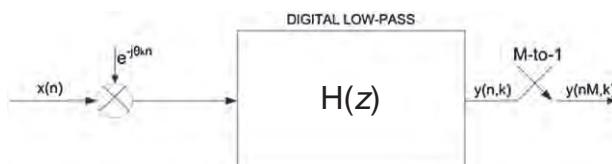

We have many options available for down converting a single channel; The standard processing chain for accomplishing this task is shown in Figure 7.26. This structure performs the standard operations of down converting a selected frequency band with a complex heterodyne, low pass filtering to reduce the output signal bandwidth to the channel bandwidth, and down sampling to a reduced rate commensurate with the reduced bandwidth. The structure of this processor is seen to be a digital signal processor implementation of a prototype analog  $I$ - $Q$  down converter. We mention that the down sampler is commonly referred to as a decimator, a term that means to destroy one sample every tenth. Since nothing is destroyed and nothing happens in tenths, we prefer, and will continue to use, the more descriptive name, down sampler.

The output data from the complex mixer is complex, hence it is represented by two time series,  $I(n)$  and  $Q(n)$ . The filter with real impulse response  $h(n)$  is implemented as two identical filters, each processing one of the quadrature time series. The convolution process between a signal and a filter is often performed by simply multiply and sum operations between signal data samples and filter coefficients extracted from two sets of addressed memory registers. In this form of the filter, one register set contains the data samples while the other contains the coefficients that define the filter impulse response.

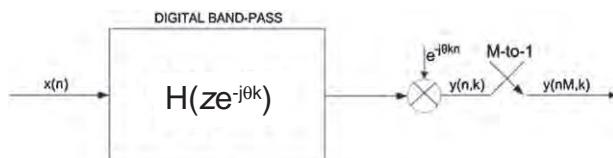

**FIGURE 7.25**

Spectrum of multichannel input signal, processing task: extract complex envelope of selected channel.

**FIGURE 7.26**

Standard single channel down converter.

**FIGURE 7.27**

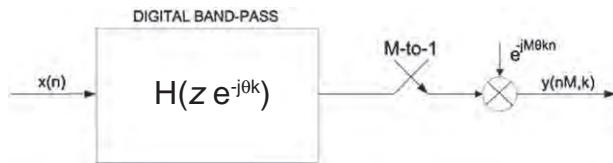

Band-pass filter version of single channel down converter.

By using the equivalency theorem, which states that *the operations of down conversion followed by a low-pass filter are equivalent to the operations of band-pass filtering followed by a down conversion*, we can exchange the positions of the filter and of the complex heterodyne achieving the block diagram shown in Figure 7.27.

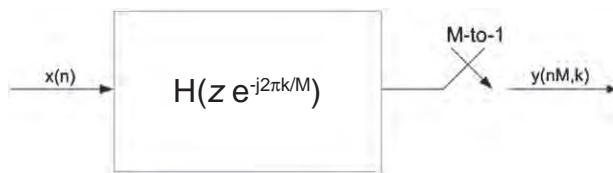

Note here that the up converted filter,  $h(n) \exp(j\theta_k n)$ , is complex and as such its spectrum resides only on the positive frequency axis without a negative frequency image. This is not a common structure for an analog prototype because of the difficulty of forming a pair of analog quadrature filters exhibiting a  $90^\circ$  phase difference across the filter bandwidth. The closest equivalent structure in the analog world is the filter pair used in image-reject mixers and even there, the phase relationship is maintained by a pair of complex heterodynes.

Applying the transformation suggested by the equivalency theorem to an analog prototype system does not make sense since it doubles the required hardware. We would have to replace a complex scalar heterodyne (two mixers) and a pair of low-pass filters with a pair of band-pass filters, containing twice the number of reactive components, and a full complex heterodyne (four mixers). If it makes no sense to use this relationship in the analog domain, why does it make sense in the digital world? The answer is found in the fact that we define a digital filter as a set of weights stored in the coefficient memory. Thus, in the digital world, we incur no cost in replacing the pair of low-pass filters  $h(n)$  required in the first option with the pair of band-pass filters  $h(n) \cos(n\theta_k)$  and  $h(n) \sin(n\theta_k)$  required for the second one. We accomplish this task by a simple download to the coefficient memory.

An interesting historical perspective is worth noting here. In the early days of wireless, radio tuning was accomplished by sliding a narrow band filter to the center frequency of the desired channel to be extracted from the FDM input signal. These radios were known as tuned radio frequency (TRF) receivers. The numerous knobs on the face of early radios adjusted reactive components of the amplifier chain to accomplish the tuning process. Besides the difficulty in aligning multiple tuned stages, shifting the center frequency of the amplifier chain often initiated undesired oscillation due to the parasitic coupling between the components in the radio. Edwin Howard Armstrong, an early radio pioneer, suggested moving the selected channel to the fixed frequency filter rather than moving the filter to the selected channel. This is known as the *superheterodyne principle*, a process invented by Armstrong in 1918 and quickly adopted by David Sarnoff of the Radio Corporation of America (RCA) in 1924. Acquiring exclusive rights to Armstrong's single-tuning dial radio invention assured the commercial dominance of RCA in radio broadcasting as well the demise of hundreds of manufacturers of TRF radio receivers. It seems we have come full circle. We inherited from Armstrong a directive to move the desired spectrum to the filter and we have readily applied this legacy to DSP-based processing. We are now proposing that, under appropriate conditions, it makes more sense to move the filter to the selected spectral region.

**FIGURE 7.28**

Down sampled band-pass down converter.

**FIGURE 7.29**

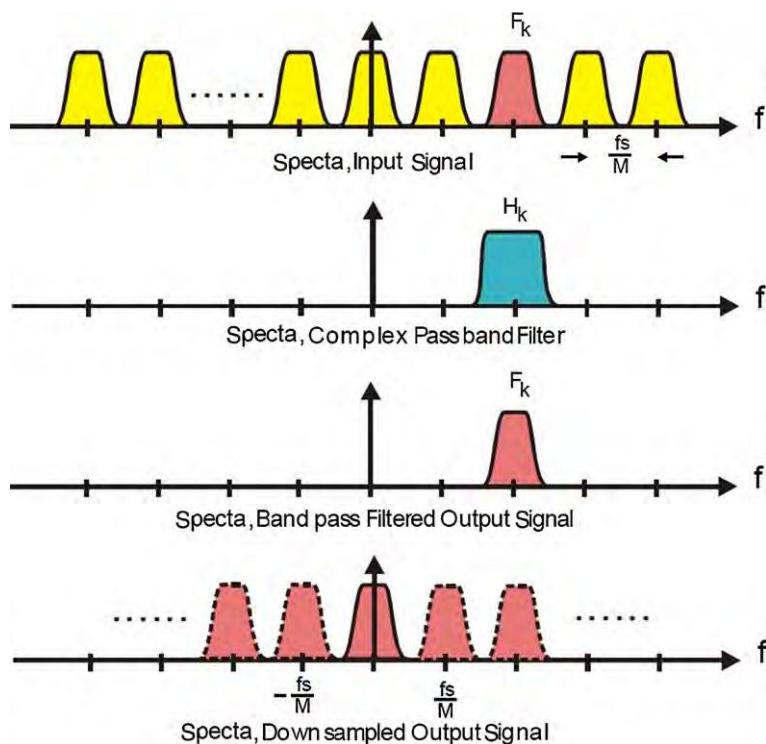

Band-pass down converter aliased to base-band by down sampler.

We still have to justify the full complex heterodyne required for the down conversion at the filter output rather than at the filter input, which is done in the subsequent paragraphs.

Examining Figure 7.27, we note that following the output down conversion, we perform a sample rate reduction in which we retain one sample out of  $M$ -samples. Because we find it useless to down convert the samples we discard in the next down sample operation, we move the down sampler before the down converter achieving the demodulator scheme shown Figure 7.28. We note in this figure that also the time series of the complex sinusoid has been down sampled. The rotation rate of the sampled complex sinusoid is  $\theta_k$  and  $M\theta_k$  radians per sample at the input and output of the  $M$ -to-1 resampler respectively. This change in observed rotation rate is due to aliasing. When aliased, a sinusoid at one frequency or phase slope appears at another phase slope due to the resampling.

We now invoke a constraint on the sampled data center frequency of the down converted channel. We choose center frequencies  $\theta_k$ , which will alias to DC as a result of down sampling to  $M\theta_k$ . This condition is assured if  $M\theta_k$  is congruent to  $2\pi$ , which occurs when  $M\theta_k = k2\pi$ , or more specifically, when  $\theta_k = k2\pi/M$ . The modification to Figure 7.28 to reflect this provision is seen in Figure 7.29. The constraint, that the center frequencies be limited to integer multiples of the output sample rate, assures aliasing to base-band by the sample rate change. When a channel aliases to base-band because the resampling operation the corresponding resampled heterodyne defaults to a unity-valued scalar, which consequently is removed from the signal processing path.

Note that if the center frequency of the aliased signal is offset by  $\Delta_\theta$  rad/smpl from a multiple of the output sample rate, the aliased signal will reside at an offset of  $\Delta_\theta$  rad/smpl from zero frequency at base-band and a complex heterodyne, or base-band converter, is needed to shift the signal by the residual  $\Delta_\theta$  offset. This base-band mixer operates at the output sample rate rather than at the input sample rate for a conventional down converter. We can consider this required final mixing operation as a post conversion task and allocate it to the next processing block.

**FIGURE 7.30**

Spectrum, down sampled output signal.

The spectral effect of the signal processing performed by the structure in Figure 7.29 is shown in Figure 7.30. The savings realized by this form of down conversion is due to the fact that we no longer require a quadrature oscillator or the pair of input mixers to effect the required frequency translation.

Applying again the idea that it is useless to filter those samples that will be later discarded by the down sampler we apply the noble identity to exchange the operations of filtering and down sampling. The noble identity states that *a filter processing every Mth input sample followed by an output M-to-1 down sampler is the same as an input M-to-1 down sampler followed by a filter processing every input sample*. Its interpretation is that the M-to-1 down sampled time series from a filter processing every  $M$ th input sample presents the same output by first down sampling the input by  $M$ -to-1, to discard the samples not used by the filter when computing the retained output samples, and then operating the filter on only the retained input samples. The noble identity works because samples of delay at the input clock rate is the same interval as one-sample delay at the output clock rate.

At this point, with only a filter followed by a resampler, we can apply the polyphase decomposition to the filter and separate it into  $M$ -parallel paths for achieving the standard  $M$ -path polyphase down

converter channelizer. In order to make the understanding process easier for the reader, we first perform the polyphase decomposition of a low-pass prototype filter and then we extend the results to the band-pass filter case. Equation (7.19) represents the  $z$  transform of a digital low-pass prototype filter  $h(n)$

$$H(z) = \sum_{n=0}^{N-1} h(n)z^{-n} = h(0) + h(1)z^{-1} + h(2)z^{-2} + \cdots + h(N-1)z^{-(N-1)}. \quad (7.19)$$

In order to achieve the polyphase partition of  $H(z)$ , we rewrite the sum in Eq. (7.19), as shown in Eq. (7.20), partitioning the one-dimensional array of weights in a two-dimensional array. In this mapping we load an array by columns but process it by rows. The partition forms columns of length  $M$  containing  $M$  successive terms in the original array, and continues to form adjacent  $M$ -length columns until we account for all the elements of the original one-dimensional array

$$\begin{aligned} H(z) = & h(0) + h(M+0)z^{-M} + h(2M+0)z^{-2M} + \cdots \\ & h(1)z^{-1} + h(M+1)z^{-(M+1)} + h(2M+1)z^{-(2M+1)} + \cdots \\ & h(2)z^{-2} + h(M+2)z^{-(M+2)} + h(2M+2)z^{-(2M+2)} + \cdots \\ & \vdots \\ & h(M-1)z^{-(M-1)} + h(2M-1)z^{-(2M-1)} + h(3M-1)z^{-(3M-1)} + \cdots \end{aligned} \quad (7.20)$$

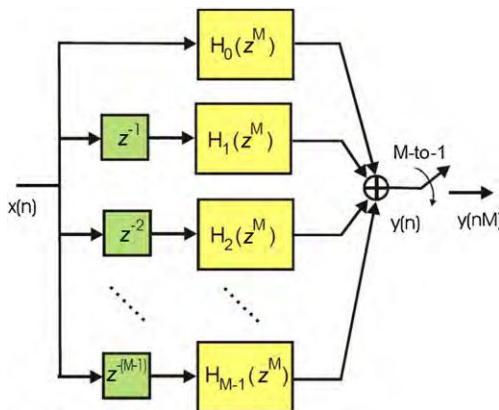

We note that the first row of the two-dimensional array is a polynomial in  $z^M$ , which we will denote  $H_0(z^M)$  a notation to be interpreted as an addressing scheme to start at index 0 and increment in strides of length  $M$ . The second row of the same array, while not a polynomial in  $z^M$ , is made into one by factoring the common term  $z^{-1}$  and then identifying this row as  $z^{-1}H_1(z^M)$ . It is easy to see that each row of the two-dimensional array described by Eq. (7.8) can be written as  $z^{-r}H_r(z^M)$  achieving the more compact form as shown in Eq. (7.9) where  $r$  is the row index which is coincident with the path index

$$H(z) = \sum_{r=0}^{M-1} z^{-r} H_r(z^M) = \sum_{r=0}^{M-1} z^{-r} \sum_{n=0}^{\frac{N}{M}-1} h(r+nM)z^{-nM}. \quad (7.21)$$

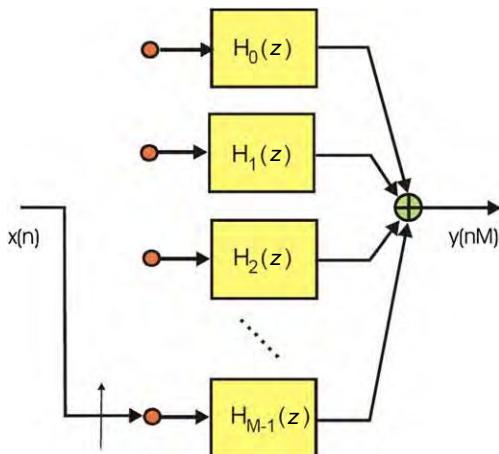

The block diagram depicting the  $M$ -path polyphase decomposition of the resampled low-pass filter of Eq. (7.21) is depicted in Figure 7.31.

At this point, in the structure depicted in Figure 7.31, we can pull the resampler on the left side of the adder and down sample the separate filter outputs performing the sum only for the retained filter output samples. With the resamplers at the output of each filter we can invoke again the noble identity and place them at the input of each filter.

The resamplers operate synchronously, all closing at the same clock cycle. When the switches are closed, the signal delivered to the filter on the top path is the current input sample. The signal delivered to the filter one path down is the content of the one stage delay line, which, of course, is the previous input sample. Similarly, as we traverse the successive paths of the  $M$ -path partition, we find upon switch closure, that the  $k$ th path receives a data sample delivered  $k$  samples ago. We conclude that the interaction of the delay lines in each path with the set of synchronous switches can be likened to an input

**FIGURE 7.31**

*M*-path partition of prototype low-pass filter with output resampler.

**FIGURE 7.32**

*M*-path partition of prototype low-pass filter with input delays and *M*-to-1 resamples replaced by input commutator.

commutator that delivers successive samples to successive arms of the *M*-path filter. This interpretation is shown in Figure 7.32 which depicts the final structure of the polyphase decomposition of a low-pass prototype filter.

At this point we can easily achieve the band-pass polyphase partition from the low-pass partition by applying the frequency translation property of the *z*-Transform that states the following.

If

$$H(z) = h(0) + h(1)z^{-1} + h(2)z^{-2} + \cdots + h(N-1)z^{N-1} = \sum_{n=0}^{N-1} h(n)z^{-n}$$

and

$$\begin{aligned} G(z) &= h(0) + h(1)e^{j\theta}z^{-1} + h(2)e^{j2\theta}z^{-2} + \cdots + h(N-1)e^{j(N-1)\theta}z^{N-1} \\ &= h(0) + h(1) \left[ e^{-j\theta}z \right]^{-1} + h(2) \left[ e^{-j\theta}z \right]^{-2} + \cdots + h(N-1) \left[ e^{-j(N-1)\theta}z \right]^{-(N-1)} \\ &= \sum_{n=0}^{N-1} h(n) \left[ e^{-j\theta}z \right]^{-n}, \end{aligned}$$

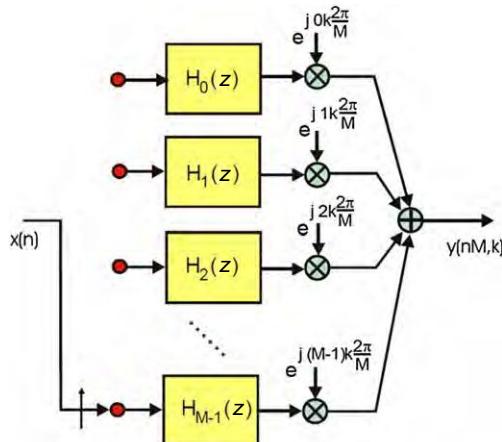

then

$$G(z) = H(z)|_{z=e^{-j\theta}z} = H \left( e^{j\theta}z \right).$$

By using this property and replacing in Eq. (7.21) each  $z^{-r}$  with  $z^{-r}e^{jr\theta}$ , where  $\theta = k \frac{2\pi}{M}$ , we achieve

$$H(ze^{-j(2\pi k/M)}) = \sum_{r=0}^{M-1} z^{-r} e^{jr(2\pi k/M)} H_r(z^M). \quad (7.22)$$

The complex scalars  $e^{jr(\frac{2\pi k}{M})}$  attached to each path of the  $M$ -path filter can be placed anywhere along the path. We choose to place them after the down sampled path filter segments  $H_r(z^M)$ . This change is shown in Figure 7.33 that depicts the standard polyphase filter bank used for down converting a single channel. The computation of the time series obtained from the output summation in Figure 7.33 is shown

**FIGURE 7.33**

Resampling  $M$ -path down converter.

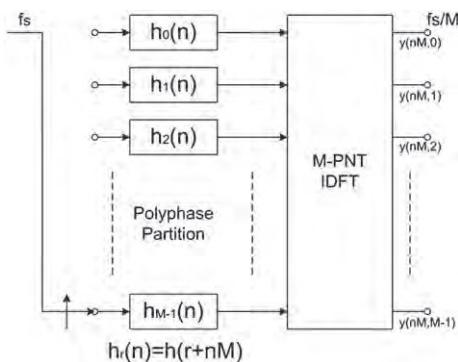

in Eq. (7.23). Here, the argument  $nM$  reflects the down sampling operation, which increments through the time index in strides of length  $M$ , delivering every  $M$ th sample of the original output series. The variable  $y_r(nM)$  is the  $nM$ th sample from the filter segment in the  $r$ th path, and  $y(nM, k)$  is the  $nM$ th time sample of the time series from the  $r$ th center frequency. Remember that the down converted center frequencies located at integer multiples of the output sample frequency alias to zero frequency after the resampling operation. Note that the output  $y(nM, k)$  is computed as a phase coherent summation of the output series  $y_r(nM)$ . This phase coherent sum is, in fact, an inverse discrete Fourier transform of the  $M$ -path outputs, which can be likened to beam forming the output of the path filters

$$y(nM, k) = \sum_{r=1}^{M-1} y_r(nM) e^{j(2\pi/M)rk}. \quad (7.23)$$

The beam forming perspective offers an interesting insight to the operation of the resampled down converter system we have just examined; the reasoning proceeds as follows: the commutator delivering consecutive samples to the  $M$  input ports of the  $M$ -path filter performs a down sampling operation. Each port of the  $M$ -path filter receives data at  $1/M$ th of the input rate. The down sampling causes the  $M$ -to-1 spectral folding, effectively translating the  $M$  multiples of the output sample rate to base-band. The alias terms in each path of the  $M$ -path filter exhibit unique phase profiles due to their distinct center frequencies and the time offsets of the different down sampled time series delivered to each port. These time offsets are, in fact, the input delays shown in Figure 7.31 and Eq. (7.3). Each of the aliased center frequency experiences a phase shift shown in Eq. (7.24) equal to the product of its center frequency and the path time delay.

$$\varphi(r, k) = w_k \Delta T_r = 2\pi \frac{f_s}{M} kr T_s = 2\pi \frac{f_s}{M} kr \frac{1}{f_s} = \frac{2\pi}{M} kr. \quad (7.24)$$

The phase shifters of the IDFT perform phase coherent summations, very much like that performed in narrowband beam forming, extracting from the myriad of aliased time series, the alias with the particular matching phase profile. This phase sensitive summation aligns contributions from the desired alias to realize the processing gain of the coherent sum while the remaining alias terms, which exhibit rotation rates corresponding to the  $M$  roots of unity, are destructively canceled in the summation. The inputs to the  $M$ -path filter are not narrowband, and phase shift alone is insufficient to cause the destructive cancellation over the full bandwidth of the undesired spectral contributions. Continuing with our beam-forming perspective, to successfully separate signals with unique phase profiles due to the input commutator delays, we must perform the equivalent of time-delay beam forming. The  $M$ -path filters, obtained by  $M$ -to-1 down sampling of the prototype low-pass filter supply the required time delays. The  $M$ -path filters are approximations to all-pass filters, exhibiting, over the channel bandwidth, equal ripple approximation to unity gain and the set of linear phase shifts that provide the time delays required for the time-delay beam-forming task. The filter achieves this property by virtue of the way it is partitioned. Each of the  $M$ -path filters,  $h_r(n)$ , for instance, with weights  $h_r(r + nM)$ , is formed by starting with an initial offset of  $r$  samples and then incrementing in strides of  $M$  samples. The initial offsets, unique to each path, are the source of the different linear phase-shift profiles. It is because of the different linear phase profiles, that the filter partition is known as *polyphase* filter. An useful perspective is that the phase rotators following the filters perform phase alignment of the band center for each aliased spectral band while the polyphase filters perform the required differential phase shift across these same channel bandwidths.

**FIGURE 7.34**

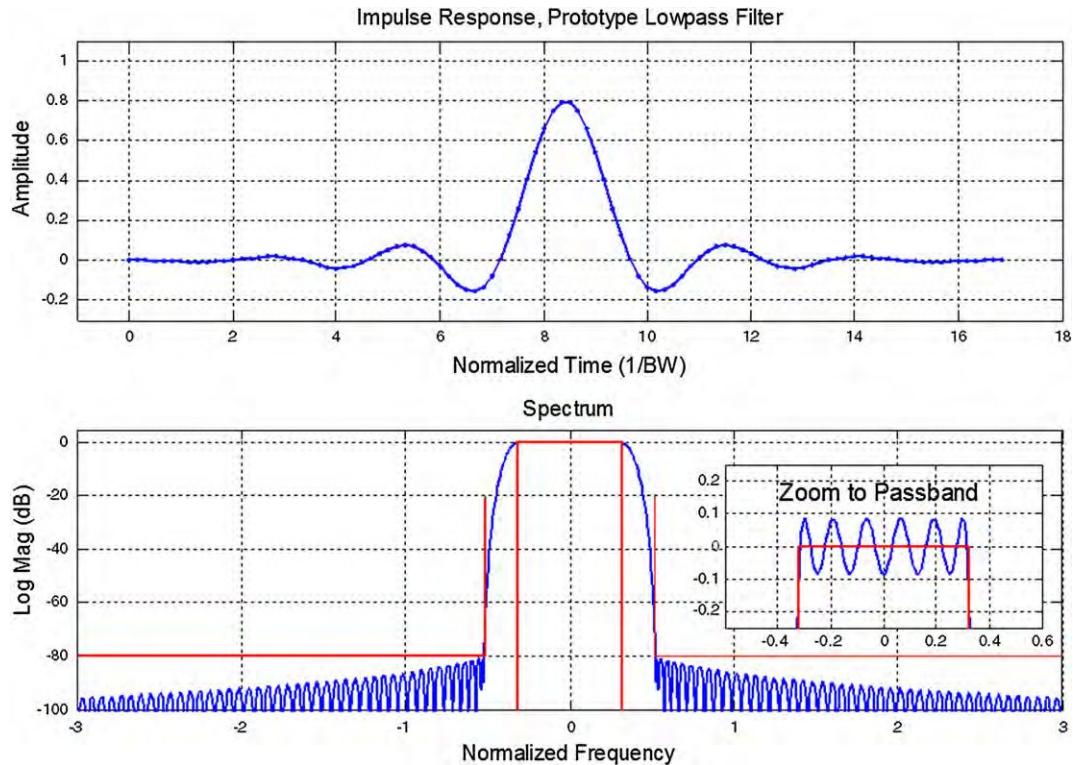

Standard polyphase down converter channelizer: commutator,  $M$ -path polyphase filter and  $M$ -point IFFT.

When the polyphase filter is used to down convert and down sample a single channel, the phase rotators are implemented as external complex products following each path filter. When a small number of channels are being down converted and down sampled, appropriate sets of phase rotators can be applied to the filter stage outputs and summed to form each channel output. Therefore the most advantageous applications of that structure are those in which the number of channels to be down converted becomes sufficiently large. Sufficiently large means on the order of  $\log_2(N)$ . Since the phase rotators following the polyphase filter stages are the same as the phase rotators of an IDFT, we can use the IDFT to simultaneously apply the phase shifters for all the channels we wish to extract from the aliased signal set. This is reminiscent of phased-array beam forming. For computational efficiency, the IFFT algorithm implements the IDFT.

The complete structure of a standard  $M$ -path polyphase down converter channelizer is shown in Figure 7.34.

To summarize: in this structure the commutator performs an input sample rate reduction by commuting successive input samples to selected paths of the  $M$ -path filter. Sample rate reduction occurring prior to any signal processing causes spectral regions residing at multiples of the output sample rate to alias to base-band. The partitioned  $M$ -path filter performs the task of aligning the time origins of the offset sampled data sequences delivered by the input commutator to a single common output time origin. This is accomplished by the all-pass characteristics of the  $M$ -path filter sections that apply the required differential time delay to the individual input time series. The IDFT performs the equivalent of a beam-forming operation; the coherent summation of the time-aligned signals at each output port with selected phase profiles. The phase coherent summation of the outputs of the  $M$ -path filters separates the various aliases residing in each path by constructively summing the selected aliased frequency components located in each path, while simultaneously destructively canceling the remaining aliased spectral components.

We conclude the reasoning on the standard  $M$ -path down converter channelizer by stating that it simultaneously performs the following three basic operations: sample rate reduction, due to the input commutator; bandwidth reduction, due to the  $M$ -path partitioned filter weights and Nyquist zone selection, due to the IFFT block.

**FIGURE 7.35**

Impulse response and frequency response of prototype low-pass filter.

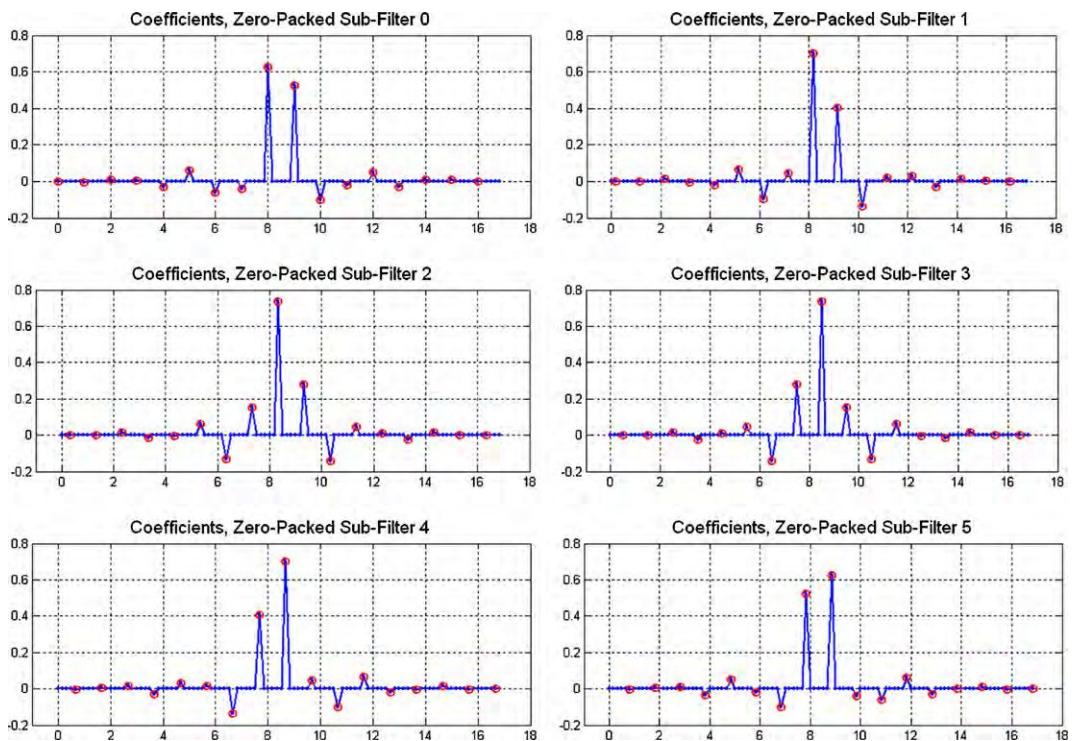

In the following, in order to facilitate the understanding process for the reader, we show some figures, which are results of Matlab simulation, to support the theoretical reasoning of the previous paragraphs. The example concerns a 6-path down converter channelizer that performs 6-to-1 down sampling. In particular Figure 7.35 shows the impulse response and the frequency response of the low-pass prototype filter used for the polyphase partition.

Figure 7.36 shows the impulse responses of the zero-packed filter on each arm of the 6-path polyphase partition while Figure 7.37 shows the spectra corresponding to the filters of Figure 7.36. It is evident from this figure that the zero packing process has the effect of producing spectral copies of the filter frequency response.

In Figure 7.38 we show the phase of each spectral copy of the zero packed prototype filter on each arm of the partition. In this figure the phases of the spectral copies of each arm are overlaid and each line of the plot corresponds to a specific arm in the partition.

In Figure 7.39 the same phase profiles of Figure 7.38 are de-trended, zoomed, and made causal.

In Figure 7.40 the 3-D view of the filter spectral copies, with their phase profiles, is shown for each path, while, in Figure 7.41, the final result of the channelization process is shown, again in a 3-D fashion.

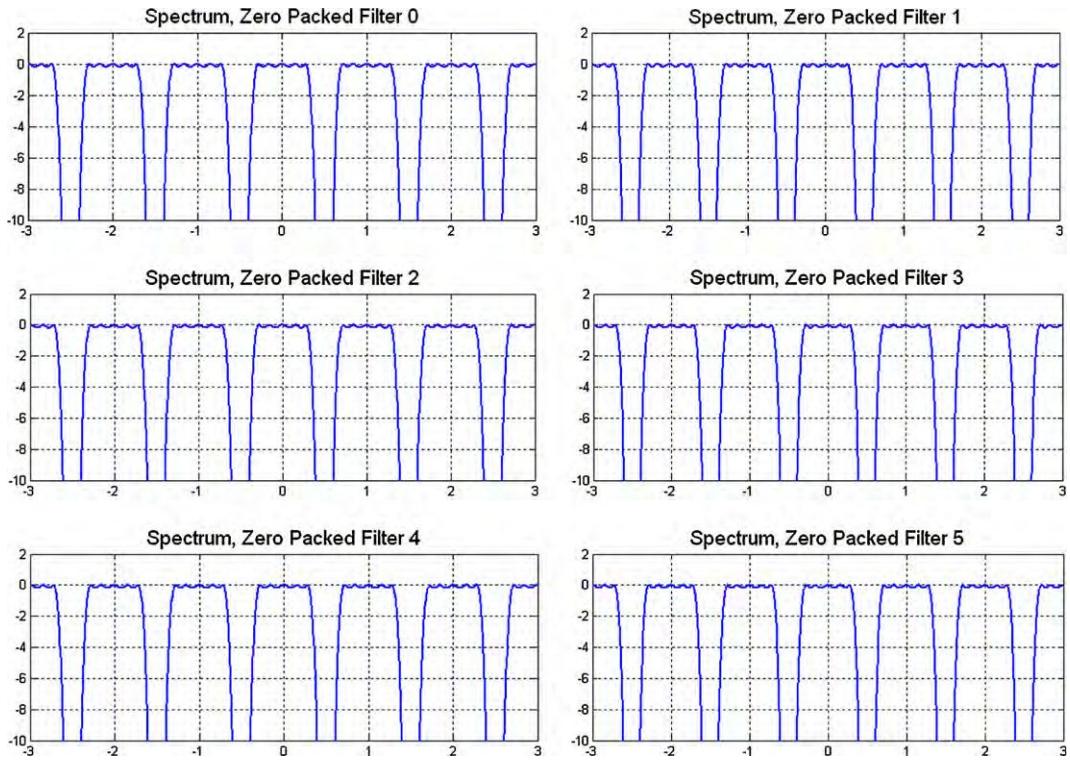

**FIGURE 7.36**

Impulse response of 6-path polyphase partition prior to 6-to-1 resampling.

### 1.07.6.1 From single channel up converter to standard up converter channelizer

The standard  $M$ -path up converter channelizer that performs 1-to- $M$  up sampling while up converting the input time series is derived from the basic structure, shown in Figure 7.11, of a single channel interpolator formed of an up sampler followed by an appropriate low-pass filter. In this configuration, the up sampler converts the Nyquist interval, which is the observable frequency span, from the input sample rate to a span  $M$  times wider, which is the output sample rate. The 1-to- $M$  up sampler zero packs the input time series, effectively decreasing the distance between the input samples without modifying the spectral content of the series. The wider Nyquist interval, spanning  $M$  input Nyquist intervals, presents  $M$  spectral copies of the input spectrum to the low-pass filter. The amplitude of each of the  $M$  copies is  $1/M$ th of the amplitude of the input signal spectrum. When a low-pass filter is scaled so that the peak coefficient is unity, the filter exhibits a processing gain inversely proportional to its fractional bandwidth. Thus, as the filter eliminates the  $M-1$  spectral copies, reducing the bandwidth by a factor of  $1/M$ , the filter gain precisely compensates for the attenuation of the input spectra due to the zero packing of the input series.

We start the modifications of this basic architecture by observing that the zero valued samples of the zero-packed input time series do not contribute to the weighted sums formed at the filter output. Since they do not contribute, there is no need to perform the product and sum from the input data registers

**FIGURE 7.37**

Frequency response of 6-path polyphase partition prior to 6-to-1 resampling.

containing the known zero-valued samples. Since only the non-zero packed samples contribute to the filter output, we can track their location in the filter and perform the weighted sum only from the register locations containing these samples. These locations are separated by  $M$  sample values, and their position shifts through the filter as each new zero-valued input is presented to the input of the filter. Keeping track of the coefficient stride and the position of each coefficient set is automatically performed by the polyphase partition of the filter which is represented in Eq. (7.25). This equation describes the filter as a sum of successively delayed sub-filters with coefficients separated by the stride of  $M$  samples. Equation (7.26) is a compact representation of Eq. (7.25) where the  $r$ th stage  $H_r(z^M)$  of the polyphase filter is formed by the coefficient set that starts at index  $r$  and increments in steps of length  $M$

$$H(z) = \sum_{r=0}^{M-1} z^{-r} \sum_{n=0}^{\left(\frac{N}{M}\right)-1} h(r + nM) z^{-nM}, \quad (7.25)$$

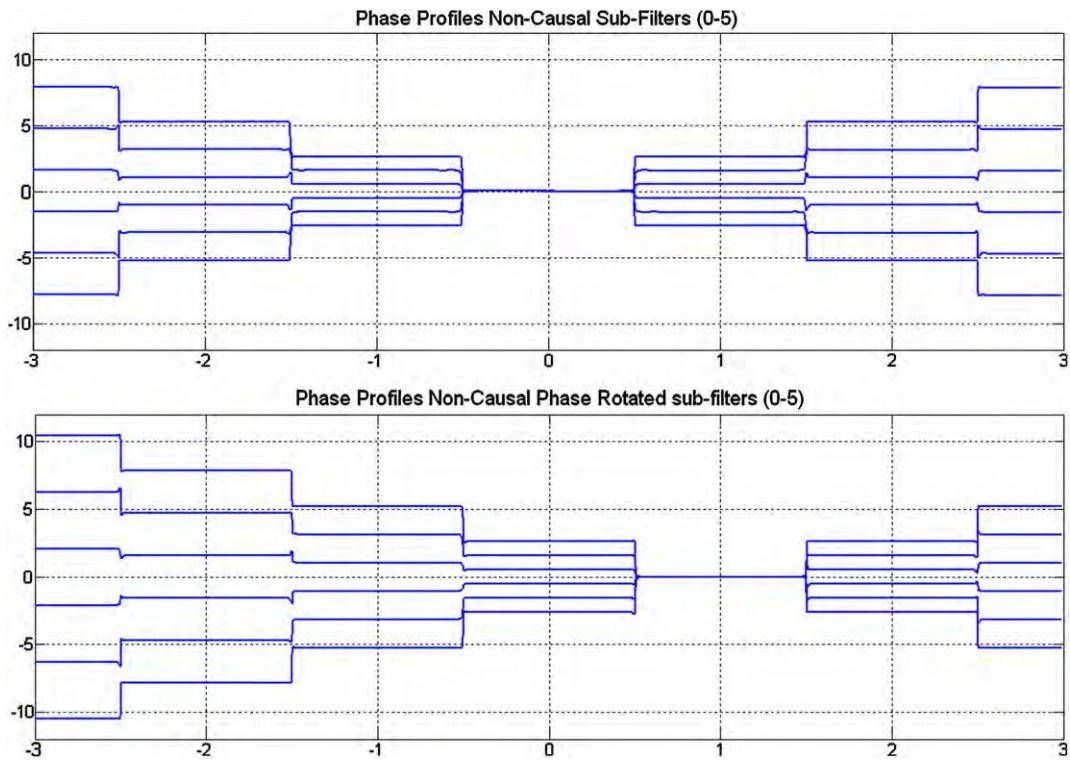

**FIGURE 7.38**

Overlaid phase response of 6-path polyphase partition prior to 6-to-1 resampling.

$$H(z) = \sum_{r=0}^{M-1} z^{-r} H_r(z^M). \quad (7.26)$$

The pictorial form of the filter in the  $M$ -path polyphase partition is shown in Figure 7.42. This structure enables the application of the noble identity in which we slide the resampler through the filter and replace the  $M$  units of delay at the output clock rate with one unit of delay at the input clock rate. Note that the resampler cannot slide through the delays  $z^{-r}$  following each filter segment  $H_r$ .

The resamplers following the separate filter stages up sample each time series by a factor of  $M$ , and the delays in each arm shift each resulting time series at different time increments so that only one non-zero time sample is presented to the summing junction at each output time. Thus, rather than performing the sum with multiple zeros, we can simply point to the arm that sequentially supplies the non-zeros samples. The output commutator, shown in Figure 7.43, performs this selective access. Figure 7.42 represents the standard polyphase interpolator or up sampler. Due to the low-pass nature of the filter on which the polyphase decomposition has been applied, this structure does not perform

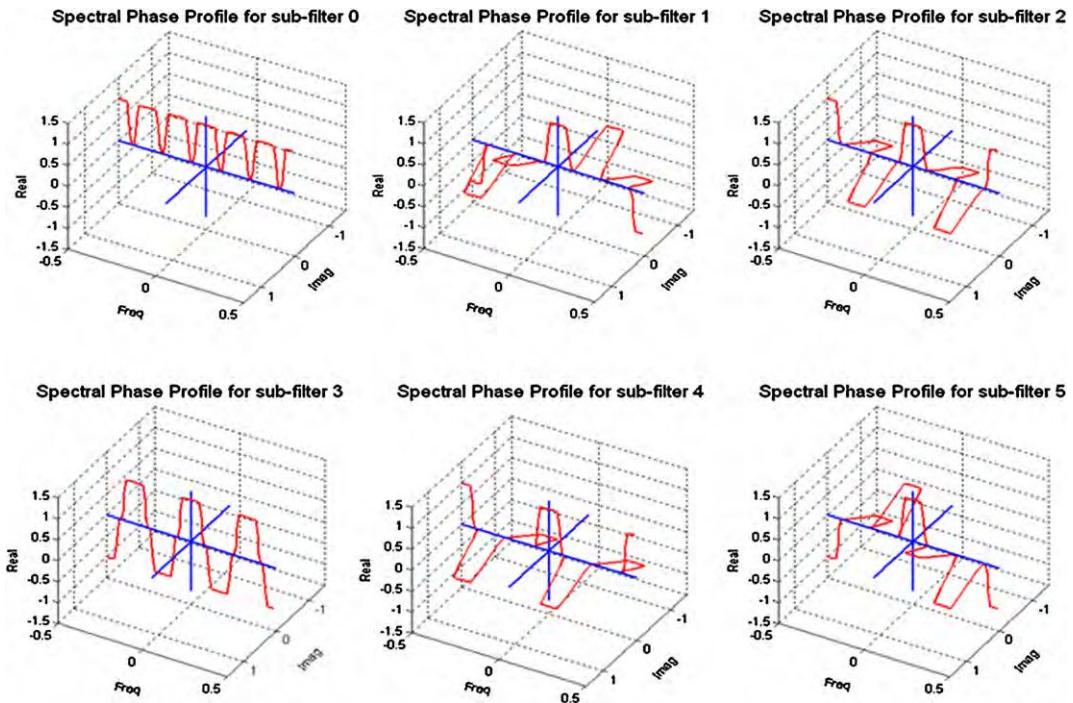

**FIGURE 7.39**

De-trended overlaid phase response; 6-path partition prior to 6-to-1 resampling.

the up conversion of the interpolated signal yet. Its output is the same low-pass input spectrum with a sample rate that is  $M$  times higher than the input sample rate.

We recall here that the purpose of the interpolation process is to increase the input sample rate while translating the input spectrum to a higher carrier frequency. If used in a communication system, such a structure directly translates the input signal to an intermediate frequency (IF), and then outputs the digital IF signal via a single DAC. This option reduces the system costs by using a single DAC and a band-pass filter to replace the standard base-band process requiring matched DACs, matched low-pass filters, matched balanced mixers, and a quadrature oscillator to form the IF frequency band.

In the structure of Figure 7.24, the 1-to- $M$  interpolating process zero packed the input data giving us access to  $M$  spectral copies of the input time series. The spectral copies reside at multiples of the input sample rate. The low-pass filter rejected the spectral copies, retrieving only the base-band copy centered at DC that is then sent through a digital up converter for translation to the desired center frequency. It is possible to perform the spectral translation as a part of the interpolation process when the desired center frequency coincides with one of the multiples of the input sample rate. Rather than extracting the spectral copy at base-band from the replicated set of spectra and then translating it by means of a

**FIGURE 7.40**

3-D Paddle-Wheel phase profiles; 6-path partition prior to 6-to-1 resampling.

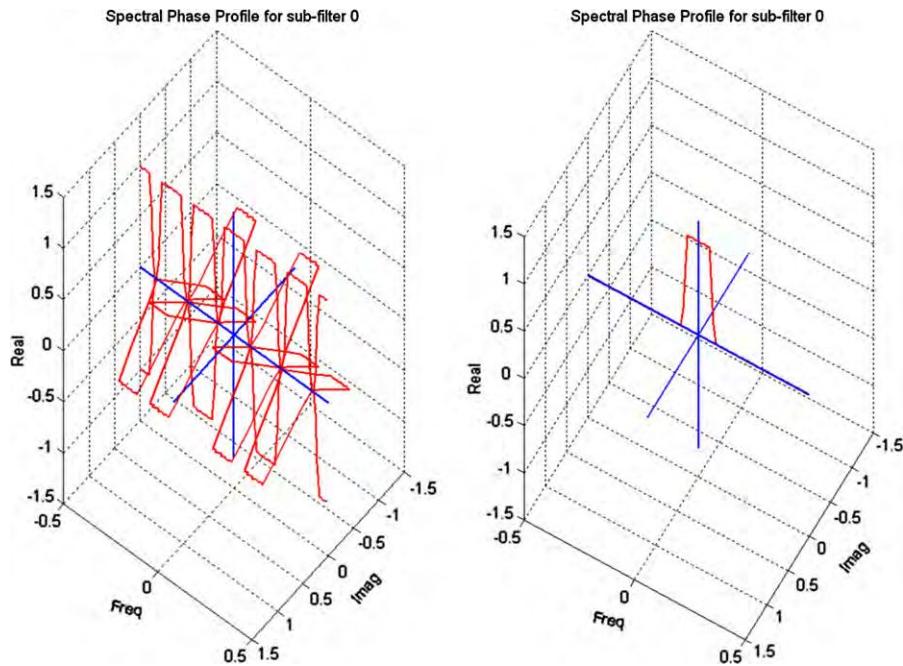

complex heterodyne, we can directly extract one of the spectral copies by using a band-pass filter as opposed to a low-pass filter. The band-pass filter is simply an up converted version of the low-pass filter  $h(n)$  with weights shown in Eq. (7.27). Here the center frequency is interpreted as the  $k$ th multiple of  $\frac{1}{M}$  of the output sample rate.

$$g(n, k) = h(n) \exp\left(j \frac{2\pi}{M} kn\right). \quad (7.27)$$

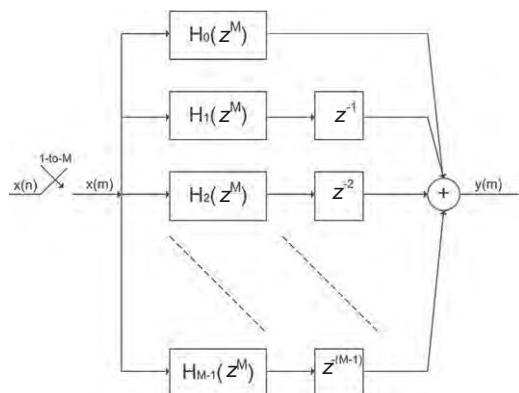

The  $z$ -transform of the band-pass filter  $g(n, k)$ , is shown in Eq. (7.28)

$$G_k(z) = \sum_{n=0}^{N-1} h(n) \exp\left(j \frac{2\pi}{M} kn\right) z^{-n}. \quad (7.28)$$

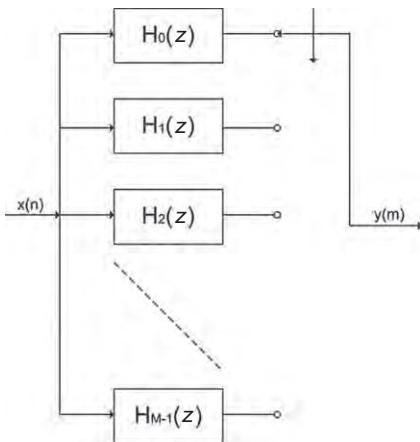

The  $z$ -transform of the polyphase decomposition of this filter is shown in Eq. (7.29). Here we see that the length  $M$  stride in coefficient index due to the 1-to- $M$  resampling aliases the phase rotators in the polyphase filter stages to DC and hence has no effect on the polyphase weights. The phase rotator does, however, have a contribution related to the delay associated with each arm of the partition. The output commutator process absorbs the delays while the phase rotators are applied to each arm to obtain the

**FIGURE 7.41**

spectral translation as a part of the interpolation.

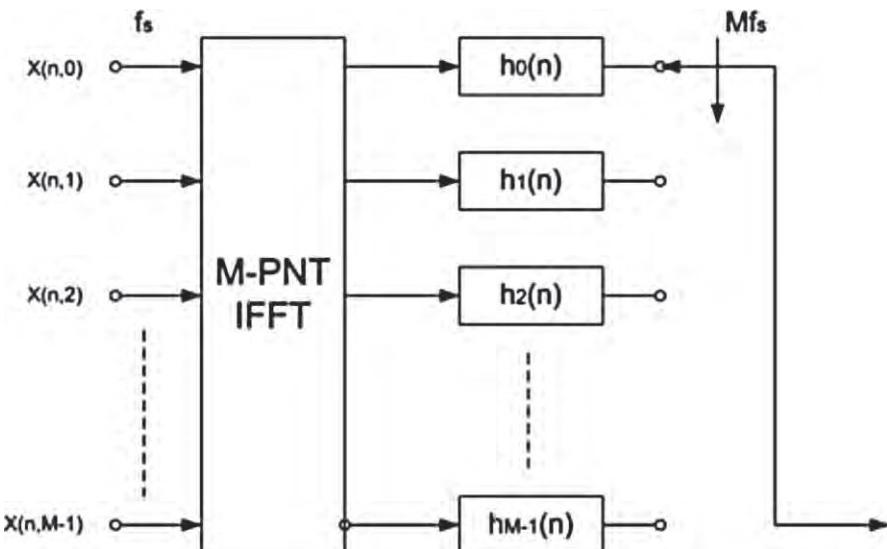

$$\begin{aligned}
 G_k(z) &= \sum_{r=0}^{M-1} z^{-r} \exp\left(j \frac{2\pi}{M} rk\right) \sum_{n=0}^{\frac{N}{M}-1} h(r + nM) \exp\left(j \frac{2\pi}{M} nM k\right) z^{-nM} \\
 &= \sum_{r=0}^{M-1} z^{-r} \exp\left(j \frac{2\pi}{M} rk\right) \sum_{n=0}^{\frac{N}{M}-1} h(r + nM) z^{-nM}.
 \end{aligned} \tag{7.29}$$

The polyphase filter that accomplishes the task of simultaneous interpolation and up conversion to the  $k$ th Nyquist zone is shown in Figure 7.44. This engine up samples and up converts, by aliasing, a single narrowband channel to a particular center frequency which is a multiple of the input sample rate. By noticing, as we did in the previous section of this chapter for the dual down converter channelizer, that the phase rotators applied in each arm are the coefficients of an inverse discrete Fourier transform it is easy to generalize this structure to the standard multichannel polyphase up converter channelizer by applying an IDFT block at the input of the filter bank.

Figure 7.45 shows the complete structure of the standard  $M$ -path polyphase up converter channelizer. It is composed of an  $M$  point IDFT block, an  $M$ -path partitioned filter and an output commutator. In this structure, we enter the  $M$ -channel process at the IDFT block and leave the process by the output commutator. The  $M$ -point IDFT performs two simultaneous tasks; an initial up sampling of 1-to- $M$ , forming an  $M$ -length vector for each input sample  $x(n, k)$  and further imparts a complex phase rotation of  $k$  cycles in  $M$ -samples on the up sampled output vector. It generates a weighted sum of complex vectors containing integer number of cycles per  $M$ -length vector. The polyphase filter forms a sequence of column coefficient weighted, MATLAB's dot-multiply, versions of these complex spinning vectors. The sum of these columns, formed by the set of inner products in the polyphase partitioned filter, is the

**FIGURE 7.44**

Structure of 1-to- $M$  polyphase interpolator with phase rotators for selecting the spectrum centered in  $M$ th nyquist zone.

Polyphase up converter channelizer:  $M$ -point IFFT,  $M$ -path polyphase filter and commutator.

shaped version of the up converted  $M$ -length vector output from the IFFT. On each output port of this engine we find the input base-band channel aliased to the specific Nyquist zone with a new sampling rate that is commensurate with its reduced bandwidth.

A closing comment on both the standard polyphase up converter and down converter channelizer is that the operations of sampling rate change, spectral shaping and Nyquist zone selection are completely independent of each other. The channel bandwidth, the channel spacing and the output sampling rate do not have necessarily to be equal but they can be all modified according to the applications.

---

### 1.07.7 Modifications of the standard down converter channelizer— $M:2$ down converter channelizer

In the standard polyphase down converter channelizer shown in Figure 7.34 the channel bandwidth  $f_{BW}$ , the channel spacing  $f_\Delta$ , and the sampling frequency  $f_s$  are fixed to be equal.

This configuration could represent a good choice when the polyphase channelizer is used for communication systems. In these kind of applications, in fact, an output sample rate matching the channel spacing is sufficient to avoid adjacent channel cross talk since the two-sided bandwidth of each channel is less than the channel spacing. An example of a signal that would require this mode of operation is the Quadrature Amplitude Modulation (QAM) channels of a digital cable system. In North America, the channels are separated by 6 MHz centers and operate with square-root cosine tapered Nyquist-shaped spectra with 18% or 12% excess bandwidth, at symbol rates of approximately 5.0 MHz. The minimum sample rate required of a cable channelizer to satisfy the Nyquist criterion would be 6.0 MHz (The European cable plants have channel spacing of 8.0 MHz and symbol rates of 7.0 MHz). The actual sample rate would likely be selected as a multiple of the symbol rate rather than as a multiple of the channel spacing. Systems that channelize and form samples of the Nyquist-shaped spectrum often present the sampled data to an interpolator to resample the time series collected at bandwidth-related Nyquist rate to a rate offering two samples per symbol or twice symbol rate. For the TV example just cited, the 6 Ms/s, 5 MHz symbol signal would have to be resampled by 5/3 to obtain the desired 10 Ms/s. This task is done quite regularly in the communication receivers and it may represent a significant computational burden. It would be appropriate if we could avoid the external interpolation process by modifying the design of the standard polyphase channelizer for directly providing us the appropriate output sampling frequency.

Many others applications desire channelizers in which the output sampling frequency is not equal to the channel spacing and the channel bandwidth. The design of software defined radio receiver and transmitter is only one of them. Another one can be found in [8].

We have concluded the previous section mentioning that the channel spacing, the channel bandwidth and the output sampling frequency of the polyphase channelizer are completely independent of each other and that they can be arbitrary selected based on the application. Figure 7.46 shows some possible options in which the channel bandwidth, the output sampling rate and the channel spacing of the channelizer are not equal. In this chapter, for the purpose of designing flexible radio architectures, the third option, when the selected low-pass prototype filter is a Nyquist filter (perfect reconstruction filter), results to be the most interesting one.

In this section of the chapter we derive the reconfigured version of the standard down converter channelizer that is able to perform the sample rate change from the input rate  $f_s$  to the output sampling rate  $2f_s/M$  maintaining both the channel spacing and the channel bandwidth equal to  $f_s$ . Similar reasoning can be applied for implementing different selections.

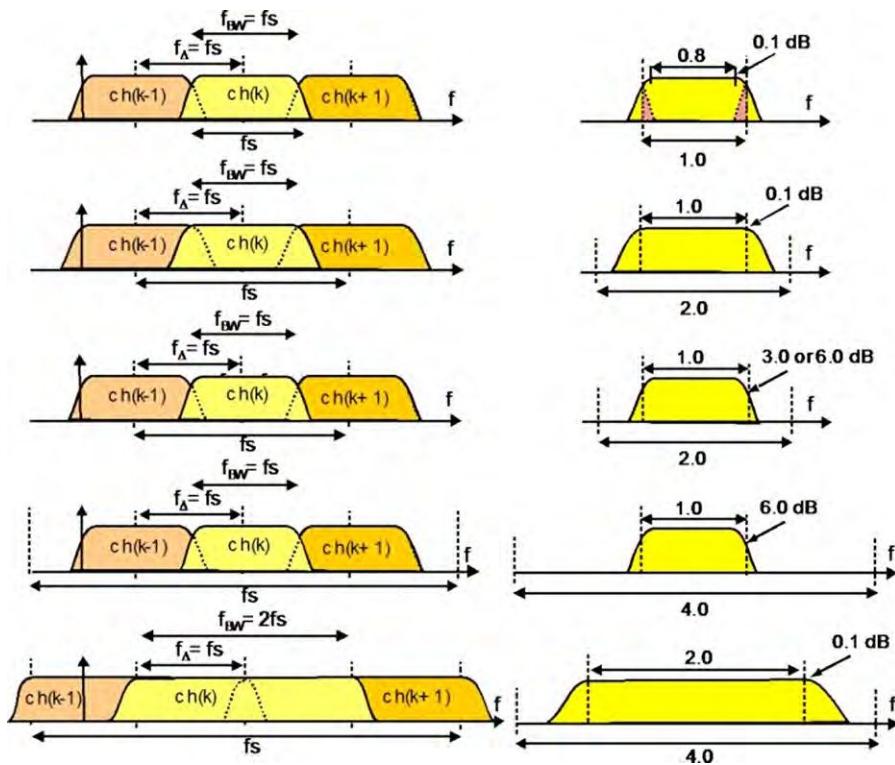

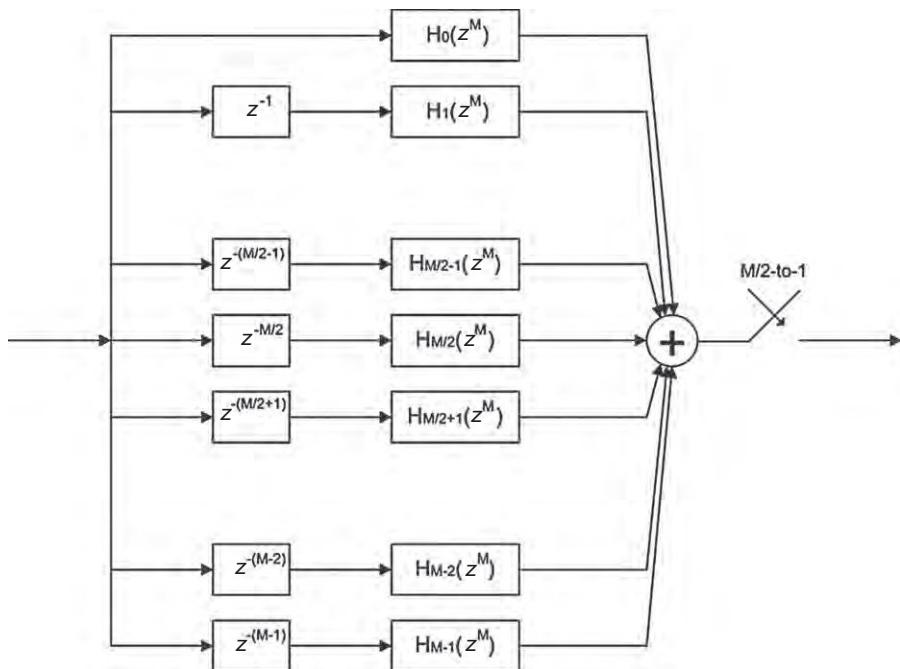

FIGURE 7.46

Some possible channel width, channel spacing, and output sampling frequency.

Note that the standard down converter channelizer is critically sampled when the channel spacing and the channel bandwidth are both equal to  $f_s$  and when the output sample rate is also equal to  $f_s/M$ . This particular choice, in fact, causes the transition band edges of the channelizer filters to alias onto itself which would prevent us from further processing the signals when they are arbitrarily located in the frequency domain which is the case of software radio. This problem can be visualized in the upper example depicted in Figure 7.46.

For the record, we remind that a polyphase filter bank can be operated with an output sample rate which can be any rational ratio of the input sample rate. With minor modifications the filter can be operated with totally arbitrary ratios between input and output sample rates. This is true for the sample rate reduction imbedded in a polyphase receiver as well as for the sample rate increase embedded in a polyphase modulator.

We have control on the output sampling rate of the down converter channelizer by means of the input commutator that delivers input data samples to the polyphase stages. We normally deliver  $M$  successive input samples to the  $M$ -path filter starting at port  $M-1$  and progressing up the stack to port 0 and by doing so we deliver  $M$  inputs per output which means to perform an  $M$ -to-1 down sampling operation.

**FIGURE 7.47**

*M*-path filter and *M*/2:1 down sampler.

To obtain the desired ( $M/2$ )-to-1 down sampling, we have to modify the input commutator in a way that it delivers  $M/2$  successive input samples starting at port  $(M/2)-1$  and progressing up the stack to port 0. We develop and illustrate the modifications with the aid of Figures 7.47–7.50.

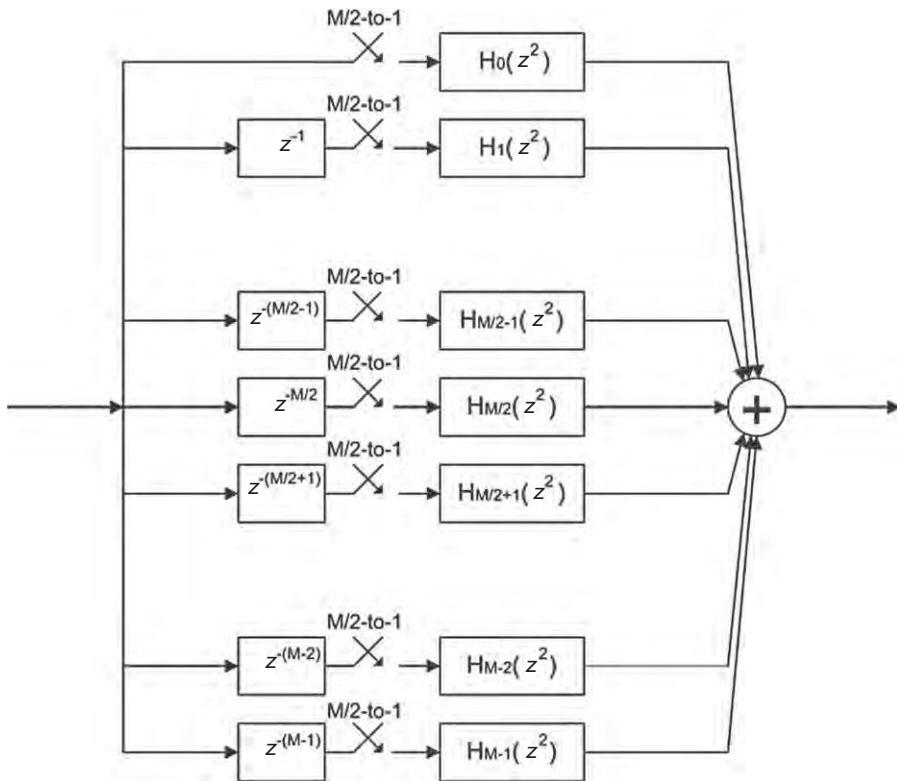

Figure 7.47 represents the polyphase  $M$ -path filter partition shown in Eq. (7.9) with an  $M/2$ -to-1 rather than the conventional  $M$ -to-1 down sample operation after the output summing junction. We need it in order to perform the desired sampling rate change.

In Figure 7.48 we apply the noble identity to the polyphase paths by pulling the  $M/2$ -to-1 down sampler through the path filters which converts the polynomials in  $z^M$  operating at the high input rate to polynomials in  $z^2$  operating at the lower output rate.

Figure 7.49 shows the second application of the noble identity in which we again take the  $M/2$ -to-1 down samplers through the  $z^{-M/2}$  parts of the input path delays for the paths in the second or bottom half of the path set.

In Figure 7.50 the  $M/2$ -to-1 down samplers switch and their delays are replaced with a two pronged commutator that delivers the same sample values to path inputs with the same path delay. Here we also merged the  $z^{-1}$  delays in the lower half of filter bank with their path filters.

Figure 7.51 shows and compares the block diagrams of the path filters in the upper and lower half of this modified polyphase partition.

**FIGURE 7.48**

Noble identity applied to  $M$ -path filters.

When the input commutator is so designed, the  $M/2$  addresses to which the new  $M/2$  input samples are delivered have to be first vacated by their former contents, the  $M/2$  previous input samples. All the samples in the two-dimensional filter undergo a serpentine shift of  $M/2$  samples with the  $M/2$  samples in the bottom half of the first column sliding into the  $M/2$  top addresses of the second column while the  $M/2$  samples in the top half of the second column slide into the  $M/2$  addresses in the bottom half of the second column, and so on. This is equivalent to performing a linear shift through the prototype one-dimensional filter prior to the polyphase partition. In reality, we do not perform the serpentine shift but rather perform an addressing manipulation that swaps two memory banks. This is shown in Figure 7.52.

After each  $M/2$ -point data sequence is delivered to the partitioned  $M$ -stage polyphase filter, in the standard channelizer configuration, the outputs of the  $M$  stages are computed and conditioned for delivery to the  $M$ -point IFFT. What we need to do at this point is the time alignment of the shifting time origin of the input samples in the  $M$ -path filter with the stationary time origin of the phase rotator outputs of the IFFT. We can understand the problem by visualizing, in Figure 7.53, a single cycle of

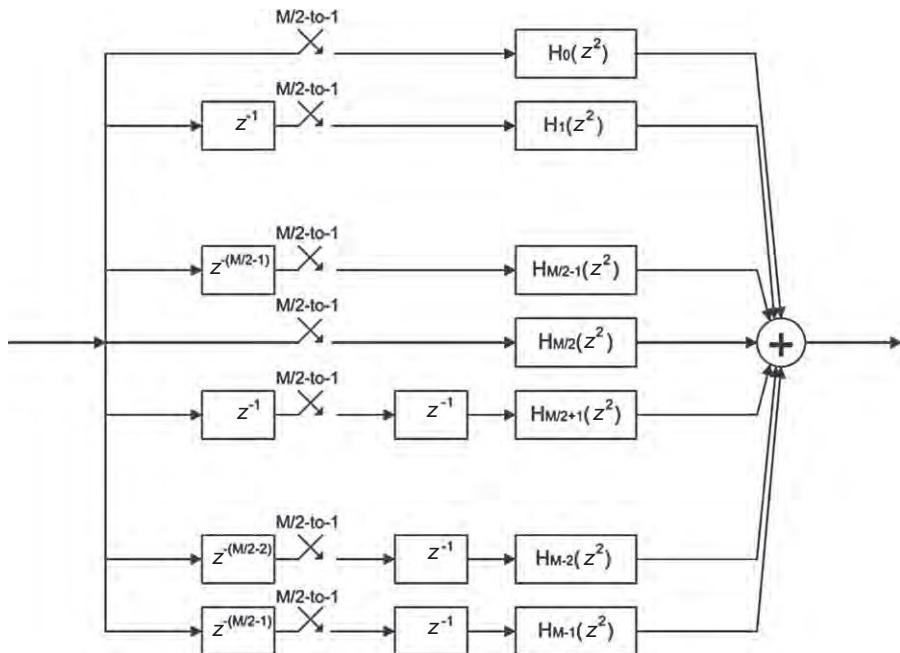

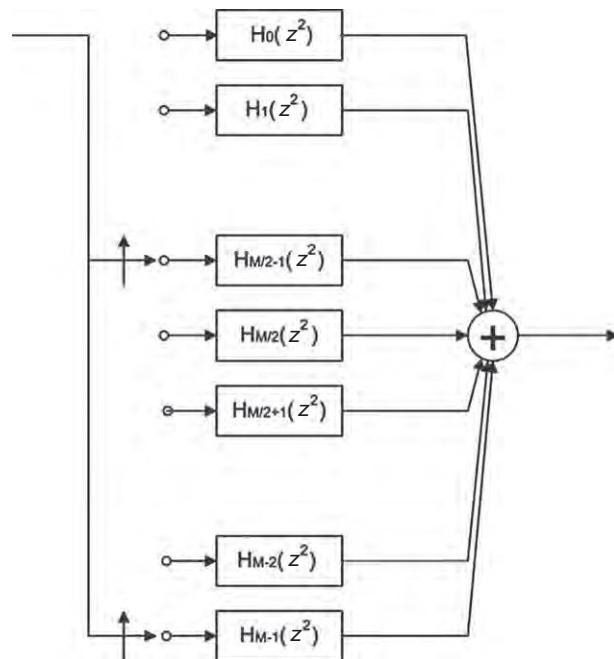

FIGURE 7.49

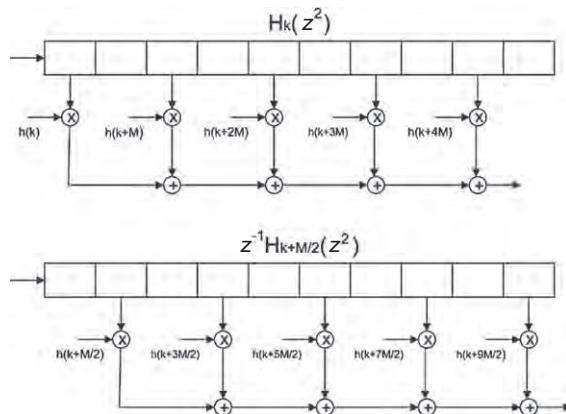

Noble identity applied to delays.

a sine wave extending over  $M$  samples being inserted in the input data register, the first column of the polyphase filter in segments of length  $M/2$ . We can assume that the data in the first  $M/2$  addresses are phase aligned with the first  $M/2$  samples of a single cycle of the sine wave offered by the IFFT.

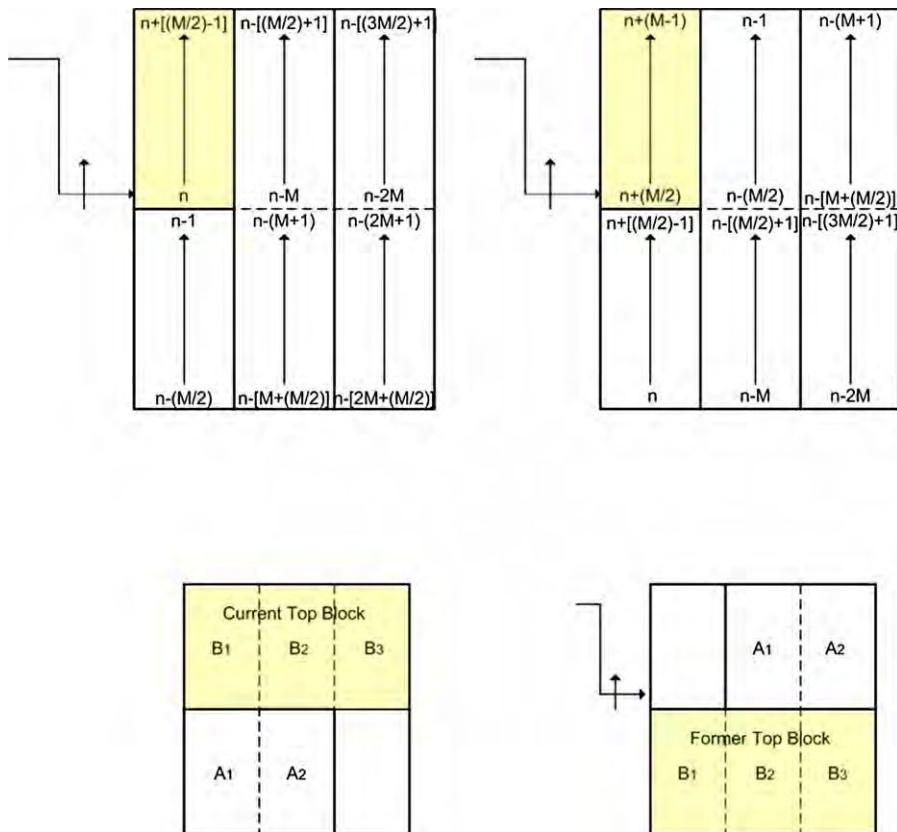

When the second  $M/2$  input samples are delivered to the input data register the first  $M/2$  input samples shift to the second half of the  $M$ -length array. Its original starting point is now at address  $M/2$  but the IFFT's origin still resides at address 0. The shift of the origin causes the input sine wave in the register to have the opposing phase of the sine wave formed by the IFFT; in fact the data shifting into the polyphase filter stages causes a frequency dependent phase shift of the form shown in Eq. (7.30). The time delay due to shifting is  $nT$  where  $n$  is the number of samples, and  $T$  is the time interval between samples. The frequencies of interest are integer multiple  $k$  of  $1/M$ th of the sample rate  $2\pi/T$ . Substituting these terms in Eq. (7.30) and canceling terms, we obtain the frequency dependent phase shift shown in Eq. (7.31). From this relationship we see that for time shifts  $n$  equal to multiples of  $M$ , as demonstrated in Eq. (7.32), the phase shift is a multiple of  $2\pi$  and contributes zero offset to the spectra observed at the output of the IFFT. The  $M$ -sample time shift is the time shift applied to the data in the normal use of the polyphase filter. Now suppose that the time shift is  $M/2$  time samples. When substituted in Eq. (7.31) we find, as shown in Eq. (7.33), as frequency dependent phase shift of  $k\pi$  from which we conclude that odd-indexed

**FIGURE 7.50**

Path delays replaced by input commutator.

**FIGURE 7.51**

M-path filters with and without extra delays.

**FIGURE 7.52**

Data memory loading for successive  $M/2$ -point sequences in an  $M$ -stage polyphase channelizer.

frequency terms experience a phase shift of  $\pi$  radians for each successive  $N/2$  shift of input data

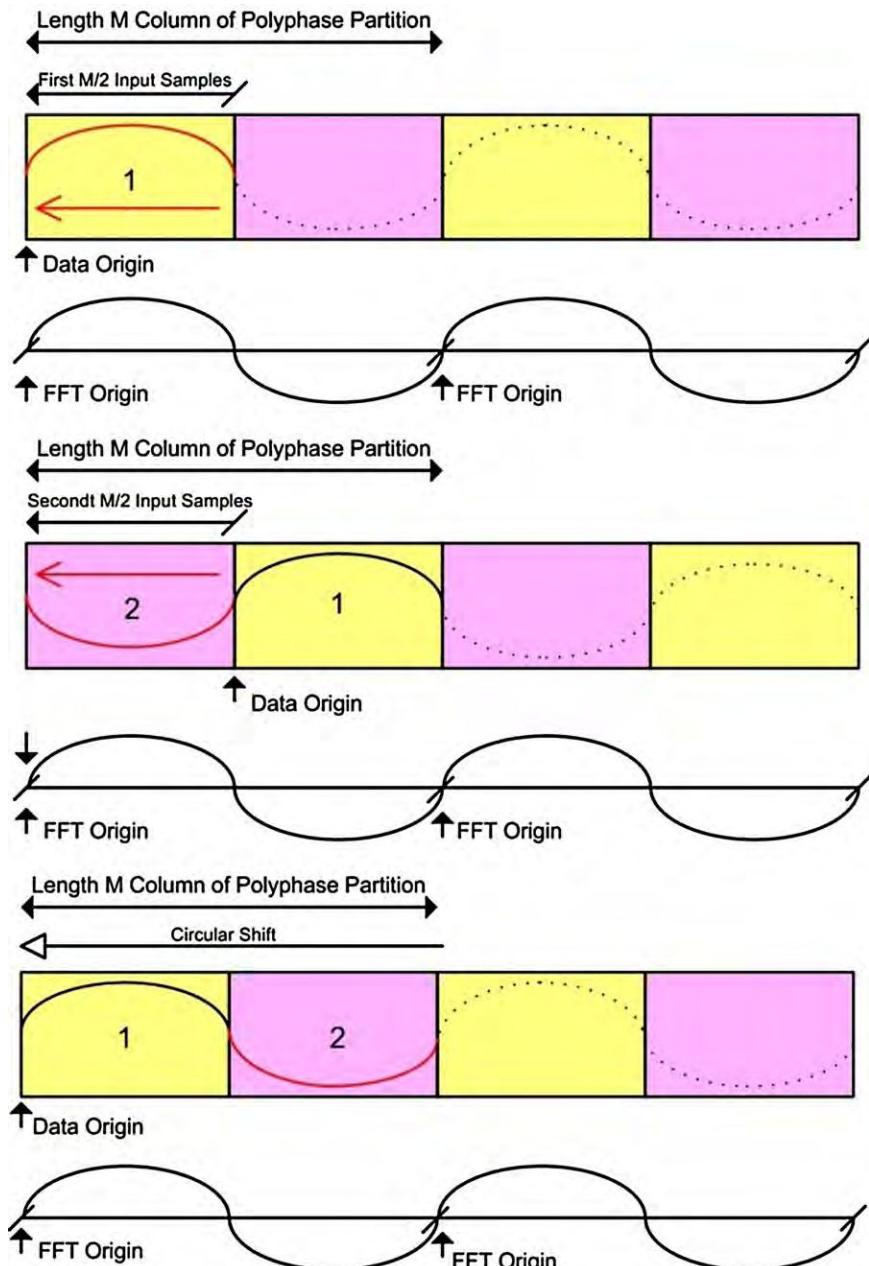

$$\theta(\omega) = \Delta t \cdot \omega, \quad (7.30)$$

$$\theta(\omega_k) = nT \cdot k \frac{1}{M} \frac{2\pi}{T} = \frac{nk}{M} 2\pi, \quad (7.31)$$

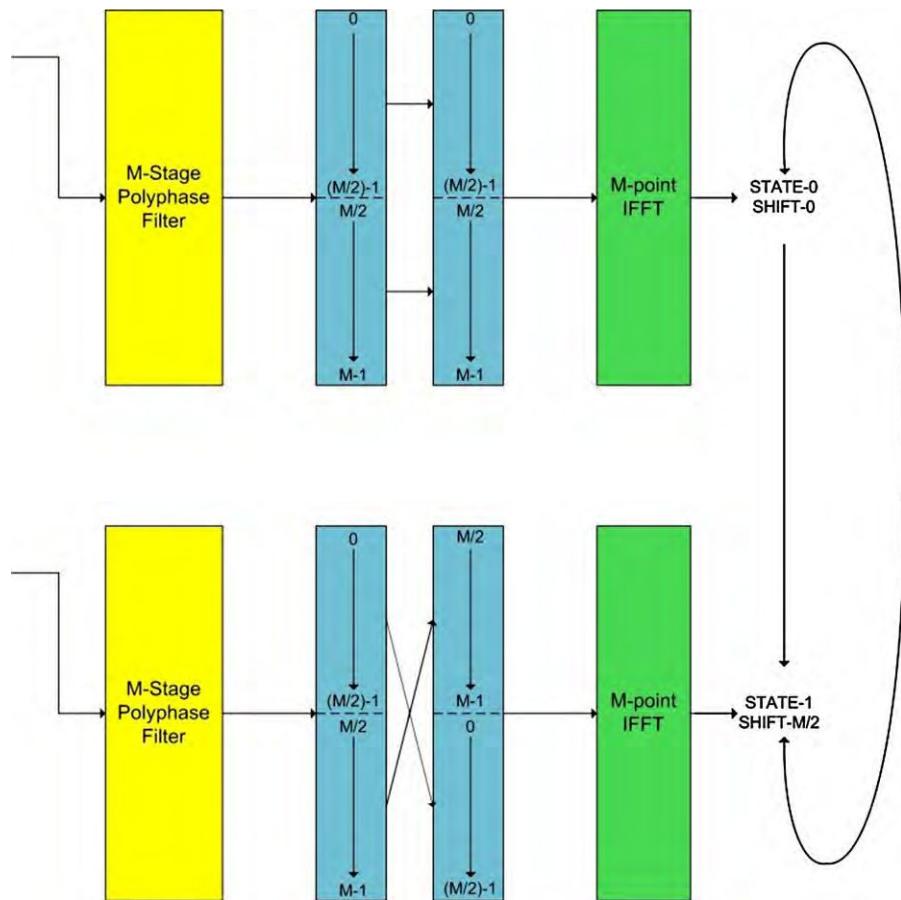

$$\theta(\omega_k)|_{n=M} = \frac{nk}{M} 2\pi \Big|_{n=M} = 2\pi k, \quad (7.32)$$

$$\theta(\omega_k)|_{n=M/2} = \frac{nk}{M} 2\pi \Big|_{n=M/2} = \pi k. \quad (7.33)$$

This  $\pi$  radians phase shift is due to the fact that the odd-indexed frequencies alias to the half sample rate when the input signal is down sampled by  $M/2$ . What we are observing is the sinusoids with an odd

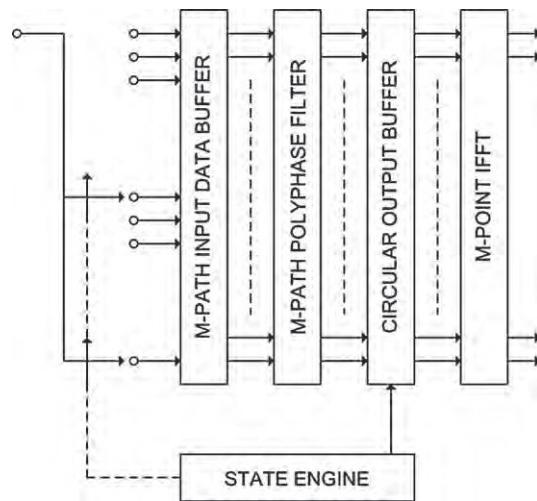

**FIGURE 7.53**

Illustrating phase reversal of  $M$ -point sinusoid input to  $M/2$  path polyphase filter.

**FIGURE 7.54**

Cyclic shift of input data to IFFT to absorb phase shift due to linear time shift of data through polyphase filter.

number of cycles in the length  $M$  array alias to the half sample rate when down sampled  $M/2$ -to-1. Note that, when down sampled  $M/2$ -to-1, the sinusoids with an even number of cycles in the length  $M$  array alias to DC. We can compensate for the alternating signs in successive output samples by applying the appropriate phase correction to the spectral data as we extract successive time samples from the odd-indexed frequency bins of the IFFT. The phase correction here is trivial, but for other down-sampling ratios, the residual phase correction would require a complex multiply at each transform output port. Alternatively, since time delay imposes a frequency dependent phase shift, we can use time shifts to cancel the frequency dependent phase shifts. We accomplish this by applying a circular time shift of  $N/2$  samples to the vector of samples prior to their presentation to the IFFT. As in the case of the serpentine shift of the input data, the circular shift of the polyphase filter output data is implemented as an

**FIGURE 7.55**

M-to-2 modified down converter channelizer.

address-manipulated data swap. This data swap occurs on alternate input cycles and a simple two-state machine determines for which input cycle the output data swap is applied. This is shown in Figure 7.54.

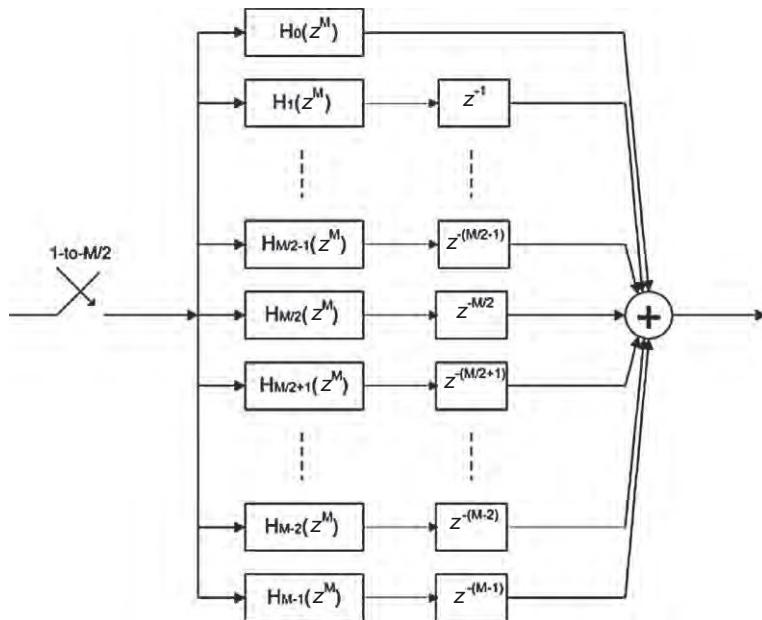

The complete structure of the modified version of the  $M$ -to-2 down converter channelizer with the input data buffer and the circular data buffer is shown in Figure 7.55.

For brevity of notation, we avoid reporting here all the dual mathematical derivations that led at the final structure of the modified up converter channelizer. We briefly explain its block diagram in the next subsection.

### 1.07.7.1 Modifications of the standard up converter channelizer—2: $M$ up converter channelizer

Dual reasoning drives us to the reconfigured version of the  $M$ -path polyphase up converter channelizer that is able to perform the sample rate change from  $2f_s/M$  to  $f_s$  maintaining both the channel spacing and the channel bandwidth equal to  $f_s$ . The choice of using a 2-to- $M$  up sampler avoids the difficulty of having the sample rate that precisely matches the two sided bandwidth of the input signals as well as permitting a shorter length prototype channelizer filter due to an allowable wider transition bandwidth. In this chapter we briefly derive its block diagram that is shown in Figure 7.45. More details on this structure can be found in [6,8,9]. We develop and illustrate the modifications with the aid of Figures 7.56–7.61. In these figures we do not consider the IFFT block because, for now, it does not affect our reasoning. Moreover we will introduce it later motivating the reason for which it is important to include a circular buffer in the design of the modified up converter channelizer.

Figure 7.56 presents the structure of the  $M$ -path filter implementation of the polyphase partition shown in Eq. (7.7). Note the 1-to- $M/2$  up-sample operation at the input port normally described as the

**FIGURE 7.56**

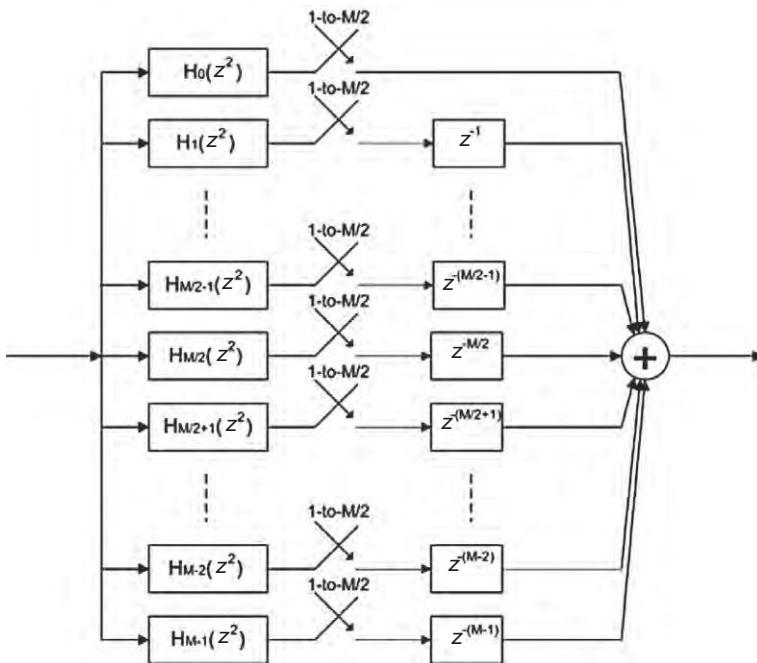

M-path polyphase filter.

zero-packing process. In Figure 7.57 we apply the noble identity to the polyphase paths and pull the 1-to- $M/2$  up sampler through the path filters which convert the polynomials in  $z^M$  operating at the high output rate to polynomials in  $z^2$  operating at the low input rate. Note that the paths are now polynomials in  $z^2$  rather than  $z^M$  as is the normal mode that we identify as the dual of the maximally decimated filter bank.

Figure 7.58 shows the second application of the noble identity in which we again take the 1-to- $M/2$  up sampler through the  $z^{-M/2}$  part of the output path delays for the paths in the second or bottom half of the path set. The resultant delay,  $z^{-1}$ , now operating at the input clock rate, is then interchanged with its path filter as shown in Figure 7.59.

In Figure 7.60 the 1-to- $M/2$  up samplers switch and their delays are replaced with a pair of commutators that add the path outputs with the same path delay. Finally, in Figure 7.61 we fold the single delay in front of the lower set of path filters into the path filter. After having changed the output sampling rate of the polyphase channelizer, the final modification we need to introduce is the time alignment of the phase rotators from the input IFFT and the shifted time origin in the  $M$ -path filter.

From Figure 7.62, we note the locations of the non-zero coefficients in the polynomials in  $z^2$  and conclude that the input sine wave only contributes to the output time samples in the path filters located in the upper half of the path set. When the next scaled sine wave output from the IFFT is inserted in the first column of the path filter memory, the previous scaled sine wave is shifted one column in the memory and it will now contribute to the output time samples from the filter paths in the lower half of the path filter set. The problem is that the sine wave samples in the lower half of the path filter set have opposite polarity of the sine wave samples in the upper half of the path filter set. The samples from the two half

**FIGURE 7.57**

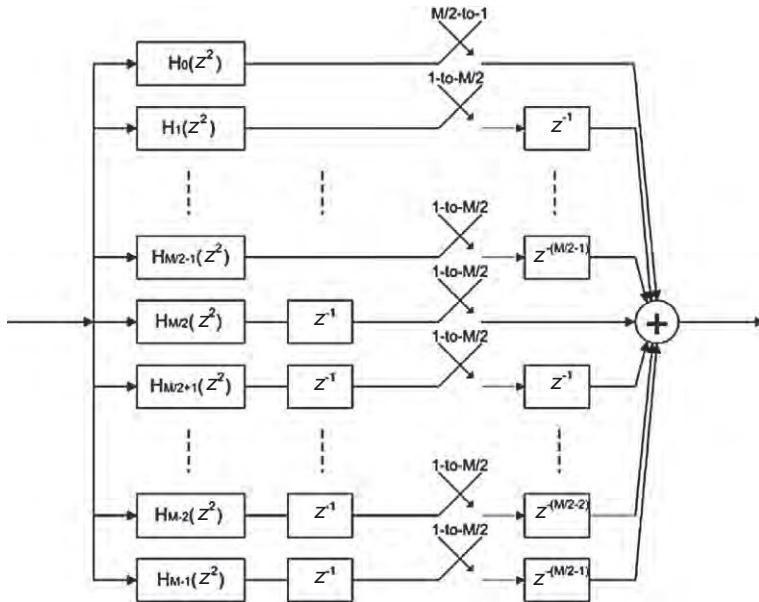

Noble identity applied to  $M$ -path filter.

filter sets are added and to do so they must have the same phase. We note that this alternating sign effect only occurs for the odd indexed IFFT frequency bins which have an odd number of cycles per interval.

An alternate description of the sign reversal is that in the  $M/2$  resampling of the modified  $M$ -path filter the even indexed frequencies alias to multiples of the input sample rate and the odd indexed frequencies alias to odd multiples of the half sample rate.

We recall here that there are two methods for performing the phase alignment of the successive output vectors from the IFFT. In the first method we simply invert the input phase of successive input samples to the odd indexed IFFT bins. In the second method, recognizing that equivalency of phase shift and time delay for sinusoids, on alternate outputs from the IFFT we apply an  $M/2$  circular shift to its output buffer prior to delivering the phase aligned vector to the path filter memory. This end around shift of the output buffer occurs during the data transfer in memory and requires no additional manipulation of the time samples.

Figure 7.63 shows the complete block diagram of the modified  $M$ -path up converter channelizer. In this engine, the input commutator delivers the samples to the  $M$ -point IFFT. It applies the complex phase rotation to the separate base-band input signals as well as performs the initial 1-to- $M$  up sampling of the input samples. The circular output buffer performs the correct data offset of the two  $M/2$  point halves of the IFFT output vector to maintain phase alignment with the  $M/2$  chan-

**FIGURE 7.58**

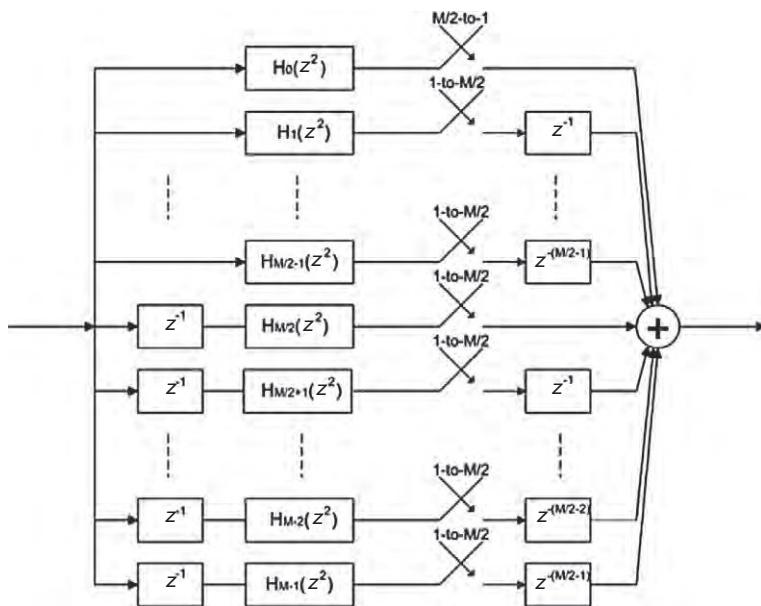

Noble identity applied to delays.

nelizer output vector. The complex sinusoid output by the IFFT always defines its time origin as the initial sample of its output vector. The output of the polyphase filter exhibits a time origin that shifts due to the  $M/2$  time sample shift embedded in the output commutator. The  $M/2$  time sample shift of the output time series causes sinusoids with an odd number of cycles in the length  $M$  array to alternate sign on successive shifts. The alternating sign is the reason that the odd indexed frequency bins up convert to a frequency  $k + N/2$  rather than frequency index  $k$ . Rather than reverse phase alternate input samples to the odd indexed IFFT bins we perform an  $M/2$  point circular shift of alternate  $M$ -length vectors from the IFFT for applying the correct phase alignment to all frequencies simultaneously.

The polyphase down converter and up converter channelizers shown in Figures 7.55 and 7.63 respectively are the key elements of the proposed receiver and transmitter structures that we present in the following sections. Because of the signal processing tasks they handle, in the following, we refer to them as analysis and synthesis channelizers respectively.

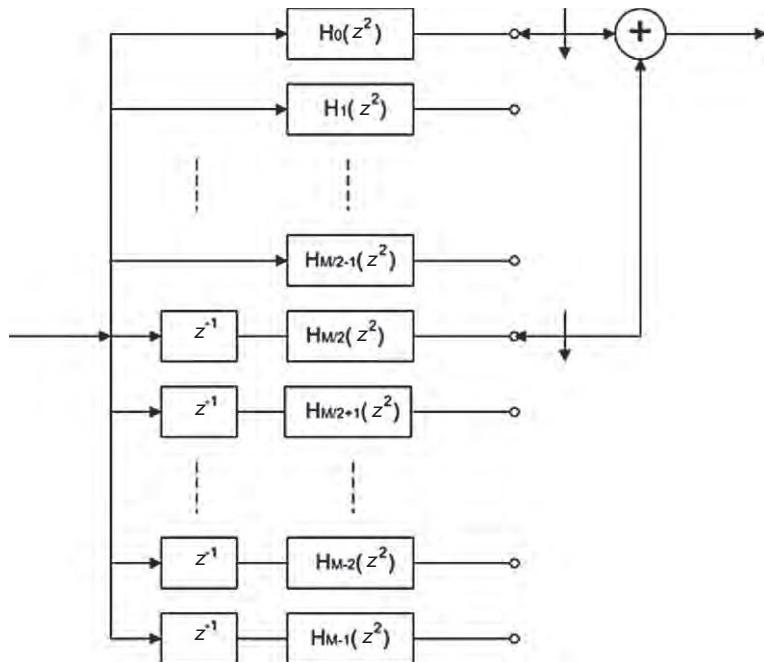

## 1.07.8 Preliminaries on software defined radios

The 20th century saw the explosion of hardware defined radio as a means of communicating all forms of data, audible and visual information over vast distances. These radios have little or no software control. Their structures are fixed in accordance with the applications; the signal modulation formats, the carrier

**FIGURE 7.59**

Interchange unit delay and path filters.

frequencies and bandwidths are only some of the factors that dictate the radio structures. The smallest change to one of these parameters could imply a replacement of the entire radio system. A consequence of this is, for example, the fact that a television receiver purchased in France does not work in England. The reason, of course, is that the different geographical regions employ different modulation standards for the analog TV as well as for digital TV. Then, the citizens cannot use the same TV for receiving signals in both countries; they need to buy a new television for each country in which they decide to live. Sometimes, even if the communication devices are designed for the same application purposes and they work in the same geographical area, they are not able to communicate between each other. One of the most evident examples of this is that the city police car radio cannot communicate with the city fire truck radio, or with the local hospital ambulance radio even if they have the common purpose of helping and supporting the citizen. Also, the city fire truck radio cannot communicate with the county fire truck radio, or with the radios of the fire truck operated by the adjacent city, or by the state park service, or the international airport. None of these services can communicate with the National Guard, or with the local Port Authority, or with the local Navy base, or the local Coast Guard base, or the US Border Patrol, or US Customs Service. In an hardware defined radio, if we decide to change one of the parameters of the transmitted signal, like bandwidth or carrier frequency (for example because the carrier frequency we want to use is the only one available at that particular moment), we need to change the transmitter. On the other side, every time we want to receive a signal having different bandwidth or center frequency, we need to change the receiver. Hardware defined transmitter and receiver devices

**FIGURE 7.60**

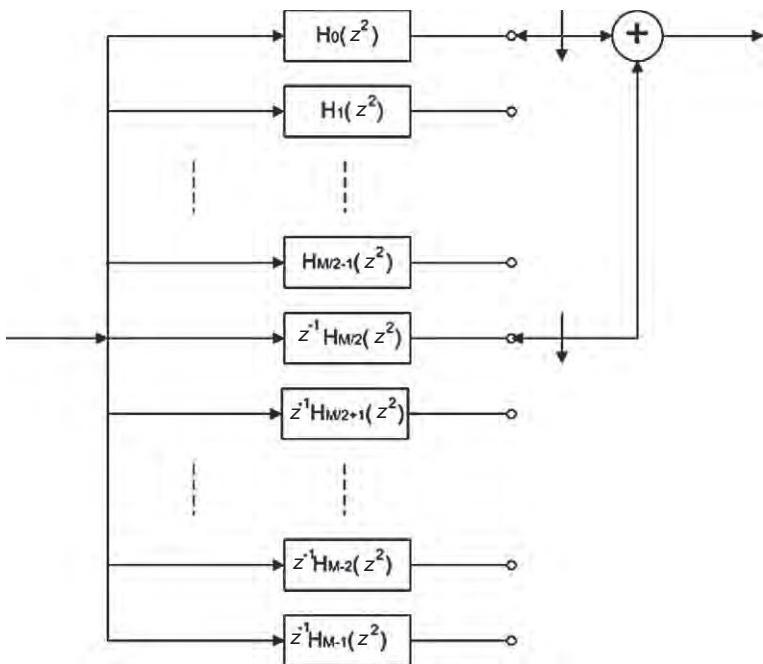

Insert commutator add same delay paths.

are not flexible at all; we must modify their structure every time we change even one of the transmitting and receiving signal parameters.

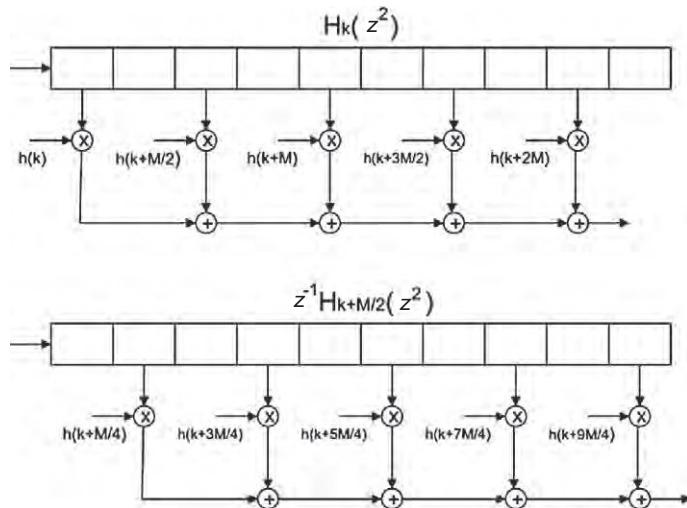

In 1991, Joe Mitola coined the term software defined radio. It was referred to a class of reprogrammable (and reconfigurable) devices. At that time it was not clear at which level the digitization should occur to define a radio as software but the concept sounded pretty interesting, and the dream of building a completely reconfigurable radio device involved scientists from all over the world. Today the exact definition of software defined radio is still controversial, and no consensus exists about the level of reconfigurability needed to qualify a radio as software.

Figure 7.64 shows, in a simple block diagram, all the possible places in which the digitization can occur in a radio receiver. The exact dual block diagram can be portrayed for the radio transmitter. Current radios, often referred to as digital but sometimes referred as software defined radios (depending on their particular structure), after shifting the signals to intermediate frequency, digitize them and assign all the remaining tasks to a digital signal processor. One of the main reasons for shifting the signals to intermediate frequency, before digitizing them, is to reduce their maximum frequency so that a smaller number of samples can be taken for preserving the information content.

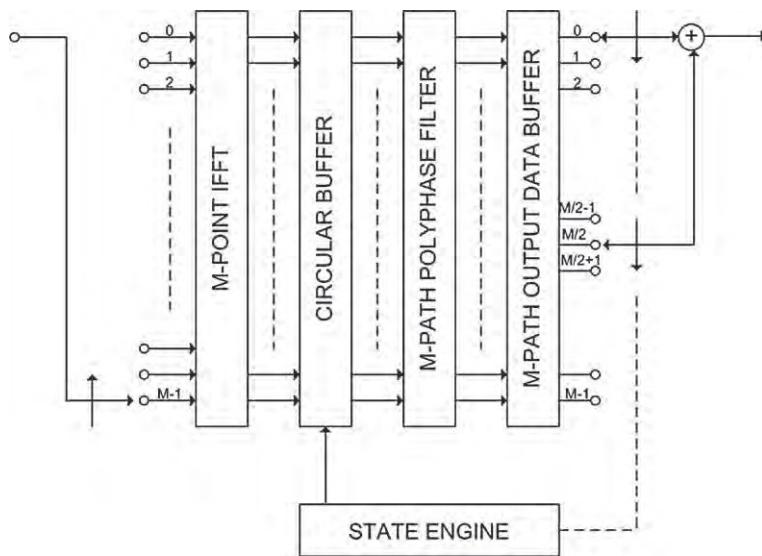

Implementation of ideal software radios requires digitization at the antenna, allowing complete flexibility in the digital domain. Then it requires both the design of a flexible and efficient DSP-based

structure and the design of a completely flexible radio frequency front-end for handling a wide range of carrier frequencies, bandwidths and modulation formats. These issues have not been exploited yet in the commercial systems due to technology limitations and cost considerations.

As pointed out in the previous section, in a current software defined radio receiver the signals are digitized in intermediate frequency bands. The receiver employs a super heterodyne frequency down conversion, in which the radio frequency signals are picked up by the antenna along with other spurious,

unwanted signals (noise and interferences), filtered, amplified with a low noise amplifier and mixed with a local oscillator to shift it to intermediate frequency. Depending on the application, the number of stages of this operation may vary. Digitizing the signal in the IF range eliminates the last analog stage in the conventional hardware defined radios in which problems like carrier offset and imaging are encountered. When sampled, digital IF signals give spectral replicas that can be placed accurately near the base-band frequency, allowing frequency translation and digitization to be carried out simultaneously. Digital filtering and sample rate conversion are often needed to interface the output of the ADC to the processing hardware to implement the receiver. Likewise, on the transmitter side, digital filtering and sample rate conversion are often necessary to interface the digital hardware, that creates the modulated waveforms, to the digital to analog converter. Digital signal processing is usually performed in radio devices using field programmable gate arrays (FPGAs), or application specific integrated circuits (ASICs).

Even if the dream of building a universal radio is still far away, current software defined radio architectures are quite flexible, in the sense that they usually down convert to IF a collection of signals and, after sampling, they are able to shift these signals to base-band via software. Changes in the signal bandwidths and center frequencies are performed by changing some parameters of the digital data section. The flexibility of such a structure can be improved by moving the analog to digital converter closest to the receiver antenna. By digitizing the signals immediately after (and before in the transmitter) the antenna, which is the ideal software radio case, the down conversion (and up conversion) processes are performed completely in software and the radio acquires the capability of changing its personality, possibly in real-time, guaranteeing a desired quality of service (QoS). The digitization after the receiver antenna, in fact, allows service providers to upgrade the infrastructure and market new services quickly. It promises multi-functionality, global mobility, ease of manufacture, compactness and power efficiency. The flexibility in hardware architectures combined with flexibility in software architectures, through the implementation of techniques such as object oriented programming, can provide software radio also with the ability to seamlessly integrate itself into multiple networks with widely different air and data interfaces.

---

### 1.07.9 Proposed architectures for software radios

A digital transmitter accepts binary input sequences and outputs radio frequency amplitude and phase modulated wave shapes. The digital signal processing part of this process starts by accepting  $b$ -bit words from a binary source at input symbol rate. These words address a look-up table that outputs gray coded ordered pairs, i.e.,  $I$ - $Q$  constellation points, that control the amplitude and phase of the modulated carrier. The  $I$ - $Q$  pair is input to DSP-based shaping filters that form 1-to-4 up sampled time series designed to control the wave shape and limit the base-band modulation bandwidth. The time series from the shaping filter are further up sampled by a pair of interpolating filters to obtain a wider spectral interval between spectral replicas of the sampled data. The interpolated data are then heterodyned by a digital up converter to a convenient digital intermediate frequency and then moved from the sampled data domain to the continuous analog domain by a digital to analog converter and analog IF filter. Further analog processing performs the spectral transformations required to couple the wave shape to the channel.

On the other side of the communication chain, a digital receiver has to perform the tasks of filtering, spectral translation and analog to digital conversion to reverse the dual tasks performed at the transmitter. The receiver must also perform a number of other tasks absent in the transmitter for estimating

the unknown parameters of the received signal such as amplitude, frequency and timing alignment. It samples the output of the analog IF filter and down converts the intermediate frequency centered signal to base-band with a digital down converter (DDC). The base-band signal is down sampled by a decimating filter and finally processed in the matched filter to maximize the signal-to-noise ratio (SNR) of the samples presented to the detector. The DSP portion of this receiver includes carrier alignment, timing recovery, channel equalization, automatic gain control, SNR estimation, signal detection, and interference suppression blocks. In order to suppress the undesired artifacts introduced by the analog components, the receiver also incorporates a number of digital signal processing compensating blocks.

Figure 7.65 shows the first tier processing block diagrams of a typical digital transmitter-receiver chain. The depicted transmitter is designed for sending, one per time, signals having fixed bandwidths at precisely located center frequencies. On the other hand, the depicted receiver is also designed for down converting to base-band fixed bandwidth signals having fixed center frequencies. Therefore, the goal of a cognitive radio is quite different: cognitive transmitter and receiver should be completely flexible. The transmitter has, in fact, to be able to simultaneously up convert, at desired center frequencies, which are selected based on the temporary availability of the radio spectrum, a collection of signals

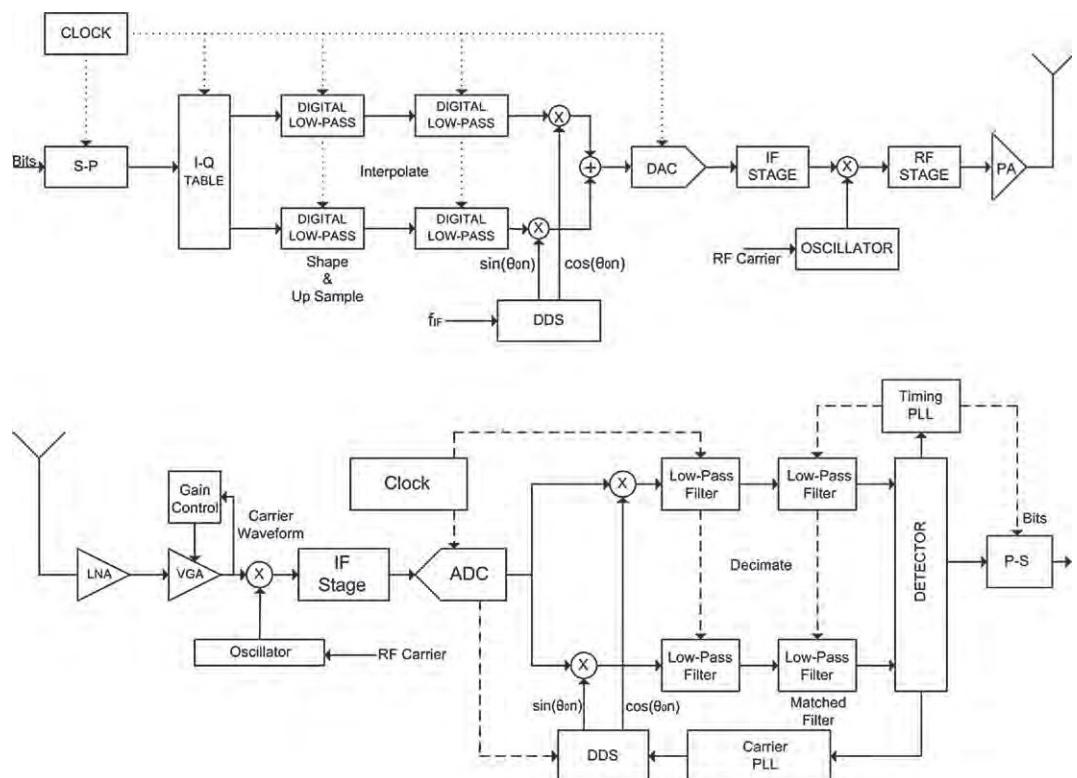

FIGURE 7.65

Block diagram of primary signal processing tasks in a typical transmitter and receiver.

having arbitrary bandwidths. It should also be able to decompose a signal in spectral fragments when a sufficiently wide portion of the radio spectrum is not available for transmission. Of course no energy loss has to occur in the partitioning process. A cognitive receiver has to be able to simultaneously down convert the transmitted signal spectra wherever they are positioned in the frequency domain and whatever bandwidths they have. Also it should have the capability of recognizing spectral segments belonging to the same information signal and recompose them, after the base-band translation, without energy losses. It could be possible to reach this goal by using the current technology but the cost would be very high: for every signal we want to transmit we have to replicate the digital data section of both the transmitter and the receiver. The more signals we have to simultaneously up and down convert, the more sampled data sections we need to implement! Also, it is not possible, by using the current technology, to fragment a single signal, transmit its spectral partitions using the temporary available spectral holes and to perfectly recombine them at the receiver. Today the transmission happens under the constraint that the available space in the radio spectrum is large enough to accommodate the entire bandwidth of the signal to be transmitted.

In the next sections of this chapter, we present novel channelizers to simultaneously up and down convert arbitrary bandwidth signals randomly located in the frequency domain. Differently from the previous contents of this document, from this point onwards the presented material reproduces the results of the authors' research on software defined radio design, thus it is new. The proposed architectures can be used for the transmitter and for the receiver devices of a cognitive radio respectively. By using them we avoid the need to replicate the sampled data sections for simultaneously transmitting and receiving more signals with arbitrary bandwidths over multiple desired center frequencies. We also gain the capability to partition the signal spectra before transmitting them and to perfectly reassemble them in the receiver after the base-band shifting.

The core of the proposed transmitter structure is the variant of the standard  $M$ -path polyphase up converter channelizer that is able to perform 2-to- $M$  up sampling while shifting, by aliasing, all the channels to desired center frequencies. It has been presented in Section 1.07.5 of this same chapter. In the following we use the term synthesis channelizer for referring to this structure. This name has been given for the tasks that this structure accomplishes when embedded in a SDR transmitter. When the input signals have bandwidths wider than the synthesis channelizer bandwidth they are pre-processed through small down converter channelizers that disassemble the signals' bandwidths into reduced bandwidth sub-channels which are matched to the base-line synthesis channelizer bandwidths. Complex sampled frequency rotators are used to offset the signal spectra by arbitrary fractions of the sample frequency before processing them through the channelizers. This is necessary for the completely arbitrary center frequency positioning of the signals.

On the other side the variation of the standard  $M$ -path down converter channelizer, presented in Section 1.07.6, represents the key element of the proposed receiver. It is able to perform  $M$ -to-2 down sampling while simultaneously down converting, by aliasing, all the received signal spectra having arbitrary bandwidths. In the following, we refer to this structure as analysis channelizer. Post-processing channelizers, that are a smaller version of the synthesis channelizer composing the transmitter, are used for reassembling, from the analysis channelizer base-line channels, signal bandwidths wider than the analysis channelizer channel bandwidth. Possible residual frequency offsets can be easily solved with the aid of a digital complex heterodyne while a post-analysis block performs further channelization,

when it is required, for separating signal spectra falling in the same channelizer channel after the analysis processing.

### 1.07.9.1 Proposed digital down converter architecture

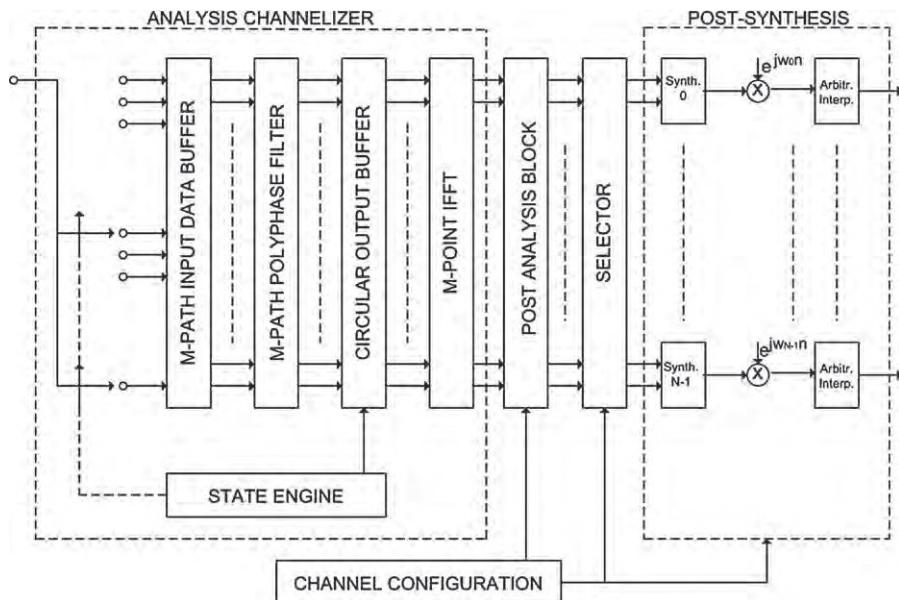

The standard  $M$ -path polyphase down converter channelizer is able to shift to base-band, by aliasing, the input signals that are exactly located on the channel's center frequencies,  $kf_c$ , where  $k = 0, 1, \dots, M-1$ . In this engine the center frequencies of the channels are integer multiples of the channelizer output sampling frequency as well as the channelizer channel bandwidth.

We recall here that the standard  $M$ -path down sampling channelizer simultaneously down converts, by aliasing, from fixed center frequencies to base-band,  $M$  bands narrower than the channelizer channel bandwidth. If  $kf_c \pm \Delta f_k$  are the center frequencies of the input spectra, where  $\pm \Delta f_k$  are the arbitrary frequency offsets from the channel center frequencies,  $kf_c$ , after the down conversion process the output spectra will be shifted by the same offset from DC, i.e., the down converted signals will be centered at the frequency locations  $\pm \Delta f_k$  because the polyphase down converter channelizer only compensates the  $kf_c$  frequency terms. It is unable to compensate the frequency offsets,  $\pm \Delta f_k$ , that are responsible for the arbitrary center frequency positioning of the input signals. The frequency offset compensation is one of the motivations for which we need to add further processing blocks in the digital down converter design when it is intended to be used in a software radio receiver. Other issues, like receiver resolution, base-band reassembly of wide bandwidths and arbitrary interpolation of the base-band shifted signals need to be considered too. All these issues are addressed and solved in the following paragraphs.

We also recall here that the standard  $M$ -to-1 down converter channelizer with the channel spacing and channel bandwidth equal to the output sampling frequency is critically sampled (see upper plot of Figure 7.29). In order to use it in a cognitive radio receiver, we need to modify it, redesigning the channel spacing, channel bandwidth, and output sampling frequency. We presented one of these modifications in Section 1.07.5, where the  $M$ -to-2 down converter channelizer has been derived. Also the selection of the low-pass prototype filter is an important issue that has to be addressed in order to avoid energy losses while the signal is processed.

Figure 7.66 shows the complete block diagram of the proposed down converting chain. The input signal is processed, at first, by an analysis channelizer which is the modified version of the standard  $M$ -to-1 down converter channelizer presented in Section 1.07.5. By performing an  $M/2$ -to-1 down sampling of the input time series this engine simultaneously shifts all the aliased channels to base-band presenting an output sampling rate that is twice the sample rate of the standard  $M$ -to-1 channelizer. Nyquist filters are used, as low-pass prototype, for avoiding energy losses while processing the signals. They are briefly described in one the next subsections. The interested reader can find more details on Nyquist filter design in [6].

Note that if more signals or even spectral fragments belonging to different signals, are channelized in the same channel, further processing is needed to separate them at the output of the analysis down converter. The extra filtering process is performed in the post-analysis block that is connected to a channel configuration block that provides the receiver with the necessary information about the input signal bandwidths and center frequencies. Different options can be implemented for simplifying the design of the post-analysis block. One of the possible options is to decrease the bandwidth of the perfect reconstruction prototype low-pass filter and to increase the number of points of the IFFT block in the

**FIGURE 7.66**

Block diagram of the proposed down converter; analysis down converter channelizer, post analysis block, synthesis up converter channelizers, complex frequency rotators and arbitrary interpolators.

analysis channelizer. By designing the channel spacing and bandwidth to accommodate the most likely expected signal width we minimize the possibility of having more than one signal in each channel. It is also possible to modify the analysis channelizer for having a more convenient frequency positioning of the aliased channels. The optimal choice, of course, depends on the receiver application and on the workload requirements.

At the output of the analysis channelizer, most of the signals with bandwidths narrower than the channel bandwidth are already down converted by means of the channelization process. However the spectra wider than the channel bandwidth, or the spectra that, as a consequence of the arbitrary center frequency positioning, are processed by two or more adjacent channels, have been fragmented and their segments have all been aliased to the first Nyquist zone; these segments need to be recomposed before being translated to DC. The recombination of spectral fragments is the task performed by the synthesis channelizers. They have been presented in Section 9.5.1 and their block diagram is depicted in Figure 7.59. These are small 2-to- $P_n$  polyphase up converters in which the IFFT size,  $P_n$ , is properly chosen in order to span the bandwidth of the  $n$ th received signal spectrum. We summarize the reason for including the synthesizers in our design in this way: at the output of the  $M$ -to-2 analysis channelizer all the signals have been down sampled and their spectra, or their spectral fragments, have been translated to the first Nyquist zone by the channelizing process. In order to reassemble the segments into a wider bandwidth super channel, the time series from each segment must be up sampled and frequency shifted to their appropriate positions so that they can be added together for forming the time series corresponding to the wider bandwidth assembled signal.

At the end of the down conversion and up conversion processes, all the received spectra have been frequency translated and, when necessary, recomposed in the first Nyquist zone. The analysis down converter channelizer shifted to base-band the signal spectra and their fragments, that are exactly centered on its channels' center frequencies. This engine was not able to compensate the frequency offsets deriving from the arbitrary frequency positioning of the received signals.

The frequency offset compensation task is accomplished by the complex frequency rotators that follow the small up converter synthesizers. They are connected with the channel configuration block that provides them proper information about the signal center frequencies.

Once the signals are perfectly centered at DC, arbitrary interpolators are used to adjust their sampling rate to provide us exactly two samples per symbol needed for the further processing stages that are performed in the digital receiver.

#### **1.07.9.1.1 Post-analysis block and synthesis up converter channelizers**

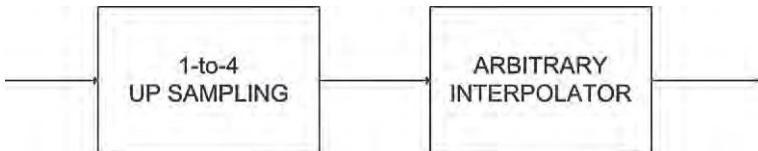

At the output of the analysis channelizer all the channels have been aliased to base-band. As a consequence of that, the channelized segments of the received spectrum have been aliased to the first Nyquist zone (see Figure 7.61).

The following three options, that cover all the possible cases of bandwidths positioning in the channelized spectrum, have to be considered and solved, by further processing the analysis channelizer outputs, in order to achieve, at the end of the analysis-synthesis chain, all the received bands shifted to base-band:

1. The aliased base-band channel could contain only one signal spectrum whose bandwidth is narrower than the channel bandwidth. The carrier frequency of the signal, generally, does not coincide with the center frequency of the channel.
2. The aliased base-band channel could contain two or more spectra, or also their fragments, belonging to different signals. These spectra are arbitrarily positioned in the channel bandwidth.
3. The base-band channel could contain only one spectral fragment belonging to one of the received signals which has bandwidth larger than the channel bandwidth.

In the first option, at the output of the analysis channelizer, the signal spectra that are entirely contained in one single channel reside in the first Nyquist zone. Eventually the receiver has to compensate the frequency offsets derived from their arbitrary center frequency positioning and resample them for obtaining the desired output sampling rate of two samples per symbol. The complex frequency rotators and the arbitrary interpolators perform these tasks at the end of the receiver chain.

For the case in which two or more spectra are processed by one single channel, more tasks need to be performed before frequency offset compensation and arbitrary interpolation occur. We, in fact, have to separate, by filtering, the bands, or their fragments, belonging to different signals before processing all of them independently. The separation task is performed by the post-analysis block. It performs a further channelization process that filters, from every base-band aliased channel, the bands belonging to different signals. Note that some of the filtered signals, and precisely the ones with bandwidths narrower than the channel bandwidth and entirely contained in the channel, only have to be frequency shifted before being delivered to the arbitrary interpolator; else, the spectral fragments belonging to signals processed in more than one channel have to be passed through the up converter synthesizers before being frequency shifted and resampled.

**FIGURE 7.67**

Two stage arbitrary interpolator.

In the third case, that concerns the signals with bandwidths wider than the channel spacing, the analysis channelizer partitioned the bandwidths into several fragments and aliased every fragments to baseband. In order to recombine them we must first, up sample each input time series and second, translate them to their proper spectral region. We can then form the sum to obtain the super channel representation of the original signal bandwidth. Those are exactly the tasks performed by the synthesis channelizers.

#### **1.07.9.1.2 High quality arbitrary interpolator**

After all the bands have been translated to zero frequency, we need to resample them for obtaining exactly the two samples per symbol needed for the subsequent processing performed in the receiver.

In this subsection we present the high quality interpolator structure used for obtaining two samples per symbol needed for the second and third tier processing tasks in a digital receiver. It is well known that the dynamic range of an arbitrary interpolator should match the system's quantization noise level [6]. The error due to the linear interpolation process, in fact, is not observable if it is below the noise level attributed to the signal quantization process. Since the error due to the  $b$ -bit quantized signal is  $2^{-b}$ , the interpolation error or, equivalently, the level of residual spectral artifacts has to be below this threshold. In other words, if the oversampling factor,  $N$ , satisfies Eq. (7.34), then the interpolation error will not be noticeable:

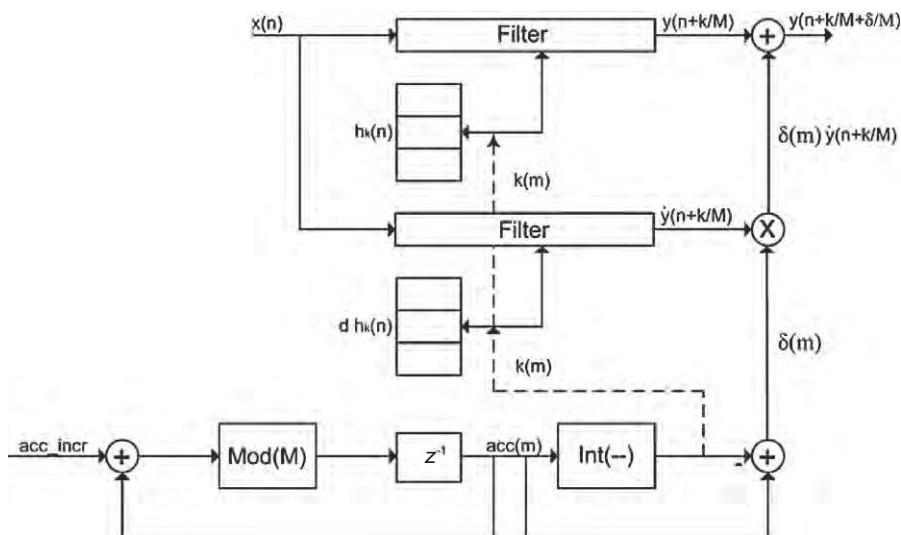

$$\left[ \frac{1}{2N} \right]^2 \leq \frac{1}{2^b}. \quad (7.34)$$

Thus, if we interpolate a 16-bit data set, we keep the spectral artifacts below the quantization noise level if  $N$  is greater than or equal to 128. To interpolate the signals by a factor of  $N = 128$ , we break the up sampling process of the base-band centered spectra in two stages.

As depicted in Figure 7.67, we perform an initial 1-to-4 up sampling followed by a 1-to-32 up sampling obtained by using the high quality arbitrary interpolator shown in Figure 7.68. The initial 4-times oversampling has the effect of strongly decreasing the length of the polyphase filters used in the interpolator which significantly reduces the total workload of this structure. More details on this topic can be found in [6].

Note that the initial 1-to-4 signal up sampling can either be achieved by using two half-band filters in cascade or we can previously up sample the signals by properly choosing  $P_n$ , the IFFT size of the synthesis channelizers. Also, at the output of the synthesizers some of the signals could be already up sampled by some factors because the IFFT size of the synthesizer has to be an even number [6] and it also has to satisfy Nyquist criteria for every signal band.

The arbitrary interpolator shown in Figure 7.68 performs the linear interpolation between two available adjacent signal samples (two neighbor interpolation). The interpolation process operates as follows:

**FIGURE 7.68**

Block diagram of high quality arbitrary interpolator.

A new input data sample is delivered to the interpolation filter register on each accumulator overflow. The integer part of the accumulator content selects one of the  $M$  filter weights,  $h_k(n)$ , and one of the  $M$  derivative filter weights,  $d h_k(n)$ , while the filters compute the amplitude  $y(n + k/M)$  and the first derivative  $\dot{y}(n + k/M)$  at the  $k$ th interpolated point in the  $M$ -point interpolated output grid. Then the structure uses the local Taylor series to form the interpolated sample value between grid points. The output clock directs the accumulator process to add the desired increment  $\Delta$  (acc\_incr in Figure 7.68) to the modulo- $M$  accumulator and increments the output index  $m$ . The increment  $\Delta$  can be computed according to the following equation:  $\Delta = M f_{\text{in}} / f_{\text{out}}$ . This process continues until the accumulator overflows at one of the output clock increments. Upon this overflow the input index is incremented, a new input data point is shifted into the filter, and the process continues as before.

### 1.07.9.1.3 Nyquist filters

Particular attention has to be paid in designing the low-pass prototype filters used in the analysis channelizer. The signal spectra have to be randomly located in the frequency domain and their bandwidths can easily span and occupy more than one base-line channel; also, in the signal disassembling and reassembling processes, we need to collect all the energy corresponding to a single signal without losses.

Nyquist filter presents the interesting property of having a band edge gain equal to 0.5 (or  $-6$  dB). By using this filter as prototype in our channelizers, we place  $M$  of them across the whole spanned spectrum with each filter centered on  $k f_s / M$ . All adjacent filters exhibit  $-6$  dB overlap at their band-edges. The channelizer working under this configuration is able to collect all the signal energy across its full operating spectrum range even if signals occupy more than one adjacent channel or it resides

in the channel's overlapping transition bandwidths. In the following paragraphs, for completeness, we provide a brief introduction on Nyquist filters.

Nyquist pulses is the name given to the wave shapes  $f(n)$  required to communicate over band-limited channels with no inter-symbol interference (ISI). When sampled at equally spaced time increments they have to verify the requirement of Eq. (7.35) which is known as Nyquist pulse criterion for zero ISI:

$$f(n) = \begin{cases} 0 & \text{if } n \neq 0, \\ 1 & \text{if } n = 0. \end{cases} \quad (7.35)$$

There are infinite such functions that satisfy this set of restrictions. The one with minimum bandwidth is the ubiquitous  $\sin(x)/x$  which is variously known as the cardinal pulse when used for band limited interpolation and the Nyquist pulse when used in pulse shaping. The transform of this wave shape,  $R(f)$ , is the unit area rectangle with spectral support 1/T Hz. Unfortunately this waveform is non-causal and further it resides on an infinite support. If the pulse resided on a finite support we could delay the response sufficiently for it to be causal. We have to form finite support approximations to the  $\sin(x)/x$  pulse. The first approximation to this pulse is obtained by convolving the rectangular spectrum,  $R(f)$ , with an even symmetric, continuous spectrum  $W(f)$  with finite support  $\alpha/T$ . The convolution between  $R(f)$  and  $W(f)$  in the frequency domain is equivalent to a product in the time domain between the  $r(t)$  and  $w(t)$ , where  $w(t)$  is the inverse transform of  $W(f)$ . The effect of the spectral convolution is to increase the two-sided bandwidth from  $1/T$  to  $(1+\alpha)/T$ . The excess bandwidth  $\alpha/T$  is the cost we incur to form filters on finite support. The term  $\alpha$  is called the roll-off factor and is typically on the order of 0.5–0.1 with many systems using values of  $\alpha = 0.2$ . The transition bandwidth caused by the convolution is seen to exhibit odd symmetry about the half amplitude point of the original rectangular spectrum. This is a desired consequence of requiring even symmetry for the convolving spectral mass function. When the windowed signal is sampled at the symbol rate 1/T Hz, the spectral component residing beyond the  $1/T$  bandwidth folds about the frequency  $\pm 1/2T$  into the original bandwidth. This folded spectral component supplies the additional amplitude required to bring the spectrum to the constant amplitude of  $R(f)$ .

Following this reasoning, we note that the significant amplitude of the windowed wave shape is confined to an interval of approximate width  $4T/\alpha$  so that a filter with  $\alpha = 0.2$  spans approximately  $20T$ , or 20 symbol durations. We can elect to simply truncate the windowed impulse response to obtain a finite support filter, and often choose the truncation points at  $\pm 2T/\alpha$ . A second window, a rectangle, performs this truncation. The result of this second windowing operation is a second spectral convolution with its transform. This second convolution induces pass-band ripple and out-of-band side-lobes in the spectrum of the finite support Nyquist filter. The description of this band-limited spectrum normalized to unity pass-band gain is presented in Eq. (7.36):

$$H_{\text{NYQ}}(w) = \begin{cases} 1 & \text{for } \frac{|w|}{w_{\text{SYM}}} \leq (1 - \alpha), \\ 0.5 * \left\{ 1 + \cos \left\{ \frac{2\pi}{\alpha} \left[ \frac{w}{w_{\text{SYM}}} - (1 - \alpha) \right] \right\} \right\} & \text{for } (1 - \alpha) \leq \frac{|w|}{w_{\text{SYM}}} \leq (1 + \alpha), \\ 0 & \text{for } \frac{|w|}{w_{\text{SYM}}} \geq (1 + \alpha). \end{cases} \quad (7.36)$$

The continuous time domain expression for the cosine-tapered Nyquist filter is shown in Eq. (7.37). Here we see the windowing operation of the Nyquist pulse as a product with the window that is the

transform of the half-cosine spectrum:

$$h_{\text{NYQ}}(t) = f_{\text{SYM}} \frac{\sin(\pi f_{\text{SYM}} t)}{(\pi f_{\text{SYM}} t)} \frac{\cos(\pi \alpha f_{\text{SYM}} t)}{[1 - (2\alpha f_{\text{SYM}} t)^2]}. \quad (7.37)$$

Since the Nyquist filter is band limited, we can form the samples of a digital filter by sampling the impulse response of the continuous filter. Normally this involves two operations. The first is a scaling factor applied to the impulse response by dividing by the sample rate, and the second is the sampling process in which we replace  $t$  with  $nT_s$  or  $n/f_s$ . The sample rate must exceed the two-sided bandwidth of the filter that, due to the excess bandwidth, is wider than the symbol rate. It is standard to select the sample rate  $f_s$  to be an integer multiple of the symbol rate  $f_{\text{SYM}}$  so that the filter operates at  $M$ -samples per symbol. It is common to operate the filter at 4 or 8 samples per symbol.

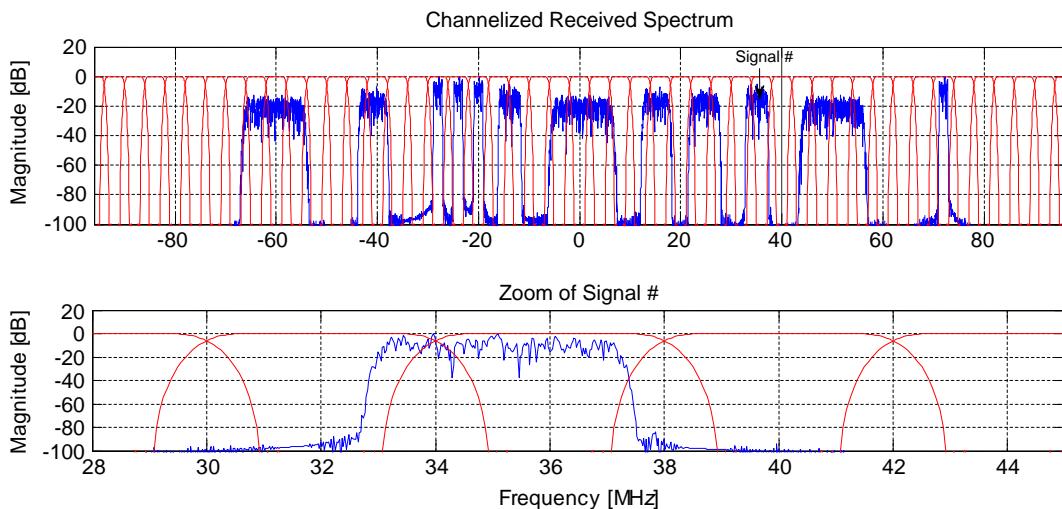

In the design of the proposed analysis channelizer, the Nyquist prototype low-pass filter has to be designed with its two sided 3 dB bandwidth equal to  $1/M$ th of the channelizer input sampling frequency. This is equivalent to the filter impulse response having approximately  $M$  samples between its peak and first zero crossing and having approximately  $M$  samples between its zero crossings. The integer  $M$  is also the size of the IFFT as well as the number of channels in the analysis channelizer. The prototype filter must also exhibit reasonable transition bandwidth and sufficient out of band attenuation or stop-band level. We designed our system for a dynamic range of 80 dB which is the dynamic range of a 16-bit processor.

### 1.07.9.2 Digital down converter simulation results

For simulation purposes, in this section we consider, at the input to the  $M$ -to-2 analysis channelizer, a composite spectrum that contains twelve QAM signals with five different bandwidths randomly located in the frequency domain. In particular, the signal constellations are 4-QAM, 16-QAM, 64-QAM, and 256-QAM while the signal bandwidths are 1.572132 MHz, 3.892191 MHz, 5.056941 MHz, 5.360537 MHz, and 11.11302 MHz respectively. It is clear that we used two different signal bandwidths for the 256-QAM constellation (5.360537 MHz and 11.11302 MHz).

The signals are shaped by square-root Nyquist filters with 20% excess bandwidth. At the input of the analysis channelizer all the signals are resampled for achieving 192 MHz sample rate. The spectrum is shown in Figure 7.56. In particular, the upper subplot of Figure 7.69 shows, superimposed on the composite received spectrum, the 61 channels of the analysis channelizer. It is easy to recognize that the received spectra are arbitrarily located. Their center frequencies do not coincide with the channel center frequencies. That is clearly shown in the lower subplot of Figure 7.69 in which the enlarged view of one of the received signals is presented. The arbitrary signal positioning is the reason for which the polyphase down converter channelizer, by itself, is not able to directly shift them to DC. The IFFT size of the analysis  $M$ -to-2 down converter channelizer is  $M = 48$  with an output sample rate of 8 MHz.

Figure 7.70 shows the impulse response and the magnitude response of the designed prototype low-pass Nyquist filter. It is designed to have 48 samples per symbol. Its length is 1200 taps while its stop band attenuation is  $-80$  dB. Note that, since this filter is  $M$ -path partitioned, the length of each filter in the  $M$ -path bank is only 25 taps.

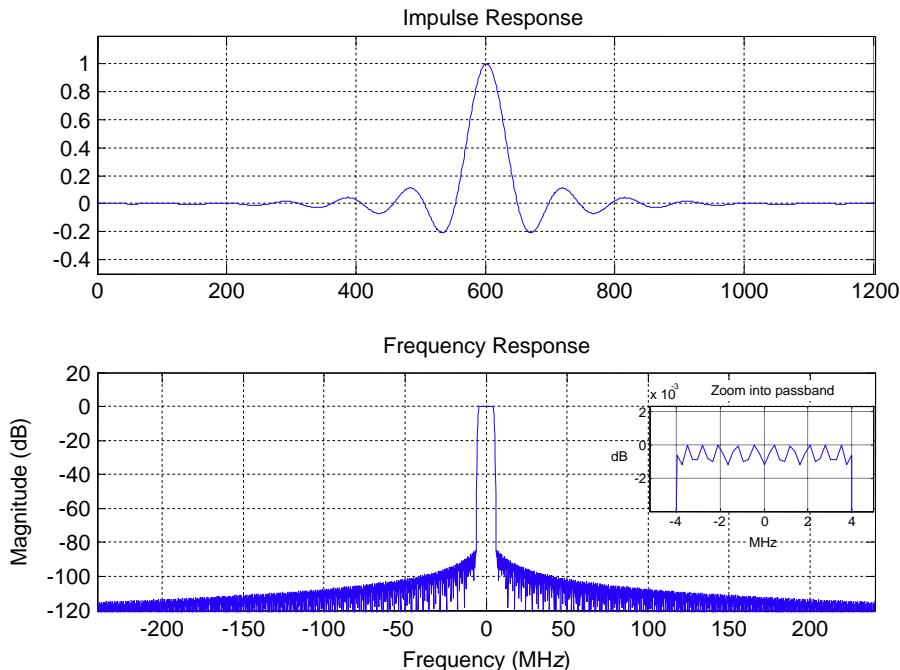

**FIGURE 7.69**

Channelized received spectrum and zoom of one of the received signals.

The 61 spectra, at the output of the analysis channelizer, are depicted in Figure 7.71. The down converter channelizer has partitioned the entire frequency range into 48 segments. It is easy to recognize in this figure the different spectra composing the received signal. Note that, because of the arbitrary frequency positioning, it is possible that also the signals having bandwidths narrower than the channelizer channel bandwidth occupy more than one analysis channelizer channel. Also in this case, before shifting these signals to zero frequency by using complex frequency rotators, we need to pass them through a synthesis channelizer that reassembles their fragments.

Before delivering the analysis channelizer outputs to the synthesis channelizers, we need to separate, if necessary, by filtering, those spectra that belong to different signals lying in the same channel. An example of this is represented by channel 30 in Figure 7.71. It contains fragments of two spectra belonging to different signals. The filter design in the post analysis block, of course, depends on the bands that have to be resolved. Their sample rate has to be the same as the analysis channelizer output rate (8 MHz). An example of post analysis filters along with the filtered signals, for the 30th analysis channelizer channel, is shown in Figure 7.72. In particular, the signal spectra and the filters used for separating them are shown in the upper subplot while the separated spectra are shown in the lower subplots.

At the output of the post analysis block all the spectra, with bandwidths narrower than the analysis channel bandwidth, lying in a single analysis channel, can be directly delivered to the complex heterodyne that translates them to DC. All the other signals, the ones with bandwidths wider than the analysis channel bandwidth and, the ones with bandwidths narrower than the analysis channelizer channel bandwidth that, as consequence of the analysis process, are delivered to two different channelizer outputs, need to be processed by the small synthesis channelizers. We have, in fact, to up sample, frequency shift, and recombine the time series from coupled analysis channelizer outputs. In the example of Figure 7.69

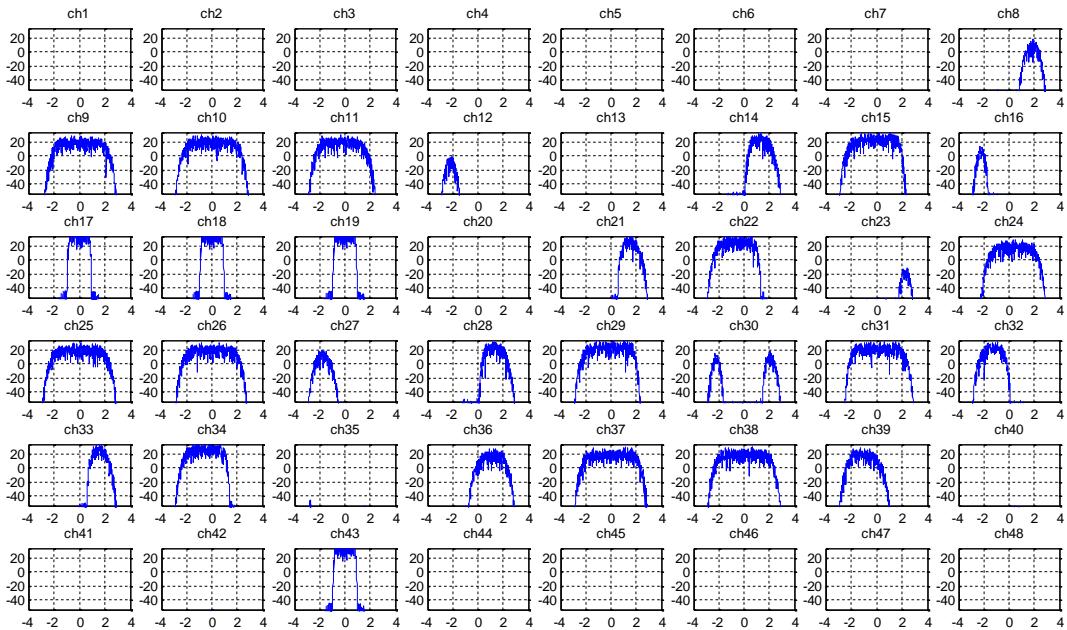

**FIGURE 7.70**

Nyquist prototype filter.

four of the received spectra, the narrowest ones, are directly sent to the frequency rotators. Eight of them are processed through the synthesis channelizer. The IFFT sizes  $P_n$ , with  $n = 0, 1, 2$ , of the synthesizers we selected to process the three remaining bandwidths are:  $P_0 = 6$ ,  $P_1 = 4$ , and  $P_2 = 2$  points. These sizes are the minimum possible chosen to satisfy Nyquist sampling criterion for each output signal. Note that because of the structure of the synthesizers, we can only have an even number of IFFT points [6].

At the output of the synthesizer, all the signal fragments are recombined in base-band but still some of them have a residual frequency offset that needs to be compensated. The signal spectra, before frequency offset compensation are shown in Figure 7.73. Here it is clearly visible that many of the signals are not centered at DC (the red<sup>1</sup> line in Figure 7.73 represents the signals' center frequency). We compensate these frequency offsets by using complex frequency rotators. Note that by estimating the signal energy in the synthesizer channels, we could easily recover the carrier offsets affecting the received spectra. The frequency offset recovery is another of the many applications of the polyphase channelizer. Other papers are being prepared for addressing this topic.

<sup>1</sup>For interpretation of color in Figure 7.73, the reader is referred to the web version of this book.

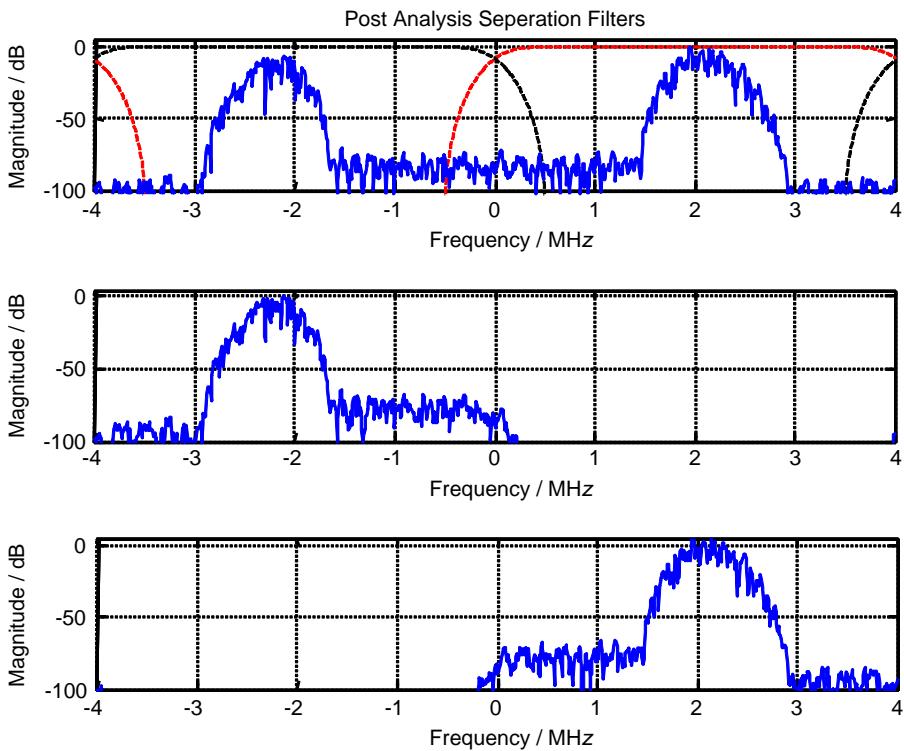

**FIGURE 7.71**

Analysis channelizer outputs.

When they are DC centered, the signals need to be resampled. The signals at the outputs of the synthesis channelizers have different sampling frequencies. All that we need at this point is to interpolate them for obtaining exactly two samples per symbol for each of them. We use an arbitrary interpolator for achieving the sample rate conversion. The interpolated, DC shifted, signals are shown in Figure 7.74. We also match-filtered each of the eight channelized and reconstructed time signals and present their constellations in Figure 7.75, here we see that all of the QAM constellations are perfectly reconstructed which demonstrates the correct functionality of the proposed receiver.

### 1.07.9.3 Proposed up converter architecture

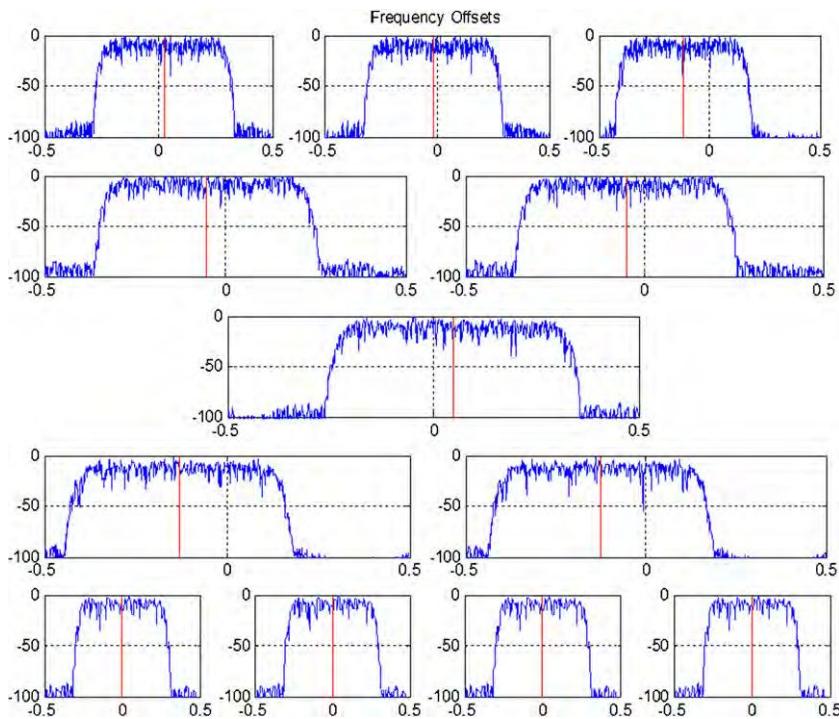

Figure 7.76 shows the complete block diagram of the proposed up converter, which has the structure that is a dual of the down converter structure presented in the previous sections. It is composed of a 2-to- $M$  up sampler synthesis channelizer, which has been presented in Section 9.5.1, preceded by  $N$  pre-processing analysis blocks which are small  $P_n$ -to-2 analysis down converter channelizers. Their number,  $N$ , corresponds to the number of the signal spectra wider than the synthesis channelizer channel bandwidth. Their IFFT size,  $P_n$ , is chosen to completely span the bandwidth of the  $n$ th input signal spectrum. Their task is to decompose the wider input spectra into  $P_n$  partitions matching the bandwidth and sample rate of the base-line synthesis channelizer which will coherently recombine them in the receiver.

**FIGURE 7.72**

Post analysis filters and filtered signals for channel 30 of the analysis channelizer.

All the input signals to the 2-to- $M$  synthesis channelizer with bandwidths less than or equal to the channel spacing are to be up sampled and translated from base-band to the selected center frequency by the channelizing process. For these signals we may only have to filter and resample to obtain the desired sampling rate of two samples per channel bandwidth. However, we expect that many of the spectra we presented to the synthesis channelizer have bandwidths that are wider than the synthesizer channel spacing. For accommodating these signals we need to use the small analysis channelizers that partition their bandwidths into several fragments, translate all of them to base-band, and reduce their sample rate to twice the channel bandwidth. The analysis channelizers are designed as  $P_n$ -to-2 polyphase down converter channelizers where  $P_n$  is approximately twice the number of base-line channels spanned by the wideband spectrum. They have been presented in Section 1.07.5 of this same document and Figure 7.55 shows their block diagram.

We briefly recall here that such a system accepts  $N/2$  input samples and outputs time samples from  $N$  output channels. The  $N$ -point input buffer is fed by a dual input commutator with an  $N/2$  sample offset. The  $N$ -path filter contains polynomials of the form  $H_r(z^2)$  and  $z^{-1}H_{r+N/2}(z^2)$  in its upper and lower halves respectively. The circular output buffer performs the phase rotation alignment of the IFFT block

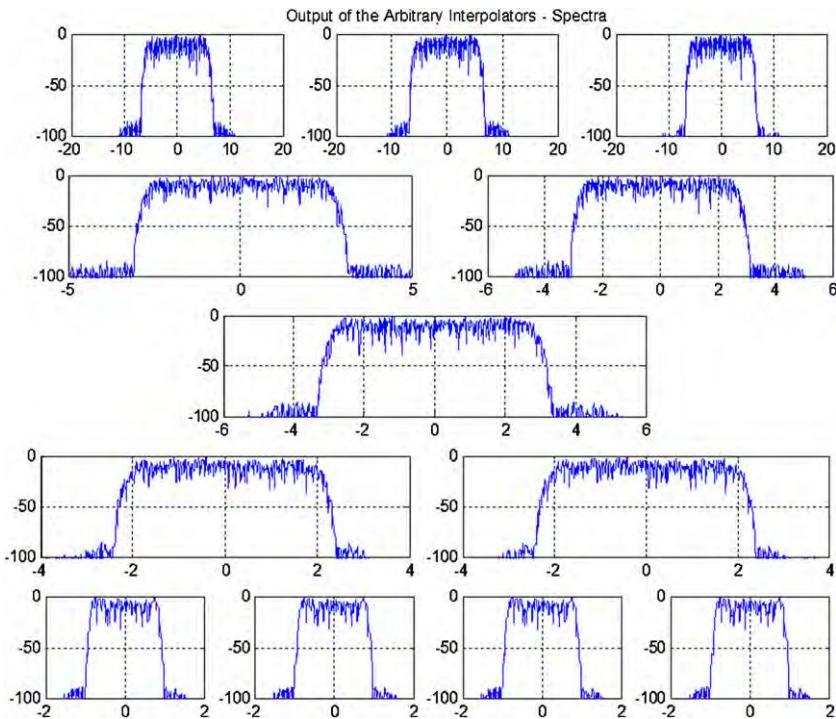

**FIGURE 7.73**

Log magnitude of synthesizer outputs with frequency offsets in the normalized frequency domain.

with the  $N/2$  stride shifting time origin of the  $N$ -path polyphase filter. The IFFT size for these analysis channelizers,  $P_n$ , is also the number of their filter outputs.

In order to recombine the segmented signal components we have to satisfy the Nyquist criteria for their sum. Since these are pre-processor analysis channelizers that feed the  $M$ -path synthesis channelizer we must have their output sample rate two times their channel bandwidth. We can achieve this by selecting  $P_n$  to be approximately twice the number of channels being merged in the synthesizer and setting its input sample rate to be  $2f_s P_n$  so that the pre-processor output rate per channel is the required  $2f_s$ . Remember that the IFFT block sizes must be even to perform the 2-to- $N$  resampling by the technique described in Section 1.07.5; also remember that, an actual system may have a few standard size IFFT's to be used for the analysis channelizer and the user may have to choose from the small list of available block sizes.

The channel selector placed between the analysis channelizer bank and the synthesis channelizer also connected with the input channel configuration block provides the correct outputs from the pre-processor analysis channelizer to the input synthesizer while the channel configuration block provides the necessary information to the selector block that is connected to the synthesis input series. The

**FIGURE 7.74**

Log magnitude of the heterodyned and interpolated spectra in the frequency domain [MHz].

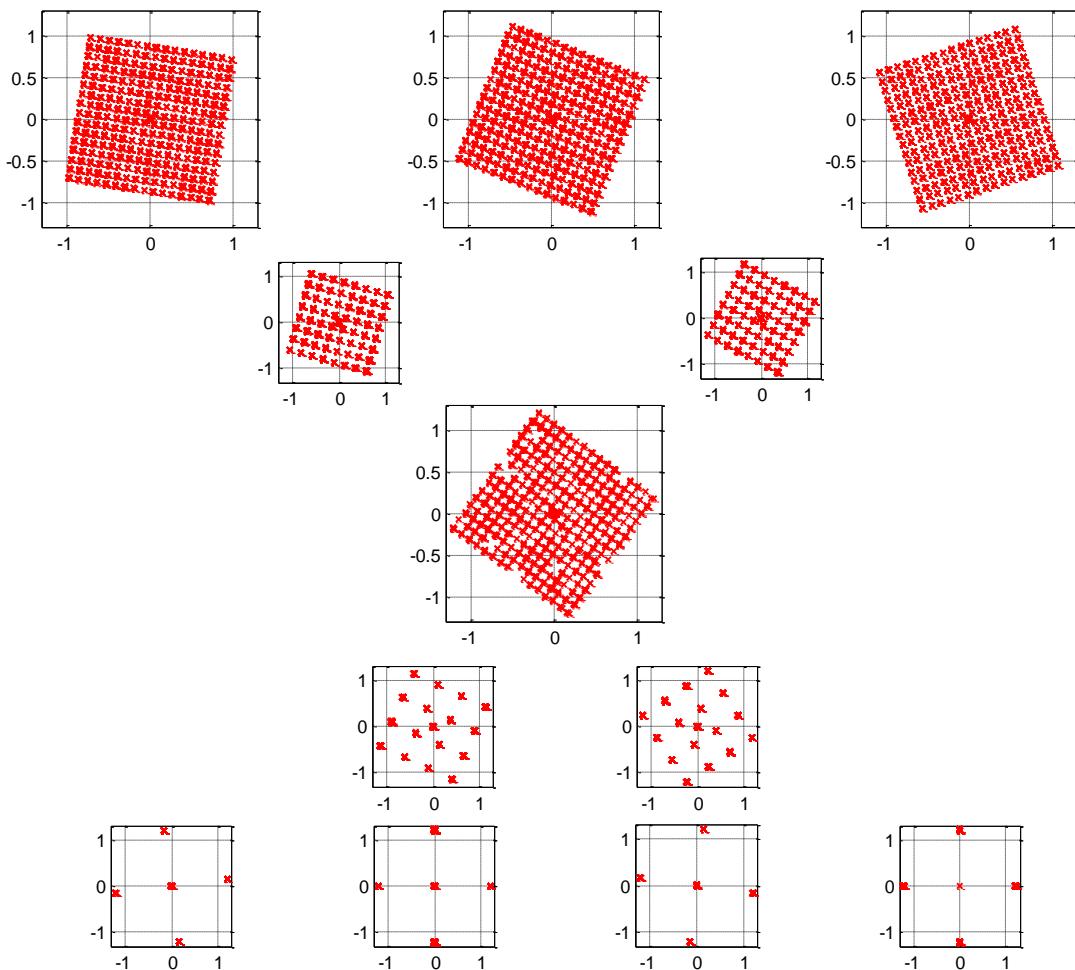

selector routes all the segments required to assemble the wider bandwidth channel to the synthesizer which performs their frequency shift and reassembly.

Depending on the desired center frequency of the disassembled spectrum an earlier complex heterodyne may be required before the analyzers to shift of the about to be disassembled signals with the proper frequency offset.

#### 1.07.9.4 Digital up converter simulation results

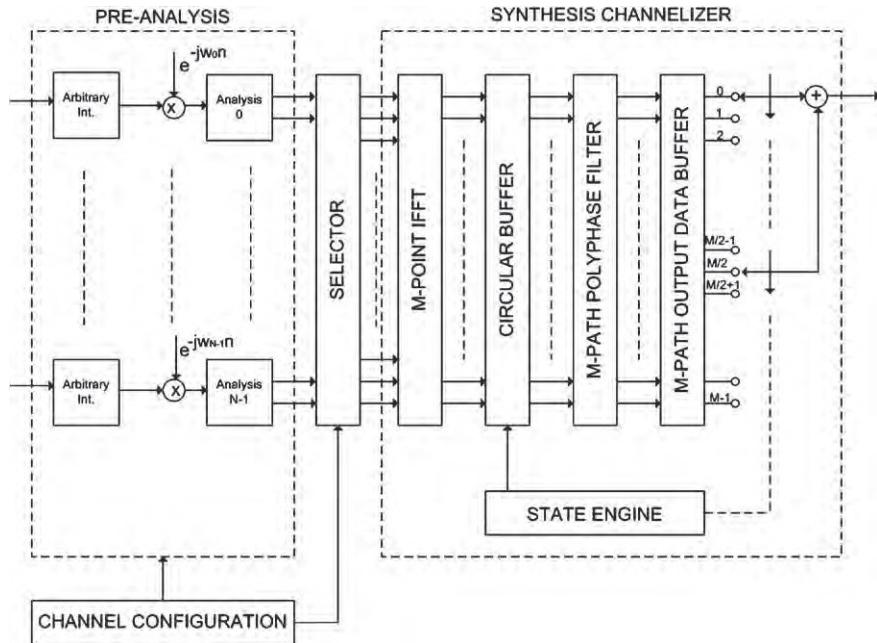

In the simulation results shown in this section we consider a set of eight distinct base-band input signals to be delivered to the 2-to- $M$  up converter synthesis channelizer. These are QPSK signals with three different bandwidths as shown in Figure 7.77. The symbol rates chosen for the three signals denoted 1, 2, and 3, are 7.5, 15.0, and 30.0 MHz. These signals are shaped by square-root Nyquist filters with 25% excess bandwidth, hence the two sided bandwidths are 7.5·1.25, 15.0·1.25, and 30.0·1.25 MHz respectively.

The IFFT size of the base-line 2-to- $M$  up converter channelizer is  $M = 48$  with 10 MHz channel spacing for which the required input sample rate per input signal is 20 MHz and for which the output

**FIGURE 7.75**

Heterodyned and interpolated constellations.

sample rate will be 480 MHz. For ease of signal generation, all three signals were shaped and up-sampled to 60 MHz sample rate with shaping filters designed for 8, 4, and 2 samples per symbol. Signal 1, represented in the first line of Figure 7.77, is down sampled 3-to-1 to obtain the desired 20 MHz sample rate for the synthesis channelizer. Signals 2 and 3, respectively on the second and third line of Figure 7.77, are down sampled 6-to-2 in the six point IFFT analysis channelizers which form 10 MHz channels at 20 MHz sample rate. Signal 2 is spanned by three 10 MHz channels which will feed 3 input ports of the 48 point synthesizer IFFT while signal 3 is spanned by five 10 MHz channels which will

**FIGURE 7.76**

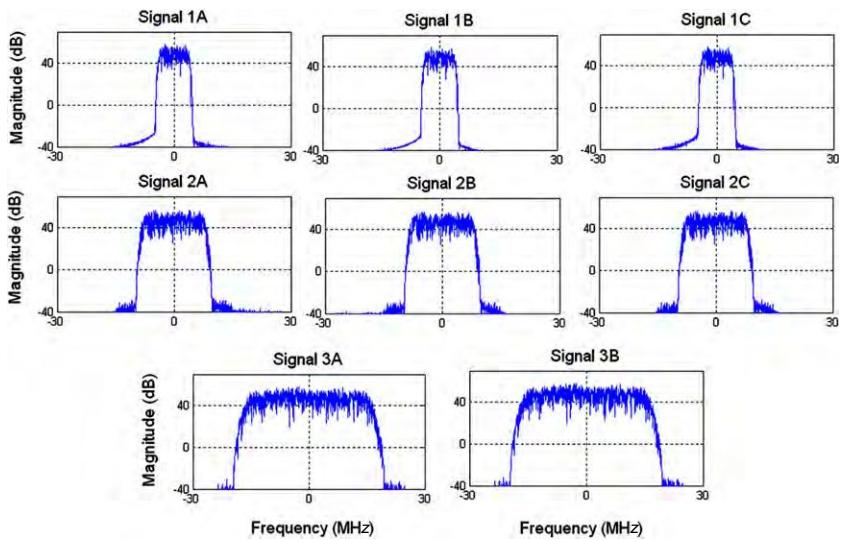

Block diagram of the proposed up converter; arbitrary interpolators, complex frequency rotators, analysis down converter channelizers and synthesis up converter channelizer.

feed 5 input ports of the 48 point IFFT. The IFFT inputs are controlled by a channel control block that routes them to the proper synthesis channelizer ports.

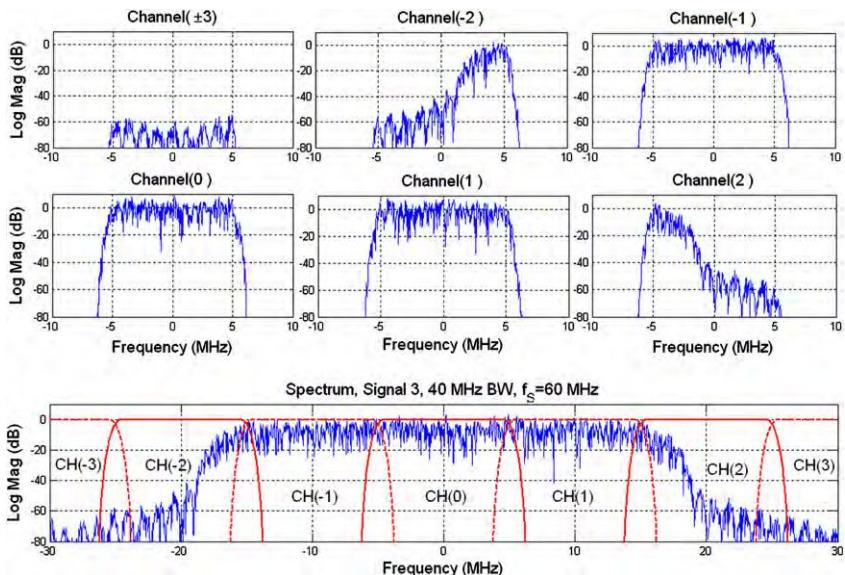

Any of the signals presented to the analysis channelizers is previously shifted to a desired frequency offset, by means of a complex heterodyne if required. The output channels that span the offset input bandwidth of the analysis channelizer are the channels passed on the synthesizer and these change due to a frequency offset. The inserted base-band frequency offset will survive the synthesis channelizer.

Figure 7.78 shows all the spectra of the output time series from the 6-channel polyphase 6-to-2 analysis channelizer engine processing signal 3 which is the signal with the widest band. Also seen, in the same figure, is the spectrum of signal 3 and the frequency response of all the 6 channels formed by one of the analysis channelizers. Note the spectra in the upper subplots have been filtered by the channelizer with the 10 MHz Nyquist pass band frequency response, have been translated to base-band and have been sampled at 20 MHz. Five of these segments are presented to the five input ports of the 2-to-48 synthesis channelizer centered on the desired frequency translation index.

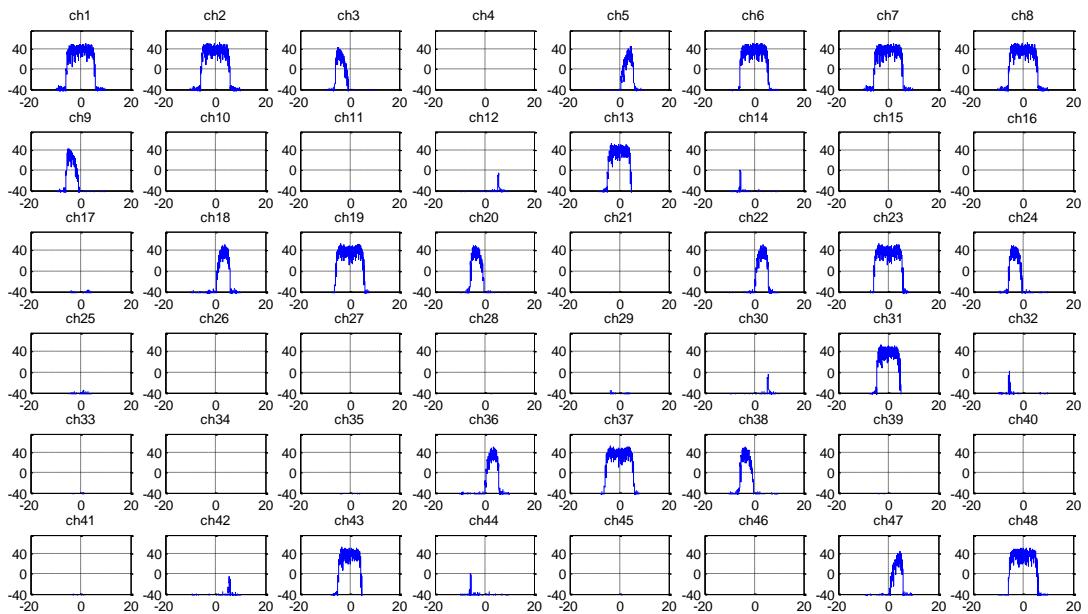

The up converter polyphase synthesis channelizer accepts time sequences sampled at 20 MHz with bandwidths less than 10 MHz. We have delivered three signals that satisfy these constraints along with four signals that were conditioned by analysis channelizers that partitioned their bandwidths into segments that also satisfied the input signal constraints. The spectra of the separate components delivered to the synthesis channelizer are shown in Figure 7.79. It is easy to recognize in this figure the different

**FIGURE 7.77**

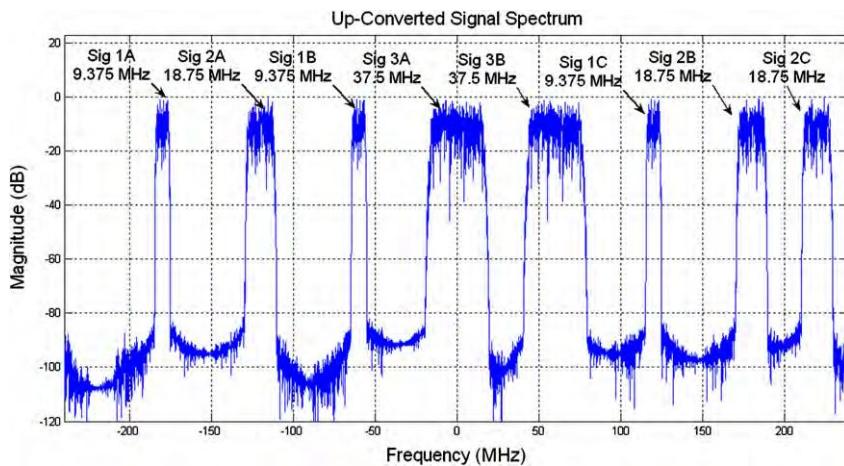

Example of base-band spectra to be up converted.

**FIGURE 7.78**

Spectral fragments formed by 6-channel 6-to-2 down sample analysis channelizer processing signal 3.

2-to- $M$  up converter channelizer inputs.

**FIGURE 7.80**

Up converted synthesized spectrum with unequal bandwidths fragmented and defragmented spectral components.

spectra composing the received signal. Here we see that filters 4-through-8 are segments of a single frequency band fragmented in Figure 7.78.

At this point, we up sample, frequency shift, and recombine the time series from coupled channel outputs using the synthesis channelizer. The frequency shifted spectra of the eight signals, including six that have been fragmented in analysis channelizers and then defragmented in the synthesis channelizer are plotted in Figure 7.80.

### 1.07.10 Closing comments

This chapter had the intention of providing the basic concepts on multirate signal processing and polyphase filter banks to which, when an IDFT block and a commutator are applied, are known as polyphase channelizer because of the processing task that they perform on the input signals. This chapter also had the intention of presenting innovative results on software and cognitive radio designs. While the polyphase filter banks and polyphase channelizers are well known topics in the DSP area, the software radio design is still an open research topic.

The document started with preliminaries, in Section 1.07.2, on the resampling process of a digital signal as opposed to the sampling process of an analog signal. In Section 1.07.3 an introduction on digital filters has been provided and the differences with the analog filters have been explained. In Section 1.07.4 an introduction on the window method for digital filter design has been provided. Multirate filters have been defined and explained in Section 1.07.5 while the polyphase decomposition of a prototype filter has been introduced in Section 1.07.6 along with the standard up sampler and down sampler polyphase channelizers. In Section 1.07.7 the modifications of the standard polyphase channelizer that allow us to change the output sampling rate have been presented. These engines are the basic components of the proposed architectures (presented in Sections 1.07.8 and 1.07.9): the synthesis and analysis channelizers, that are suitable for being used as software defined transmitter and receiver respectively.

The synthesis channelizer, in fact, when supported by small analysis channelizers, is able to simultaneously up convert multiple signals having arbitrary bandwidths to randomly located center frequencies. In this engine small analysis channelizers pre-process wider bandwidth signals into segments acceptable to the following synthesis channelizer that up samples, translates to the proper center frequency, and reassembles them. A channel selector block, connected with a channel configuration block, is used to properly deliver the analysis channelizer outputs to the synthesis channelizer.

On the other side of the communication chain, the analysis channelizer, that is thought for being embedded in a SDR receiver, when supported by small synthesis channelizers, is able to simultaneously demodulate these signals. A channel configuration block, inserted in the receiver, communicates with a selector block that properly delivers the analysis channelizer outputs to the synthesizer up converters that follow it. These synthesizers up sample, translate and reassemble the spectral fragments when they belong to the same source signal. Nyquist prototype low-pass filters, which are perfect reconstruction filters, are used to allow the reconstruction of the signal fragments without energy losses.

Complex frequency rotators are used for compensating residual frequency offsets and arbitrary interpolators provide us exactly two samples per symbol required for the following processing tasks of the receiver.

Theoretical reasoning and simulation results are presented, for both the receiver and the transmitter, in order to demonstrate their correct functionality.

Note that because in both of the proposed DUC and DDC structures, the IFFT sizes of the small synthesis and analysis channelizers are chosen in order to give us at least two samples per symbol for every processed bandwidth, they result to be very efficient, from a computational point of view, when the received signal is composed of spectra with widely varying bandwidths.

Slightly different versions of channelizers can be used based on different input signals and/or for adding functionalities to the proposed architectures. Channelizers are, in fact, highly efficient and very flexible structures. Among their most common applications we find spectral analysis, modem synchronization (phase, frequency and time) and channel equalization.

## Glossary

Filter	calculation procedure that transforms the input signals into others
Digital filter	filter that operates on digital signals
Multirate filter	digital filter that contains a mechanism to increase or decrease the sampling rate while processing input signals
Polyphase filter	digital filter partitioned by following Eq. (7.3)
Polyphase channelizer	flexible digital device which can arbitrarily change the sample rate and the bandwidth of the input signal and can also select randomly located Nyquist zones
Software radio	radio device in which the digitization of the signal occurs before the intermediate frequency translation
Cognitive radio	software radio with the capability to adapt its operating parameters according to the interactions with the surrounding radio environment

# Modern Transform Design for Practical Audio/Image/Video Coding Applications

Trac D. Tran

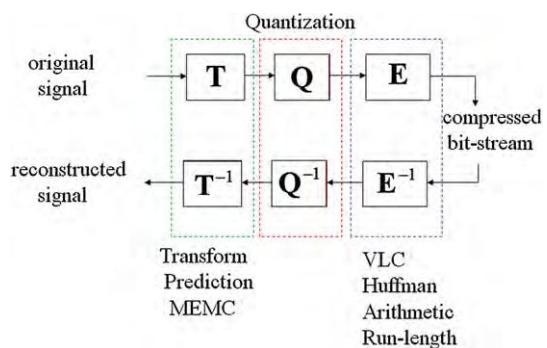

*Department of Electrical and Computer Engineering, The Johns Hopkins University, MD, USA*

## 1.8.1 Introduction

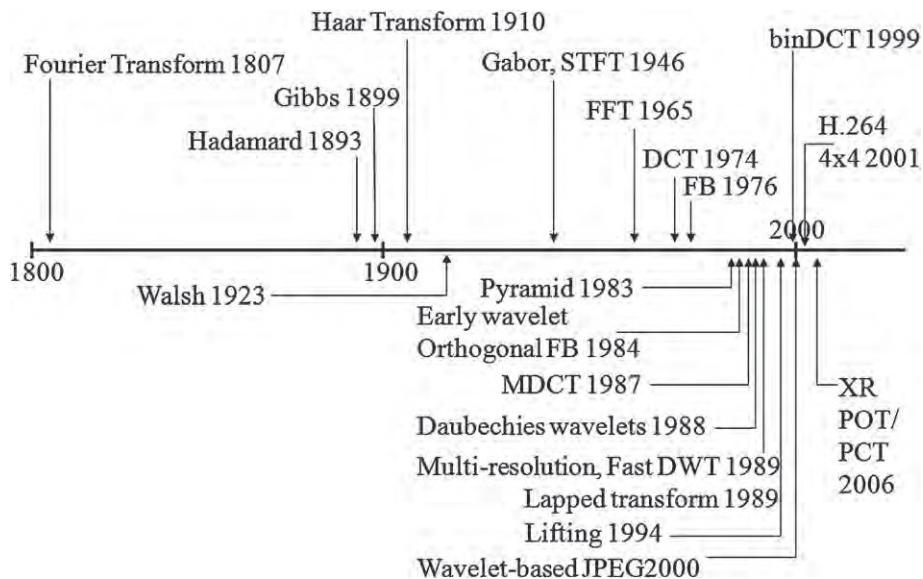

With the recent explosion in popularity of the Internet, wireless communication, and portable computing, the demands for and the interests in digital multimedia (digitized speech, audio, image, video, computer graphics, and their combination) are growing exponentially. A high-performance filter bank is typically at the heart of every state-of-the-art digital multimedia system whose compression paradigm is illustrated in Figure 8.1. Current popular international image/video compression standards such as JPEG [1], MPEG2 [2], and H.263 [3] are all based on the  $8 \times 8$  Discrete Cosine Transform (DCT), an 8-channel 8-tap orthogonal filter bank with fast computational algorithms based on sparse factorizations. The latest image compression JPEG2000 standard [4] is employing the wavelet transform, an iterated 2-channel bi-orthogonal filter bank, as its de-correlation engine. Of extreme importance is the ability to design a filter bank that can fully exploit (i) the statistical properties of a particular signal or class of signals; (ii) the goals of the applications; and (iii) the computational resources available.

Although the roots of signal transformations can be traced back to works in the 19th century by prominent mathematicians such as Laplace and Fourier, the exciting development of modern, practical digital transforms and filter banks only have a few years of history [5–8] as illustrated in the timeline of Figure 8.2. These new systems provide more effective tools to represent digital signals not only for analysis but also for processing and compression purposes. For multimedia signals, representations by transform coefficients are usually more compact and efficient than the time representations, but are just as informative. Taking advantage of the normally sparse transform coefficient matrix, we can perform a majority of signal processing tasks directly in the transform domain at a lower level of computational complexity.

On the other hand, fast, efficient, and low-cost transforms have played a crucial role in revolutionary advances throughout the history of digital signal processing. The Discrete Fourier Transform (DFT) is an excellent signal analysis tool. However, its popularity in practical systems was not widespread until the discovery of the Fast Fourier Transform (FFT) by Cooley and Tukey in 1965 that reduces the complexity level from  $\mathcal{O}(n^2)$  to  $\mathcal{O}(n \log n)$  [9]. Another example, the  $8 \times 8$  Discrete Cosine Transform [10], has a theoretically elegant closed-form expression. It was chosen as the transform-of-choice in most of current image and video coding standards mainly because it possesses various fast algorithms [11] that can reduce the transform complexity from 64 multiplications and 56 additions to as low as 5 multiplications and 29 additions per 8 transform coefficients.

**FIGURE 8.1**

Standard compression paradigm in current digital multimedia systems.

**FIGURE 8.2**

A historical timeline of significant developments in signal decomposition and transformation.

In this chapter, we review the design and development progress of modern transforms for application in digital image/video coding and processing. These new state-of-the-art transforms provide versatility and flexibility in time-frequency mapping, coding performance, cost of implementation as well as integration into modern digital multimedia processing/communication systems. We assert that the most successful philosophy in transform design is to construct highly-complex systems from modular

cascades of similar, simple building blocks, each propagating a set of desired transform properties. These novel transforms will be designed to have as many of the following features as possible:

- orthogonal or at least near-orthogonal,
- symmetric/anti-symmetric (linear-phase) basis functions,
- good stop-band attenuation,
- smoothness of the basis functions for perceptually pleasant reconstruction,
- integer-to-integer mapping capability with exact recovery for a unifying lossless/lossy coding framework,
- fast computation and efficient implementations in both software and hardware: multiplier-less property for low-power real-time systems; in-place computation; low memory buffering; VLSI-friendliness with high modularity and regularity in construction; facilitating region-of-interest coding/decoding and computational parallelism.

The organization of the chapter is as follows. In Section 1.8.2, we offer a review of important background materials, concepts, motivations, and previous related works in transform design. Common design strategy and desirable cost functions are discussed in Section 1.8.3. Next, Section 1.8.4 describes the direct scaling-based design method for modern integer-coefficient transforms. Section 1.8.5 presents a totally different philosophy in transformation design via general parameterization and construction of polyphase matrices based on lifting steps (also known as ladder structures). The section also discusses in details the subset of solutions that allows the construction and implementation of various dyadic-coefficient transforms purely from shift-and-add operations. The design procedure of spectral factorization of maxflat half-band filters that lead to popular wavelet filter pairs is described in Section 1.8.6. Advanced design mainly via optimization with a larger number of channels and/or longer filter lengths is covered in Section 1.8.7. Numerous design examples along with current practical applications will be demonstrated throughout along with discussions on each design's advantages as well as disadvantages and other interesting properties. Finally, we briefly summarize the chapter with a few concluding remarks in Section 1.8.8.

## 1.8.2 Background and fundamentals

We provide in this section the notation, common background, a brief description of the historical development of transforms (especially for compression applications), and a discussion on desirable properties of a state-of-the-art modern transform in multimedia coding and processing.

### 1.8.2.1 Notation

Let  $\mathcal{R}$ ,  $\mathcal{Q}$ , and  $\mathcal{Z}$  denote the sets of real numbers, rational numbers, and integers, respectively. Also, let  $\mathcal{D}$  denote the set of dyadic rationals, i.e., all rational numbers that can be represented in the form of  $\frac{k}{2^m}$  where  $k, m \in \mathcal{Z}$ . Bold-faced lower case characters are used to denote vectors while bold-faced upper case characters are used to denote matrices. Let  $\mathbf{A}^T$ ,  $\mathbf{A}^{-1}$ ,  $|\mathbf{A}|$ , and  $a_{ij}$  denote respectively the transpose, the inverse, the determinant, and the  $i$ th  $j$ th element of the matrix  $\mathbf{A}$ . Several special matrices with reserved symbols are: the polyphase matrix of the analysis bank  $\mathbf{E}(z)$ , the polyphase matrix of the synthesis bank  $\mathbf{R}(z)$ , the identity matrix  $\mathbf{I}$ , the reversal or anti-diagonal matrix  $\mathbf{J}$ , the null matrix

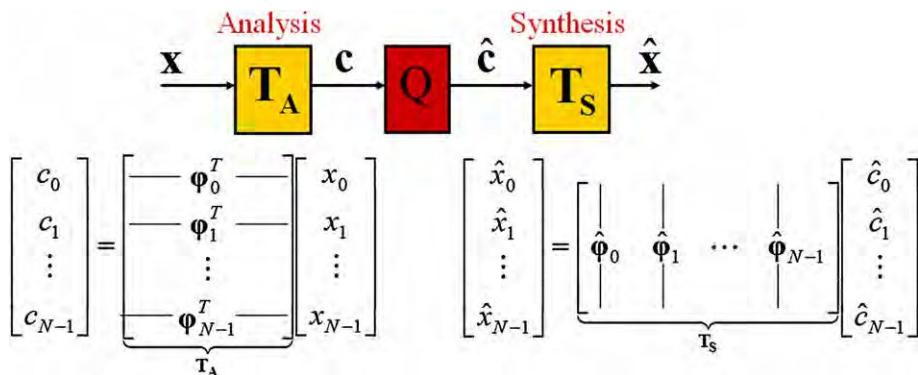

(or vector) **0**, the unity vector **1**, the permutation matrix **P**, and the diagonal matrix **D**. The letter  $M$  is usually reserved for the number of channels of the filter bank or the size of the transform. Finally, we denote the  $\ell_p$  norm of an  $N$ -point vector  $\mathbf{x}$  as  $\|\mathbf{x}\|_p = \left(\sum_{i=0}^{N-1} |x_i|^p\right)^{1/p}$  where the  $\ell_2$  norm  $\|\mathbf{x}\|_2 = \sqrt{\mathbf{x}^T \mathbf{x}}$  is of special interest.

### 1.8.2.2 Transform fundamentals

A transform is most often thought of as a linear mapping which can be carried out by a simple matrix multiplication. A block transform  $\mathbf{T}_A$  of size  $M$  is simply an  $M \times M$  scalar matrix, mapping the signal vector  $\mathbf{x}$  to its corresponding transform coefficients  $\mathbf{c}$ . Here, the subscript  $A$  is used to denote the analysis transform often employed in an encoder to analyze or to de-correlate input data samples. At the decoder, we need the inverse operator  $\mathbf{T}_S$  to recover  $\mathbf{x}$  back where the subscript  $S$  denotes the synthesis or signal reconstruction operation. The series of mappings are depicted in Figure 8.3. The operation  $\mathbf{Q}$  in the middle of Figure 8.3 represents either approximation (in the form of quantization for instance), processing, coding, communication or any combination thereof. Obviously, if the coefficients can be recovered losslessly or  $\hat{\mathbf{c}} = \mathbf{c}$ , we simply require  $\mathbf{T}_S$  to be the exact inverse of  $\mathbf{T}_A$  to reconstruct the input signal perfectly.

The columns  $\phi_i$  of  $\mathbf{T}_A^T$  are often called the analysis basis functions while the columns  $\hat{\phi}_i$  of  $\mathbf{T}_S$  are called the synthesis basis functions.  $\mathbf{T}_A$  is said to be an invertible transform or a transform that has perfect reconstruction or bi-orthogonal when  $\mathbf{T}_S \mathbf{T}_A = \mathbf{T}_A \mathbf{T}_S = \mathbf{I}$ . In the special case that the synthesis transform has real coefficients and is simply the transpose of the analysis transform  $\mathbf{T}_S = \mathbf{T}_A^{-1} = \mathbf{T}_A^T$ , then the transform  $\mathbf{T}_A$  is said to be orthogonal. In this case, we can conceptually think of representing the  $N$ -point input signal as

$$\mathbf{x} = c_0 \phi_0 + c_1 \phi_1 + \cdots + c_{N-1} \phi_{N-1} = \sum_{i=0}^{N-1} c_i \phi_i, \quad \text{where } c_i = \langle \phi_i, \mathbf{x} \rangle. \quad (8.1)$$

**FIGURE 8.3**

Signal decomposition and reconstruction as matrix operations.

However, our interest is to design the transform that yields the sparsest and most compact representation

$$\mathbf{x} = \sum_{i \in \mathcal{S}; |\mathcal{S}|=K \ll N} c_i \boldsymbol{\phi}_i. \quad (8.2)$$

In (8.2) above, the set of significant coefficients are indexed by the set  $\mathcal{S}$  whose cardinality  $K$  is much smaller than the signal dimension  $N$ .

For two-dimensional signals such as still images or frames in video sequences, we typically employ the separable transformation approach where all rows are transformed and then all columns are transformed or vice versa. Mathematically, if we let  $\mathbf{X}$  be the image of interest in the form of a matrix, then the transform coefficients  $\mathbf{C}$  of  $\mathbf{X}$  can be computed as

$$\mathbf{C} = \mathbf{T}_A \mathbf{X} \mathbf{T}_A^T, \quad (8.3)$$

while the inverse synthesis mapping can be computed as

$$\mathbf{X} = \mathbf{T}_S \mathbf{C} \mathbf{T}_S^T. \quad (8.4)$$

Note that the computation order of rows or columns in 8.3 and 8.4 is not critical and the strategy can be straightforwardly extended to signals of any higher dimension.

### 1.8.2.3 Optimal orthogonal transform

Obtaining the sparsest representation as in (8.2) above is certainly a signal-dependent task. Let  $\mathbf{c}$  be the coefficients of the input signal  $\mathbf{x}$ , obtained from a certain linear transformation  $\mathbf{T}$ . Let us further assume that the input signal  $\mathbf{x}$  can be modeled as a white-sense stationary stochastic process. Then, the correlation matrix of the output signal  $\mathbf{c}$  is

$$\mathbf{R}_{cc} = E\{\mathbf{T}\mathbf{x}\mathbf{T}^T\} = \mathbf{T}\mathbf{R}_{xx}\mathbf{T}^T.$$

The optimal orthogonal linear transform  $\mathbf{T}$  here is the one that can fully de-correlate  $\mathbf{x}$ . In order to achieve this,  $\mathbf{R}_{cc}$  must be a diagonal matrix with the eigenvalues of  $\mathbf{R}_{xx}$  being its diagonal entries, and each row of  $\mathbf{T}$  being an eigenvector of  $\mathbf{R}_{xx}$ . This optimal transform is often called the Karhunen-Loëve Transform (KLT) of signal  $\mathbf{x}$ , also known as principal component analysis (PCA) or the Hotelling transform. Obviously, the KLT depends on the auto-correlation matrix  $\mathbf{R}_{xx}$ . Thus it is signal dependent, computationally expensive, and costly to communicate to the decoder if the signal of interest is not stationary. To find fast algorithms and signal-independent transforms for practical applications, a typical approach is to start with a simplified stationary signal model, try to find the approximation of its KLT, and then develop fast computational algorithms of the resulting approximation. The Discrete Cosine Transform (DCT) is developed following this approach [10,11].

### 1.8.2.4 Popular transforms in signal processing: DFT, WHT, DCT

The problem of transform design has undergone several important evolutions. In the beginning, transformation is mainly thought of as a continuous-time continuous-amplitude change of basis operation

(and often in infinite-dimension functional space) to solve complicated set of equations. Discrete-time transforms are often obtained from sampling the continuous-time version. Four popular discrete-time transforms in signal processing are the Discrete Fourier Transform (DFT), the Walsh-Hadamard Transform (WHT), the type-II Discrete Cosine Transform (DCT) and the type-IV Discrete Cosine Transform (DCT), shown below in the matrix representation format respectively.

$$[\mathbf{F}] = \frac{1}{\sqrt{M}} [W_M^{mn}]; \quad 0 \leq m, n \leq M - 1; \quad W_M = e^{-j \frac{2\pi}{M}}. \quad (8.5)$$

$$\mathbf{H}_2 = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}; \quad \mathbf{H}_{2^m} = \mathbf{H}_2 \otimes \mathbf{H}_{2^{m-1}} = \begin{bmatrix} \mathbf{H}_{2^{m-1}} & \mathbf{H}_{2^{m-1}} \\ \mathbf{H}_{2^{m-1}} & -\mathbf{H}_{2^{m-1}} \end{bmatrix}; \quad m \in \mathcal{Z}, m \geq 2. \quad (8.6)$$

$$[\mathbf{C}_M^{II}] = \sqrt{\frac{2}{M}} \left[ K_m \cos \left( \frac{m(n + 1/2)\pi}{M} \right) \right]; \quad 0 \leq m, n \leq M - 1; \quad K_i = \begin{cases} \frac{1}{\sqrt{2}} & i = 0 \\ 1 & i > 0 \end{cases}. \quad (8.7)$$

$$[\mathbf{C}_M^{IV}] = \sqrt{\frac{2}{M}} \left[ \cos \left( \frac{(m + 1/2)(n + 1/2)\pi}{M} \right) \right]; \quad 0 \leq m, n \leq M - 1. \quad (8.8)$$

Out of the three mentioned above, only the Hadamard transform has integer coefficients. Unfortunately, it is too simplistic to offer reasonable coding performance. On the other hand, the DCT offers very good compression performance but it has irrational coefficients. The DFT is not only irrational, but it also has complex-valued coefficients.

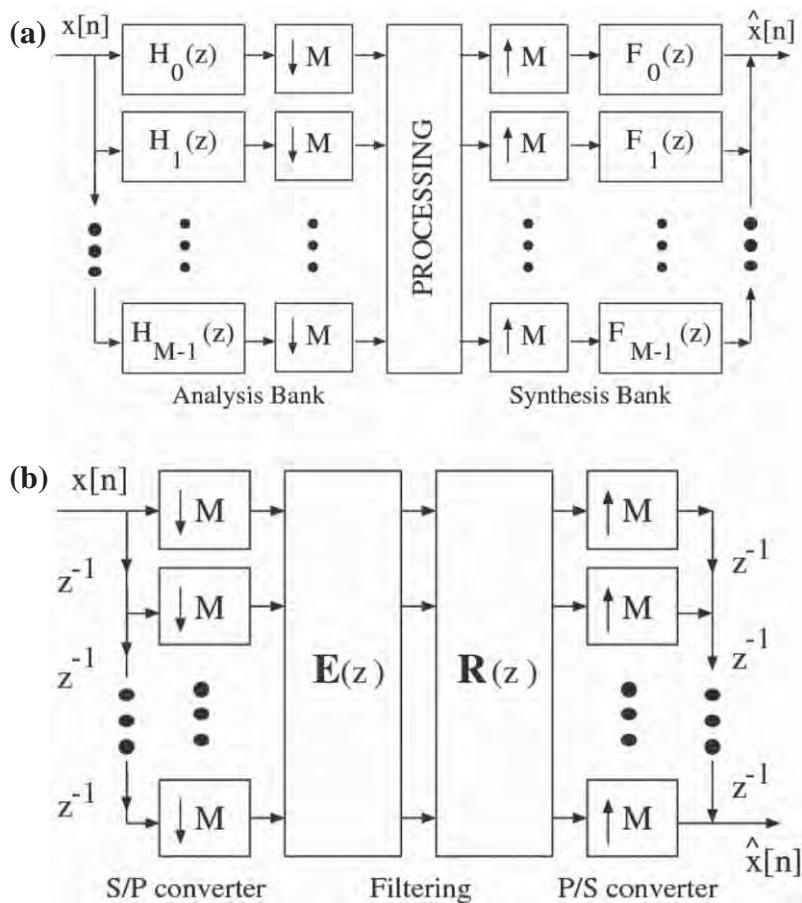

### 1.8.2.5 The filter bank connection

A typical discrete-time, maximally-decimated  $M$ -channel filter bank is depicted in Figure 8.4. At the analysis stage, the input signal  $x[n]$  is passed through a bank of  $M$  analysis filters  $H_i(z)$ ,  $i = 0, 1, \dots, M - 1$ , each of which preserves a frequency band. These  $M$  filtered signals are then decimated by  $M$  to preserve the system's overall sampling rate. The resulting subband signals can be coded, processed, and/or transmitted independently or jointly. At the synthesis stage, the subbands are combined by a set of upsamplers and  $M$  synthesis filters  $F_i(z)$ ,  $i = 0, 1, \dots, M - 1$ , to form the reconstructed signal  $\hat{x}[n]$ . In the absence of processing errors (e.g., quantization), filter banks that yield the output  $\hat{x}[n]$  as a pure delayed version of the input  $x[n]$ , i.e.,  $\hat{x}[n] = x[n - n_0]$ , are called *perfect reconstruction* filter banks. From a traditional transform perspective, the analysis filter  $h_i[n]$  is the  $i$ th analysis basis function  $\phi_i$ . Similarly, the synthesis filter  $f_i[n]$  yields the  $i$ th synthesis basis function  $\hat{\phi}_i$ .

The filter bank in Figure 8.4a can also be represented in terms of its polyphase matrices as shown in Figure 8.4b.  $\mathbf{E}(z)$  is the analysis bank's polyphase matrix and  $\mathbf{R}(z)$  is the synthesis bank's polyphase matrix. Note that both  $\mathbf{E}(z)$  and  $\mathbf{R}(z)$  are  $M \times M$  matrices whose elements are polynomials in  $z$  [7]. If  $\mathbf{E}(z)$  is invertible with a minimum-phase determinant (stable inverse), one can obtain perfect reconstruction by simply choosing  $\mathbf{R}(z) = \mathbf{E}^{-1}(z)$ . In other words, any choice of  $\mathbf{R}(z)$  and  $\mathbf{E}(z)$  that satisfies

$$\mathbf{R}(z)\mathbf{E}(z) = \mathbf{E}(z)\mathbf{R}(z) = z^{-l}\mathbf{I}, \quad l \geq 0 \quad (8.9)$$

yields perfect reconstruction. Since filter banks with finite impulse response (FIR) filters are very valuable in practice, we can restrict the determinants of both polyphase matrices need to be monomials

**FIGURE 8.4**

$M$ -channel filter bank. (a) Conventional representation. (b) Polyphase representation.

[6–8] as well:

$$|\mathbf{R}(z)| = z^{-m} \quad \text{and} \quad |\mathbf{E}(z)| = z^{-n} \quad m, n \in \mathbb{Z}. \quad (8.10)$$

A popular choice of  $\mathbf{R}(z)$  yielding *paraunitary* or *orthogonal* systems is

$$\mathbf{R}(z) = z^{-K} \mathbf{E}^T(z^{-1}), \quad (8.11)$$

where  $K$  is the order of a properly-designed  $\mathbf{E}(z)$ . In the case where  $\mathbf{E}(z)$  may not be paraunitary but (8.9) still holds, the filter bank is said to be *bi-orthogonal*. Now, the design of a complicated  $M$ -band FIR perfect reconstruction filter bank is reduced to choosing appropriate polynomial matrices  $\mathbf{E}(z)$  and  $\mathbf{R}(z)$  such that (8.9) and (8.10) are satisfied.

When the filter length equals the number of channel  $M$ , the polyphase matrices  $\mathbf{E}(z)$  and  $\mathbf{R}(z)$  become scalar matrices of zero order and they become equivalent to the conventional transforms above, i.e.,  $\mathbf{E}(z) = \mathbf{T}_A$  and  $\mathbf{R}(z) = \mathbf{T}_S$ . When the filter length is higher than the number of channel, we have to deal with matrices whose entries are polynomials in  $z$ . In the wavelet transform,  $M = 2$  and we almost never have a scalar polyphase matrix, except the Haar wavelet. When  $M$  equals the support of the input signal, we have a global transform and maximum frequency resolution becomes achievable. On the other hand, when  $M$  is much smaller than the input size (for example, most imaging applications have the transform size of  $16 \times 16$  or less), we have a block transform coding framework where the down-samplers and the delay chain on the left of Figure 8.4b serve as serial-to-parallel blocking mechanism whereas the up-samplers and the delay (or advance) chain on the right of Figure 8.4b implement the parallel-to-serial unblocking mechanism. In this case, the global transform matrices  $\mathbf{T}_A$  and  $\mathbf{T}_S$  have block-diagonal structure and maximum time/space resolution becomes achievable.

### 1.8.2.6 The lapped transform connection

The lapped transform (LT) is defined as a linear transformation that partitions the input signal into small *overlapped* blocks and then processes each block independently. The equivalence between the lapped transform, the filter bank in Section 1.8.2.5, as well as the general linear transformation in Section 1.8.2.2 has been well-established in [12].

Consider the  $M$ -channel perfect-reconstruction filter bank with FIR filters, all of length  $L = KM$  for presentation elegance. The polyphase matrix  $\mathbf{E}(z)$  as shown in Figure 8.4b is of order  $K - 1$  and can be expressed as  $\mathbf{E}(z) = \sum_{i=0}^{K-1} \mathbf{E}_i z^{-1}$ . Similarly, the synthesis polyphase matrix  $\mathbf{R}(z)$  can be represented as  $\mathbf{R}(z) = \sum_{i=0}^{K-1} \mathbf{R}_i z^{-1}$ . With  $\mathbf{J}$  as the time-reversal matrix, if we define

$$\mathbf{E} = [\mathbf{E}_{K-1}\mathbf{J} \cdots \mathbf{E}_1\mathbf{J} \mathbf{E}_0\mathbf{J}] \quad \text{and} \quad \mathbf{R} = \begin{bmatrix} \mathbf{JR}_0 \\ \mathbf{JR}_1 \\ \vdots \\ \mathbf{JR}_{K-1} \end{bmatrix},$$

then the global transform matrices can be shown to take the following forms

$$\begin{aligned} \mathbf{T}_A &= \begin{bmatrix} \ddots & & & \mathbf{0} \\ & \mathbf{E} & & \\ & & \mathbf{E} & \\ & \mathbf{0} & & \ddots \end{bmatrix} \\ &= \begin{bmatrix} \ddots & & & \ddots & & & & \mathbf{0} \\ & \mathbf{E}_{K-1}\mathbf{J} & \mathbf{E}_{K-2}\mathbf{J} & \cdots & \mathbf{E}_0\mathbf{J} & & & \\ & \mathbf{E}_{K-1}\mathbf{J} & \mathbf{E}_{K-2}\mathbf{J} & \cdots & & \mathbf{E}_0\mathbf{J} & & \\ & & \mathbf{E}_{K-1}\mathbf{J} & \mathbf{E}_{K-2}\mathbf{J} & \cdots & & \mathbf{E}_0\mathbf{J} & \\ & \mathbf{0} & & & & & & \ddots & \ddots & \ddots \end{bmatrix} \end{aligned} \tag{8.12}$$

and

$$\begin{aligned}
 \mathbf{T}_S &= \begin{bmatrix} \ddots & & & \mathbf{0} \\ & \mathbf{R} & & \\ & & \mathbf{R} & \\ & & & \ddots \\ \mathbf{0} & & & & \end{bmatrix} \\
 &= \begin{bmatrix} \ddots & & & \mathbf{0} \\ \ddots & \mathbf{JR}_0 & & \\ & \mathbf{JR}_1 & \mathbf{JR}_0 & \\ \vdots & & \mathbf{JR}_1 & \mathbf{JR}_0 \\ & \mathbf{JR}_{K-1} & \vdots & \mathbf{JR}_1 \\ & & & \vdots \\ & & & \mathbf{JR}_{K-1} \\ \mathbf{0} & & & & \ddots \end{bmatrix}. \tag{8.13}
 \end{aligned}$$

Although the blocking windows overlap, the total number of produced transform coefficients is the same as the total number of input samples. Hence, the lapped transform does not introduce any redundancy. In traditional block-transform processing, the number of input samples from each block is the same as the number of basis functions, i.e.,  $L = M$ . In this case, the transform matrix  $\mathbf{P}$  becomes square ( $M \times M$ ) and there is no overlapping between neighboring blocks. However, as the basis vectors of block transforms do not overlap, there may be discontinuities along the boundary regions of the blocks when heavy quantization is involved. Different approximations of those boundary regions in each side of the border may cause an artificial “edge” in between blocks. This is the so-called *blocking* effect. Allowing overlapping block boundary leads to coding improvement over non-overlapped transforms such as the DCT on two counts: (i) from the analysis viewpoint, the overlapping basis takes into account inter-block correlation, hence, provides better energy compaction; (ii) from the synthesis viewpoint, the overlapping basis either eliminates or significantly reduces blocking discontinuities.

However, the global transform matrices  $\mathbf{T}_A$  and  $\mathbf{T}_S$  remain to be very sparse, leading to fast computation of transform coefficients  $\mathbf{c}$ . The philosophy is that a few borrowed samples are enough to eliminate blocking artifacts and to improve coding performance.

### 1.8.3 Design strategy

All of the transforms presented in the previous sections are designed to have high practical value. They all have perfect reconstruction. Some of them even have real and symmetric basis functions. However, for the transforms to achieve high coding performance, several other properties are also needed. Transforms can be obtained using unconstrained nonlinear optimization where some of the popular cost criteria are:

coding gain  $C_{CG}$ , DC leakage  $C_{DC}$ , attenuation around mirror frequencies  $C_M$ , and stop-band attenuation in both analysis and synthesis bank— $C_A$  and  $C_S$ . In the particular field of image compression, all of these criteria are well-known desired properties in yielding the best reconstructed image quality [6]. The cost function in the optimization process can be a weighted linear combination of these measures as follows

$$C_{\text{Overall}} = \alpha_1 C_{CG} + \alpha_2 C_{DC} + \alpha_3 C_M + \alpha_4 C_A + \alpha_5 C_S, \quad (8.14)$$

where each of the individual cost function will be further elaborated in the next section.

### 1.8.3.1 Desirable transform properties

- *Symmetry:*  $\mathbf{J}\phi_i = \pm\phi_i$ . Linear-phase basis functions are critical in image/video processing applications (but not so much in audio processing applications).
- *Orthogonality:* offers mathematically elegance and norm preservation property. However, practical codecs often employ bi-orthogonal transforms (e.g., the 9/7-tap wavelet in JPEG2000). In other words, the relaxation of the tight orthogonal constraint can sometimes provide a much needed flexibility in transform design.
- *Energy compaction:* also known as coding gain

$$C_{CG} = 10 \times \log_{10} \left( \frac{\sigma_{\text{input}}^2}{\left[ \prod_{i=1}^M \sigma_i^2 \|\hat{\phi}_i\|^2 \right]^{1/M}} \right), \quad (8.15)$$

where  $\sigma_{\text{input}}^2$  is the variance of the input signal;  $\sigma_i^2$  is the variance of the  $i$ th subband (generated from the  $i$ th analysis basis function  $\phi_i$ ); and  $\|\hat{\phi}_i\|^2$  is the norm-squared of the  $i$ th synthesis basis function. Note that for orthogonal transforms, this term disappears and Eq. 8.15 reduces down to the ratio (in dB) of the arithmetic mean over the geometric mean of the sub-band variances. The signal model is the commonly used AR(1) process with intersample autocorrelation coefficient  $\rho = 0.95$ . As aforementioned, the coding gain can be thought of as an approximate measure of the transform's energy compaction capability. Among the listed criteria, higher coding gain correlates most consistently with higher objective performance (measured in MSE or PSNR) in coding applications. Transforms with higher coding gain compact more signal energy into a fewer number of coefficients, leading to a sparser, more compact, representation and more efficient entropy coding.

- *Stop-band attenuation:* defined as the summation of the stop-band energy of all analysis and/or synthesis basis functions. It can be formulated as

$$\text{Analysis stop-band attenuation } C_A = \sum_{i=0}^{M-1} \int_{\omega \in \Omega_i} |\phi_i(e^{j\omega})|^2 d\omega, \quad (8.16)$$

$$\text{Synthesis stop-band attenuation } C_S = \sum_{i=0}^{M-1} \int_{\omega \in \Omega_i} |\hat{\phi}_i(e^{j\omega})|^2 d\omega, \quad (8.17)$$

where  $\Omega_i$  denotes the stop-band of the  $i$ th basis function.

Stop-band attenuation is a classical performance criterion in filter design. On the analysis side, the stop-band attenuation cost helps in improving the signal decorrelation and decreasing the amount of aliasing. In meaningful images, we know *a priori* that most of the energy is concentrated in the low frequency region. Hence, besides the few basis functions that are designated to cover this low frequency range, high stop-band attenuation for the remaining in this part of the frequency spectrum becomes extremely desirable. On the contrary, at the synthesis side, the synthesis basis functions (or filters) covering low-frequency bands need to have high stop-band attenuation near and/or at  $\omega = \pi$  to enhance their smoothness.

- *Zero DC leakage:* The DC leakage cost function measures the amount of DC energy that leaks out to the bandpass and highpass subbands. The main idea is to concentrate all signal energy at DC into the DC coefficients. This proves to be advantageous in both signal decorrelation and in the prevention of discontinuities in the reconstructed signals. Low DC leakage can prevent the annoying checkerboard artifact that usually occurs when high frequency bands are severely quantized. Zero DC leakage is equivalent to attaining one vanishing moment in wavelet design (a necessary condition for the convergence of the wavelet construction):  $\langle \phi_i, \mathbf{1} \rangle = 0; \forall i \neq 0$ . Depending on whether the focus is on the transform coefficients or the filter bank coefficients, it can be stated as

$$C_{DC} = \sum_{i \neq 0} \langle \phi_i, \mathbf{1} \rangle \quad \text{or} \quad C_{DC} = \sum_{i=1}^{M-1} \sum_{n=0}^{L-1} h_i[n]. \quad (8.18)$$

- *Attenuation at mirror frequencies:* The mirror frequency cost function is a generalization of  $C_{DC}$  above. The concern is now at every aliasing frequencies  $\omega_m = \frac{2m\pi}{M}; m \in \mathcal{Z}, 1 \leq m \leq \frac{M}{2}$ , instead of just at DC. Frequency attenuation at mirror frequencies are very important in the further reduction of blocking artifacts: the filter responses (except the only high-pass filter in the system) should vanish at these mirror frequencies as well. The corresponding cost function is:

$$C_M = \sum_{i=0}^{M-2} |H_i(e^{j\omega_m})|^2; \quad \omega_m = \frac{2m\pi}{M}, \quad m \in \mathcal{Z}, \quad 1 \leq m \leq \frac{M}{2}. \quad (8.19)$$

Low DC leakage and high attenuation near the mirror frequencies are not as essential to the coder's objective performance as coding gain. However, they do improve the visual quality of the reconstructed signal significantly.

- *Integer-to-integer mapping* with exact invertibility and tight dynamic range extension: these two properties are critical for lossless coding applications.
- *Practical considerations:* integer or dyadic-rational coefficients; hardware and software friendly; low latency; small bus-width; parallelizability; structural regularity; low memory buffering; and in-place computation.

## 1.8.4 Approximation approach via direct scaling

The simplest approach to design an integer transform is to approximate a well-known infinite-precision (represented using floating-point precision) transform by a close finite-precision (fixed-point) version.

For instance, an integer-coefficient transform  $\mathbf{T}_M$  can be obtained from a well-known irrational-coefficient transform  $\mathbf{C}_M$  as follows

$$\mathbf{T}_M(\alpha, \mathbf{C}_M) = \text{round}(\alpha \mathbf{C}_M), \quad (8.20)$$

where  $\alpha$  is a parameter to control the precision of the approximation. Obviously, the larger  $\alpha$  is, the closer the approximation gets along with a higher implementation cost and a larger output dynamic range.

### 1.8.4.1 H.264 4 × 4 Transform design

The most well-known integer transform successfully designed from this scaling approach is the 4-point bit-exact DCT approximation in the latest video coding international standard H.264 or MPEG-4 Part 10 [13, 14]. In this particular example, the target transform is the 4-point type-II DCT in (8.7), which can be expressed as follows

$$\mathbf{C}_4 = \begin{bmatrix} 1 & 1 & 1 & 1 \\ c & s & -s & -c \\ 1 & -1 & -1 & 1 \\ s & -c & c & -s \end{bmatrix}; \quad c = \sqrt{2} \cos \frac{\pi}{8}, \quad s = \sqrt{2} \sin \frac{\pi}{8}. \quad (8.21)$$

In the earlier design, the approximation  $\mathbf{T}_4$  transform is designed with the scaling parameter  $\alpha = 26$  yielding the following integer version

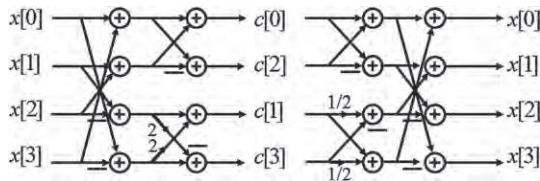

$$\mathbf{T}_4(26) = \text{round}(26\mathbf{C}_4) = \begin{bmatrix} 13 & 13 & 13 & 13 \\ 17 & 7 & -7 & -17 \\ 13 & -13 & -13 & 13 \\ 7 & -17 & 17 & -7 \end{bmatrix}, \quad (8.22)$$

which happens to retain symmetry, orthogonality, as well as the coding gain of the DCT. The only drawback here is the extended dynamic range which requires the transformation stage to be implemented on a 32-bit architecture. The standardization committee later selected the following integer transform, proposed independently by Microsoft and Nokia [14]

$$\mathbf{T}_4\left(\frac{5}{2}\right) = \text{round}\left(\frac{5}{2}\mathbf{C}_4\right) = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 2 & 1 & -1 & -2 \\ 1 & -1 & -1 & 1 \\ 1 & -2 & 2 & -1 \end{bmatrix}, \quad (8.23)$$

whose inverse turns out to be

$$\mathbf{T}_4^{-1}\left(\frac{5}{2}\right) = \frac{1}{20} \begin{bmatrix} 5 & 4 & 5 & 2 \\ 5 & 2 & -5 & -4 \\ 5 & -2 & -5 & 4 \\ 5 & -4 & 5 & -2 \end{bmatrix}. \quad (8.24)$$

**FIGURE 8.5**

Fast implementation of the H.264 transform (left) and inverse transform (right). No multiplications are needed, only binary additions and shifts.

The current transform in H.264 is designed with the scaling parameter  $\alpha = 2.5$  (actually, any parameter in the range  $2.3 \leq \alpha < 3$  also yields exactly the same result). Its coding gain as defined in (8.15) is only 0.02 dB lower than the original DCs. Similar to the earlier design, this transform retains symmetry as well as orthogonality, and offers an efficient multiplier-less implementation as depicted in Figure 8.5. Most importantly, the lower dynamic range allows the entire transformation stage to fit within a 16-bit architecture. It is interesting to note that when the binary shifts of 2 and  $\frac{1}{2}$  in the structures of Figure 8.5 are removed, we are left with the Walsh-Hadamard transform  $\mathbf{H}_4$  as defined in (8.6). Despite the important improvements, several drawbacks still exist: (i) it is not an integer-to-integer transform with exact invertibility (its inverse involves a division by 5); and (ii) its dynamic range control is still not tight enough. Hence, H.264 loses the capability of lossy and lossless coding based on the same compression framework.

### 1.8.4.2 Integer DCT design via the principle of dyadic symmetry

The direct scaling approach is actually studied extensively by Cham, whose focus is on the two cases  $M = 8$  and  $M = 16$  [15–17]. Cham's approach can be characterized as direct scaling with orthogonal constraint. In other words, since there is no guarantee that scaling retains the orthogonality property, we seek additional condition(s) on the integer transform coefficients such that the scaled-up integer transform is always orthogonal. Let us illustrate this design procedure with the  $M = 8$  case, in which the free integer parameters come from the set of  $\{a, b, c, d, e, f\}$ .

$$\text{ICT}_8 = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ a & b & c & d & -d & -c & -b & -a \\ e & f & -f & -e & -e & -f & f & e \\ 1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 \\ c & -a & d & b & -b & -d & a & -c \\ f & -e & e & -f & -f & e & -e & f \\ d & -c & b & -a & a & -b & c & -d \end{bmatrix}. \quad (8.25)$$

In this particular case, it can be proven that the only condition they have to satisfy in order for the resulting integer cosine transform (ICT) to be orthogonal [15] is

$$ab = ac + bd + cd. \quad (8.26)$$

An exhaustive search, where the cost function is set to be the transform coding gain  $C_{CG}$  as defined in (8.15), up to a certain maximum resolution is performed to identify a rather large family of ICTs. One example of a parameter set that yields a high-performance ICT is  $a = 230$ ,  $b = 201$ ,  $c = 134$ ,  $d = 46$ ,  $e = 3$ , and  $f = 1$ .

### 1.8.4.3 Direct scaling of a rotation angle

It is worth noting that although direct scaling of a given orthogonal matrix does not generally retain orthogonality, it always holds in the  $2 \times 2$  case. In this special case, any orthogonal matrix can be characterized by a single rotation angle, and it is easy to see that orthogonality is robust under direct scaling. For any rotation angle  $\mathbf{R}_\theta$ , the direct scaling method produces the approximation

$$\hat{\mathbf{R}}_\theta = \text{round}(\alpha \mathbf{R}_\theta) = \text{round}\left(\alpha \begin{bmatrix} \cos \theta & \sin \theta \\ -\sin \theta & \cos \theta \end{bmatrix}\right) = \begin{bmatrix} \hat{c} & \hat{s} \\ -\hat{s} & \hat{c} \end{bmatrix} \quad (8.27)$$

that always maintain orthogonality regardless of the scaling parameter choice:

$$\hat{\mathbf{R}}_\theta^T \hat{\mathbf{R}}_\theta = \begin{bmatrix} \hat{c} & -\hat{s} \\ \hat{s} & \hat{c} \end{bmatrix} \begin{bmatrix} \hat{c} & \hat{s} \\ -\hat{s} & \hat{c} \end{bmatrix} = \begin{bmatrix} \hat{c}^2 + \hat{s}^2 & 0 \\ 0 & \hat{c}^2 + \hat{s}^2 \end{bmatrix}. \quad (8.28)$$

The observation above leads to the following systematic integer-approximating design procedure which does not require complicated orthogonality constraints on the parameter set:

- Obtain a rotation-based sparse factorization of the target transform.
- Apply direct scaling to each rotation.

Note that each rotation angle can be approximated independently with a different degree of accuracy. This independent approximation approach above is actually very well-known in practical fixed-point implementations. Most fixed-point IDCT structures are obtained following this procedure [18].

The direct scaling design approach in this section offers a few practical advantages:

- Several desirable properties of the original transform can be robustly retained (most importantly, symmetry, orthogonality, and high coding gain).
- The design procedure leads to efficient integer implementations that are often equivalent to fixed-point hardware implementations.

However, this approach is only applicable to transform approximation, not construction of new ones. Furthermore, a few disadvantages still remains in this ad-hoc trial-and-error method:

- There is in general no exact inverse (not useful for lossless coding).
- In fact, the inverse operation often involves division operations.
- It is difficult to control the dynamic range expansion and to apply when the transform size/complexity increases.

---

### 1.8.5 Approximation approach via structural design

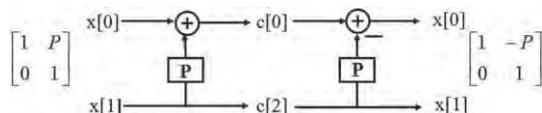

The structural design approach seeks to capture structurally as many desirable properties as possible and then optimize the parameters of the structure for high coding gain (or any other desirable property

for the targeted application). In other words, we use basic low-order building blocks (such as butterflies, lifting steps, scaling factors, delay elements) to construct much more complicated high-order transforms with certain predetermined properties (such as integer-mapping, perfect invertibility, symmetry). This design approach can be applied to transform approximation as well as new transform construction. Integer- or dyadic-rational-coefficient transforms can be easily designed by approximating the optimal structural parameters by (dyadic) rationals.

### 1.8.5.1 Lifting step

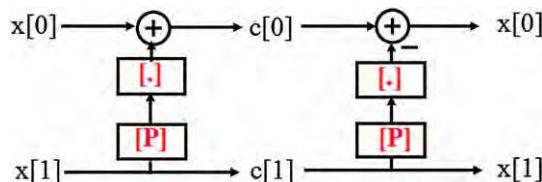

One critical component in modern transform design is the lifting step [19], which is simply an elementary upper-triangular or a lower-triangular matrix with unity diagonal elements, also known as a shear operation in matrix theory or the ladder structure in signal processing literature [20]. Figure 8.6 depicts a typical lifting step on the left and its corresponding inverse on the right. The upper-triangular matrix as shown in Figure 8.6 is often referred to as the update lifting step while the lower-triangular matrix is called the prediction lifting step in the literature. The operator  $P$  in Figure 8.6 is very general as far as perfect reconstruction is concerned:  $P$  can certainly be any scalar value;  $P$  actually can be any polynomial with delays (as popularized in fast wavelet transform implementation); in fact,  $P$  can even be any non-linear operator (to generate morphological wavelet for instance). Invertibility is structurally guaranteed since to invert a lifting step, we only need to subtract out (add in) what has been added in (subtracted out) at the forward transform.

One advantage that the lifting scheme offers is the versatility and the simplicity in constructing fast transforms that can map integers to integers. If a *floor* (or *round*, or *ceiling*, or any other quantization) operator is placed after  $P$  in the lifting step in Figure 8.6, the transformation can now map integers to integers with perfect reconstruction regardless of the lifting step has integer coefficients or not. This property can be confirmed through a simple inspection as demonstrated in Figure 8.7.

**FIGURE 8.6**

A lifting step (left) and its corresponding inverse (right).

**FIGURE 8.7**

Integer-to-integer mapping with exact invertibility of a lifting step.

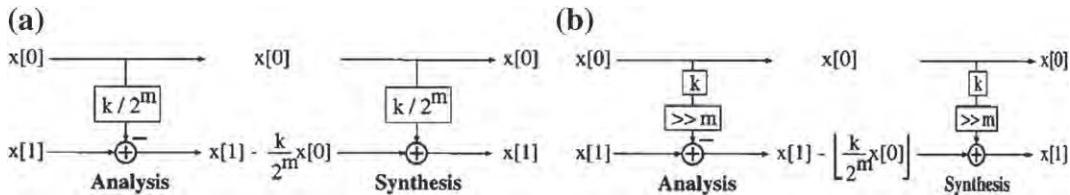

FIGURE 8.8

Lifting step with (a) dyadic rational coefficient and (b) the resulting multiplier-less implementation.

Moreover, if the lifting step is chosen to be dyadic, the nonlinear operation can be incorporated into the division using binary shift as illustrated in Figure 8.8. A scalar lifting step of value  $\frac{k}{2^m}$  can be implemented as a multiplication by  $k$  followed by a division by  $2^m$ . Division by  $2^m$  followed by a truncation is equivalent to a binary right-shift by  $m$  places. The numerator  $k$  can be easily implemented using bit shift and add operations as well, or we can split the fraction  $\frac{k}{2^m}$  into a cascade of pure power-of-two lifting steps, i.e.,  $\frac{k}{2^m} = \sum_i \frac{1}{2^i}$ . The latter approach leads to an implementation with solely binary right-shifts, preventing the bit-depth expansion in intermediate results. With all scaling factors set to unity, multiplier-less transforms can be easily constructed via a cascade of multiple lifting steps. If the scaling factors are powers of two, we can still retain the multiplier-less feature on both analysis and synthesis side. Besides the integer-friendly property, the lifting scheme also offers several other interesting advantages: simplicity of wavelet design on irregular intervals, in-place computation, connection to spatial prediction, and capability of incorporating nonlinear filtering.

It is quite straightforward to extend the lifting result above to the higher dimension case of any arbitrary  $M \times M$  matrix since it is well-known from the LDU matrix factorization that every  $M \times M$  invertible matrix  $\mathbf{V}$  can be completely characterized by  $M(M - 1)$  elementary matrices,  $M$  diagonal scaling factors, and a permutation matrix. In other words, any invertible matrix  $\mathbf{V}$  can be factorized as  $\mathbf{V} = \mathbf{P}\mathbf{L}\mathbf{D}\mathbf{U}$  where the upper-triangular matrix  $\mathbf{U}$  can be constructed from  $\frac{M(M-1)}{2}$  elementary update lifting steps labeled  $u_{ij}$ , the lower-triangular matrix  $\mathbf{L}$  can be constructed from  $\frac{M(M-1)}{2}$  elementary prediction lifting steps labeled  $p_{ij}$ , and the diagonal matrix  $\mathbf{D}$  contains the scaling factors  $\alpha_i$ . The construction of  $\mathbf{V}$  as described above is depicted in Figure 8.9. Note that the parameterization can be accomplished with rotation angles and diagonal scaling factors as well (see Figure 8.10).

**FIGURE 8.11**

Representation of a rotation angle via either 3 lifting steps or 2 lifting steps and 2 scaling factors.

### 1.8.5.2 Lifting-based approximation

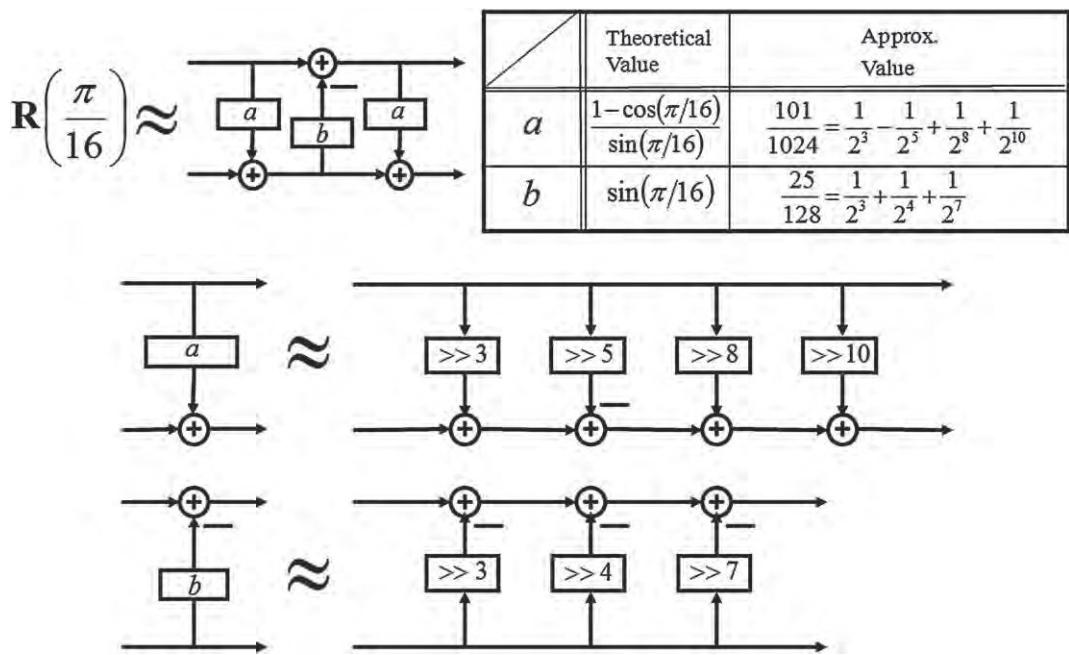

Lifting steps are also very convenient in transform approximation as well. Figure 8.11 shows the equivalent representation of the popular rotation angle by 3 lifting steps or 2 lifting steps and 2 scaling factors. Sometimes, the latter representation can lead to a more efficient approximation since the 2 scaling factors can be absorbed into the quantization stage. Figure 8.12 demonstrates a systematic approach to rotation approximation via multiplier-free lifting:

- first compute the theoretical values of the lifting steps,
- obtain dyadic-rational approximating values from theoretical ones (the resolution of the approximating values is the trade-off between computational complexity and coding performance),
- obtain the multiplier-less implementation from the dyadic-rational lifting steps.

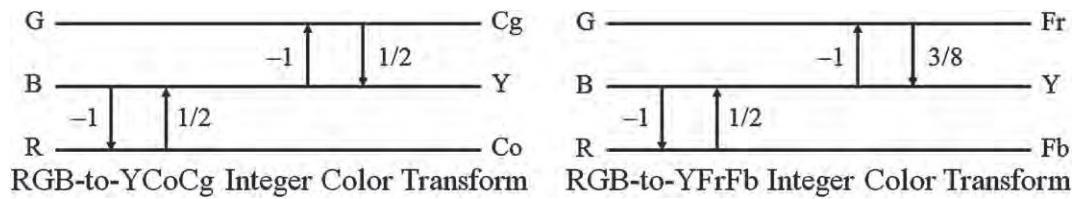

Since most existing fast transform algorithms are obtained from sparse factorization of the transform matrix as a cascade of rotation angles, we can systematically break down the design procedure one rotation independently at a time. An example of a successful application of this lifting-based approximation approach is the design of multiplier-less IDCT for video coding in an effort to end the drifting effects from IDCT mismatch. Liu et al shows that standard-compliance IDCT can be achieved on a 16-bit architecture whereas on a 32-bit architecture, approximation via lifting and butterfly can be so accurate that the reconstructed video sequences are virtually drifting-free when pairing with a 64-bit floating-point IDCT [21].

### 1.8.5.3 Lossless color transform design

We demonstrate in this section the simplest design example based on lifting construction for  $M > 2 - 3 \times 3$  color transforms. Figure 8.13 depicts two different designs developed independently and submitted to the JVT standardization committee at the same time: the RGB-to-YCoCg transform

**FIGURE 8.12**

Example of a rotation approximation by dyadic-rational lifting steps.

**FIGURE 8.13**

Multiplierless  $3 \times 3$  color transforms with exact invertibility.

(on the left of Figure 8.13) by Malvar et al. [22] and the RGB-to-YFbFr transform (on the right of Figure 8.13) by Topiwala et al. [23].

It is interesting to note that two designs are remarkably similar since they are both designed using our lifting approximation framework described in the previous sections. First, the optimal KLT is obtained where the auto-correlation matrix is derived from a set of high-quality test color images acquired by Kodak. Lifting-based approximation is then applied to obtain the dyadic lifting coefficients. Practical experiments show that both transforms de-correlate the three color planes more efficiently than existing

popular color transforms such as the RGB-to-YUV and the RGB-to-YCbCr transform while additionally providing the pivotal feature of lossless integer mapping with low dynamic range (there is only a 1-bit expansion on the two chrominance components).

Finally, both transforms only utilize four lifting steps (instead of theoretically six) without any diagonal scaling. At the cost of one more addition and one more bit-shift operation per luminance sample, the RGB-to-YFbFr transform attains a coding gain of 4.812 dB while the RGB-to-YCoCg transform achieves  $CCG = 4.619$  dB (the optimal KLT in this case has a coding gain of 4.966 dB).

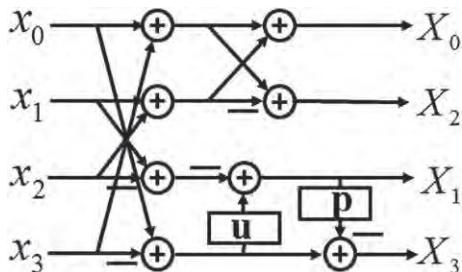

#### 1.8.5.4 Integer DCT design

The DCT is the most widely used transform in current international image/video compression standards. This 4-point dyadic-coefficient design example is a close approximation of the 4-point DCT and it follows the DCT's factorization very closely. The resulting structure is depicted in Figure 8.14.

In the sparse 4-point DCT factorization case, there are three butterflies and only one irrational rotation angle of  $\frac{\pi}{8}$  [24]. We can employ only 2 lifting steps for this rotation angle (since the scaling factors associated with the 2-lifting-step structure can be combined with the quantization step sizes to save computational complexity further) while keeping the butterflies intact. Many different transforms can be represented using this structure the difference between them lies only in the parameter choices as demonstrated below:

- $u = 1; p = 1/2$ : essentially the Walsh-Hadamard transform,
- $u = 7/16; p = 3/8$ : Liang et al. submission to H.264 [25, 26],
- $u = 1/2; p = 2/5$ : the current 4-point H.264 transform (the last 2 basis functions are off by 2, 5/2 scaling),
- $u = 1/2; p = 1/2$ : the current 4-point Photo Core Transform (PCT) in HD-Photo/JPEG-XR [27, 28].

It is interesting to note that the last two options yield two transforms with identical coding gain of 7.55 dB. The lifting implementation allows the PCT [27, 28] to map integers to integers losslessly and to have a much tighter dynamic range control comparing to the rotation-based implementation of H.264 transform (this is where H.264 loses its lossless coding capability). The second option with  $u = 7/16$

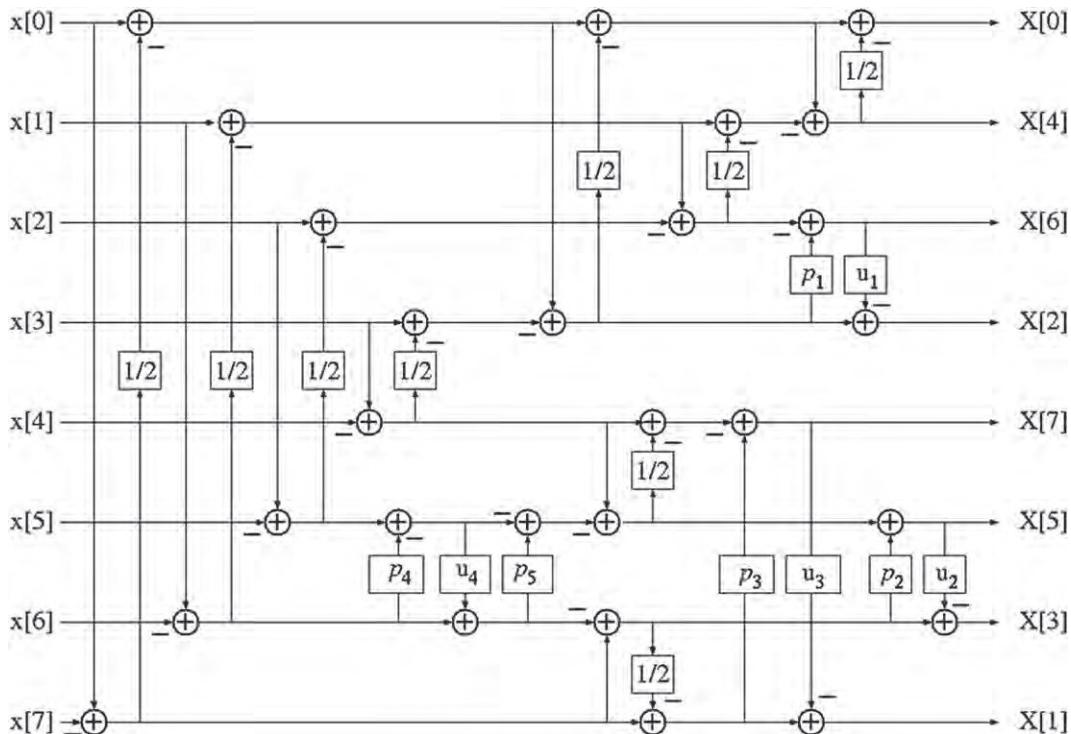

**FIGURE 8.14**

4 × 4 integer DCT structure.

and  $p = 3/8$  essentially achieves the same coding gain as the theoretical 4-point DCT (7.57 dB for  $AR(1)$  signal model with  $\rho = 0.95$ ). Note that all four options allow 16-bit implementation with 9-bit input data.

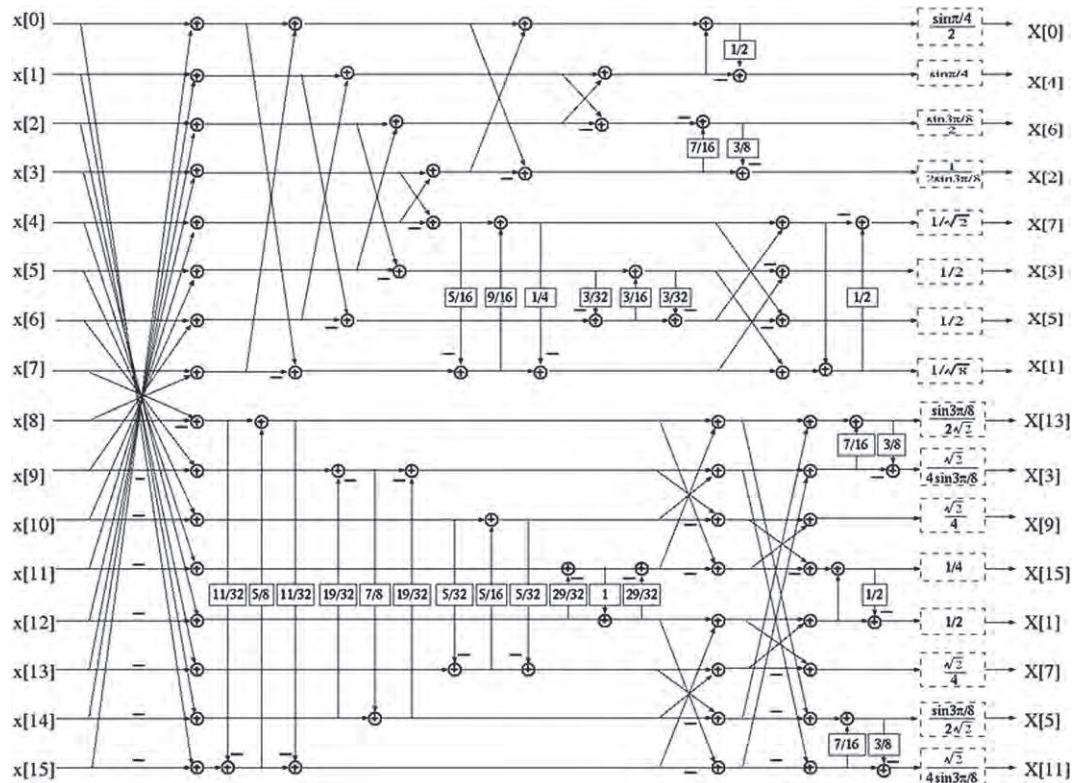

Integer DCTs of larger sizes ( $M > 4$ ) can be easily designed using the same procedure. The rotation-factorized representation of the transform of interest is first obtained, then each rotation angle can be approximated methodically as demonstrated in Section 1.8.5.2. With various degrees of approximation accuracy (more accuracy obviously requires more complexity), these integer DCT can be tuned to cover the gap between the Walsh-Hadamard transform and the original DCT. The corresponding solutions often allows a 16-bit implementation, enables lossless compression, and maintains satisfactory compatibility with the floating-point DCT. The  $8 \times 8$  and  $16 \times 16$  integer DCT are depicted in Figures 8.15 and 8.16, respectively.

Table 8.1 lists the analytical values of all the lifting parameters and some configurations of the integer DCT family (called binary DCT or binDCT in short) as shown in Figure 8.15. The dyadic lifting values are obtained by truncating or rounding the corresponding analytical values with different accuracy levels.  $C_g(8)$  and  $C_g(4)$  are the coding gains of these  $8 \times 8$  binDCTs and the  $4 \times 4$  binDCTs embedded

**FIGURE 8.15**

$8 \times 8$  integer DCT.

**FIGURE 8.16**

16 × 16 integer DCT.

in them. Table 8.1 also shows the MSE between the binDCT output and the true DCT output for the popular  $8 \times 8$  case. The MSE here is the expected  $\ell_2$ -norm of the error in the produced coefficients and it is computed as follows. Assume that  $\mathbf{C}$  is the true  $M \times M$  DCT, and  $\hat{\mathbf{C}}$  is its approximated integer version. For an input column vector  $\mathbf{x}$ , the difference between the DCT coefficients and the binDCT coefficients is:

$$\mathbf{e} = \mathbf{Cx} - \hat{\mathbf{C}}\mathbf{x} = (\mathbf{C} - \hat{\mathbf{C}})\mathbf{x} \triangleq \mathbf{Dx} \quad (8.29)$$

and the MSE of each coefficient is

$$\epsilon \triangleq \frac{1}{M} E[\mathbf{e}^T \mathbf{e}] = \frac{1}{M} \text{trace}\{\mathbf{e} \mathbf{e}^T\} = \frac{1}{M} \text{trace}\{\mathbf{DR}_{xx} \mathbf{D}^T\}, \quad (8.30)$$

where  $\mathbf{R}_{xx} \triangleq \mathbf{E}[\mathbf{xx}^T]$  is the autocorrelation matrix of the input signal. The low MSE level as depicted in Table 8.1 indicate that the integer transform approximation is very accurate. The interested reader is referred to [21, 26] for more details on the design of this particular family of multiplier-less cosine transforms.

### 1.8.5.5 Lifting for complex-coefficient transforms

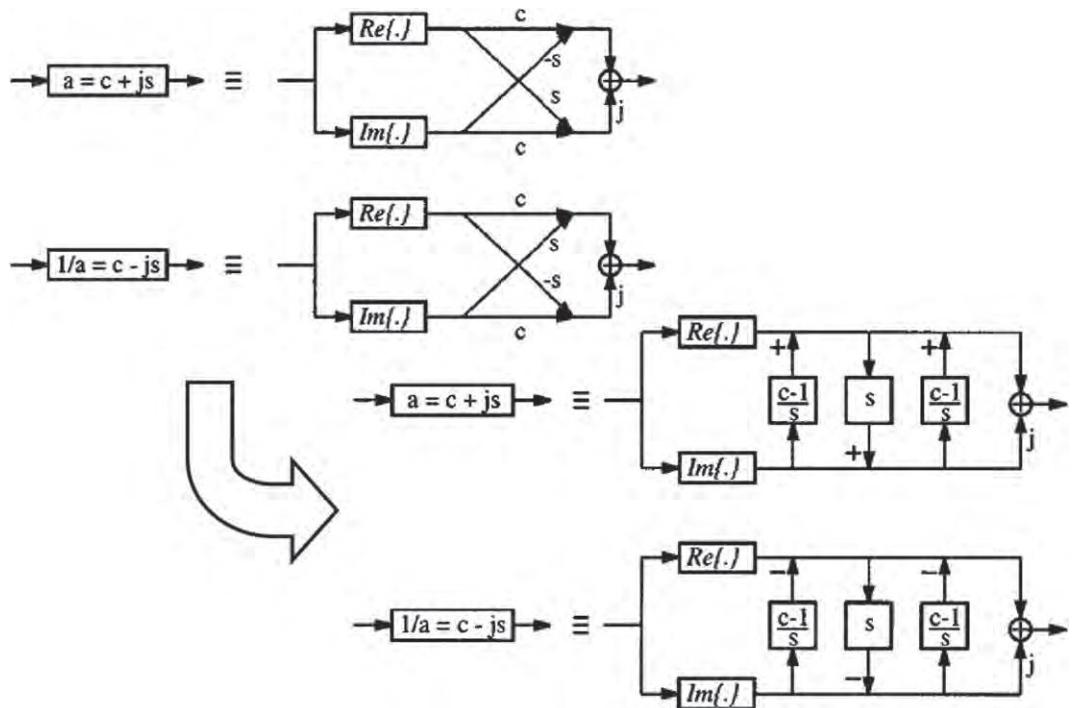

So far, we have focused on real-coefficient transforms since they are mostly employed in image/video coding applications. For complex-coefficient transforms such as the FFT, it turns out that lifting steps can be as easily applied as in the real-coefficient case. Figure 8.17 illustrates how to model a complex multiplication operation by a rotation angle and the resulting equivalent lifting representation [20,29]. Each lifting step in Figure 8.17 can then be approximated by a dyadic-rational value as previously shown. One particularly nice feature of the FFT is its regularity in factorized format: its implementation is recursive and all values of rotation angles involved are easily computed. Hence, complex-coefficient transforms such as the FFT can be easily constructed or approximated in multiplier-less fashion as well. Again, the lifting coefficients appearing in the structures can be quantized directly to obtain different resolutions (resulting in trade-off in computational cost) while preserving the exact reversibility property.

---

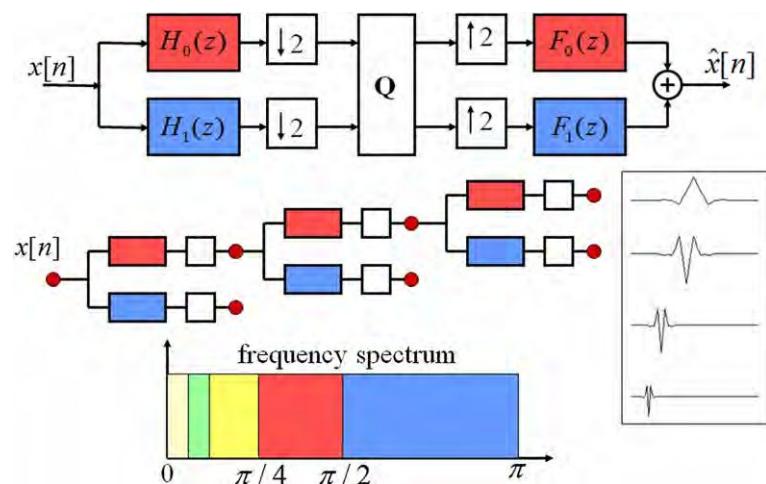

## 1.8.6 Wavelet filters design via spectral factorization

### 1.8.6.1 Wavelets and filter banks

One of the newest additions to the transform field is the wavelet transform which can be interpreted as an iteration of a two-channel filter bank with certain degrees of regularity on its low-pass output depicted in Figure 8.18. Part of the beauty and power of wavelets is their elegance: complicated tiling of the time-frequency plane can be easily achieved by merely iterating a two-channel decomposition. Furthermore, the wavelet representation of signals as a coarse approximation and detailed components at

**FIGURE 8.17**

Implementation of a complex multiplication operation via lifting steps.

**FIGURE 8.18**

The discrete wavelet transform as iteration of a special two-channel filter bank on its low-pass output.

different resolutions allows fast execution of many DSP applications such as image browsing, database retrieval, scalable multimedia delivery, etc.

The theory and design of two-channel filter banks as well as two-band wavelets have been studied extensively and we refer the readers to several excellent text books on the topic [5–8,30]. The simplest design procedure is the spectral factorization of a low-pass half-band filter with some regularity constraints (vanishing moments). Unlike all other transforms mentioned in this chapter, all of the degrees of freedom in wavelet design are allocated to regularity. In the scope of this chapter, we will only briefly cover this most successful wavelet filters design approach for completeness only.

### 1.8.6.2 Spectral factorization

It can be verified in a straightforward fashion that in order for the 2-channel filter bank in Figure 8.18 to have perfect reconstruction (i.e.,  $\hat{x}[n] = x[n - D]$ , where  $D$  is a certain time delay), the four filters involved have to satisfy the following two conditions

$$\text{Aliasing Cancellation: } F_0(z)H_0(-z) + F_1(z)H_1(-z) = 0, \quad (8.31)$$

$$\text{Distortion Elimination: } F_0(z)H_0(z) + F_1(z)H_1(z) = 2z^{-D}. \quad (8.32)$$

The following alternating-sign construction provides an elegant way to cancel aliasing and to reduce the design parameters involved by a factor of two

$$\begin{cases} F_0(z) = H_1(-z), \\ F_1(z) = -H_0(-z). \end{cases} \quad (8.33)$$

With the relationship between the analysis and synthesis filters set as in (8.33), the Distortion Elimination condition in (8.32) reduces to

$$F_0(z)H_0(z) - F_0(-z)H_0(-z) = 2z^{-D}. \quad (8.34)$$

If we define the product filter  $P_0(z)$  as  $P_0(z) \stackrel{\Delta}{=} F_0(z)H_0(z)$ , then it has to satisfy the following condition

$$P_0(z) - P_0(-z) = 2z^{-D}, \quad (8.35)$$

which is well-known in the signal processing community as the half-band condition (a filter that has one and only one odd power of  $z^{-1}$ ). Hence, the design of a 2-channel perfect-reconstruction filter bank with all four FIR filters can follow the standard procedure listed below:

- Design a low-pass half-band filter  $P_0(z)$ .
- Factor  $P_0(z)$  into  $H_0(z)$  and  $F_0(z)$ .
- Use the aliasing cancellation condition in (8.33) to obtain  $H_1(z)$  and  $F_1(z)$ .

The difference between any common filter pair designed from the approach above and a good wavelet filter pair is the degree of regularity or the level of smoothness of the resulting basis functions, called the scaling function and the wavelet function, after many levels of repeated iterations. As aforementioned, Daubechies decided to allocate all of the degrees of freedom in the design to the degree of regularity or the number of vanishing moments [30]. In other words, an additional constraint labeled *maxflat* is

imposed on top of the half-band condition in (8.35), resulting in the maxflat half-band filter defined as follows

$$P_0(z) = (1 + z^{-1})^{2P} Q_0(z). \quad (8.36)$$

This key filter has  $2P$  zeroes (roots) at  $z = -1$  or  $\omega = \pi$  and  $Q_0(z)$  is the polynomial of minimum order (which turns out to be  $2P - 2$ ) such that the half-band condition in (8.35) is met. The closed-form expression of this family of maxflat half-band filter can be found in [5, 6, 8, 30].

The key step in the design process obviously lies in the second spectral factorization procedure. There are multiple ways to split the roots  $\{z_i\}$  of  $P_0(z)$  and the desirable properties of the resulting filters  $\{H_0(z), H_1(z), F_0(z), F_1(z)\}$  dictate the constraints in the root assignment. Here are three popular desirable properties and their associated constraints in spectral factorization

- For the filters to have real coefficients, we need  $z_i$  and  $z_i^*$  to stay together: assign both to the same filter.
- To obtain orthogonal solutions, we need to separate  $z_i$  and  $z_i^{-1}$  to different filters: we must assign  $z_i$  to  $H_0(z)$  and  $z_i^{-1}$  to  $F_0(z)$  or vice versa.
- On the contrary, to obtain linear-phase solutions, we need  $z_i$  and  $z_i^{-1}$  to stay together: both are either assigned to  $H_0(z)$  or to  $F_0(z)$ .

Note that, from the second and third condition above, we cannot design a solution with both orthogonality and linear phase in the 2-channel case (except the trivial 2-tap Haar solution). When the number of channels increases ( $M > 2$ ), having both orthogonality and linear phase is actually quite easy to achieve—the type-II DCT in (8.7) and the WHT in (8.6) are two typical examples.

### 1.8.6.2.1 5-/3-tap symmetric and 4-tap orthogonal wavelet filters

Let's consider the following maxflat half-band filter with four roots at  $z = -1$  and two real roots at  $z^{-1} = 2 \pm \sqrt{3}$ :

$$\begin{aligned} P_0(z) &= \frac{1}{16} \left( -1 + 9z^{-2} + 16z^{-3} + 9z^{-4} - z^{-6} \right) \\ &= \frac{1}{16} \left( 1 + z^{-1} \right)^4 \left( -1 + 4z^{-1} - z^{-2} \right). \end{aligned} \quad (8.37)$$

Assigning two roots at  $z = -1$  to  $F_0(z)$  and the rest to  $H_0(z)$ , we obtain the following real-coefficient symmetric filter pair

$$\begin{cases} H_0(z) = -\frac{1}{8} + \frac{1}{4}z^{-1} + \frac{3}{4}z^{-2} + \frac{1}{4}z^{-3} - \frac{1}{8}z^{-4}, \\ H_1(z) = -\frac{1}{2} + z^{-1} - \frac{1}{2}z^{-2}. \end{cases} \quad (8.38)$$

This particular solution is first published in [31], so they are often referred to as the Le Gall 5/3 filters. Not only do they have dyadic coefficients; their lifting multiplier-less implementation also provides an efficient reversible integer-to-integer mapping as discuss later in Section 1.8.6.3. The discrete wavelet transform with these 5-/3-tap filters is the default transformation option for the lossless mode in the international image coding standard JPEG2000 [4].

On the other hand, if we assign the roots  $\{-1, -1, 2 - \sqrt{3}\}$  to  $H_0(z)$  while giving the roots  $\{-1, -1, 2 + \sqrt{3}\}$  to  $F_0(z)$ , we arrive at the celebrated compact-support orthogonal Daubechies D4 wavelet pair

$$\begin{cases} H_0(z) = \frac{1}{4\sqrt{2}} \left[ (1 + \sqrt{3}) + (3 + \sqrt{3})z^{-1} + (3 - \sqrt{3})z^{-2} + (1 - \sqrt{3})z^{-3} \right], \\ H_1(z) = \frac{1}{4\sqrt{2}} \left[ (1 - \sqrt{3}) - (3 - \sqrt{3})z^{-1} + (3 + \sqrt{3})z^{-2} - (1 + \sqrt{3})z^{-3} \right]. \end{cases} \quad (8.39)$$

With this particular maxflat half-band filter  $P_0(z)$ , there are only two possible orthogonal solutions. The pair in (8.39) above is called the minimum-phase solution. Switching the role of  $H_i(z)$  and  $H_i(z)$  yields the other maximum-phase solution. There are quite a few more real symmetric solutions. In fact, the 2-/6-tap and the 4-/4-tap pair are also quite popular in the image processing community.

#### 1.8.6.2.2 9-/7-tap symmetric and 8-tap orthogonal wavelet filters

Let's consider the higher-order symmetric maxflat half-band filter with eight roots at  $z = -1$ , two real roots, and four complex roots; the complex plane of  $P_0(z)$  is shown on the top part of Figure 8.19

$$P_0(z) = \frac{(1 + z^{-1})^8}{2048} \left( -5 + 40z^{-1} - 131z^{-2} + 208z^{-3} - 131z^{-4} + 40z^{-5} - 5z^{-6} \right).$$

There are exactly four orthogonal solutions from spectral factorization in this case: one minimum-phase, one maximum-phase, and two mixed-phase solutions (they are time-reversal of each other just like the minimum-phase is the time-reversed version of the maximum-phase) as illustrated in Figure 8.19.

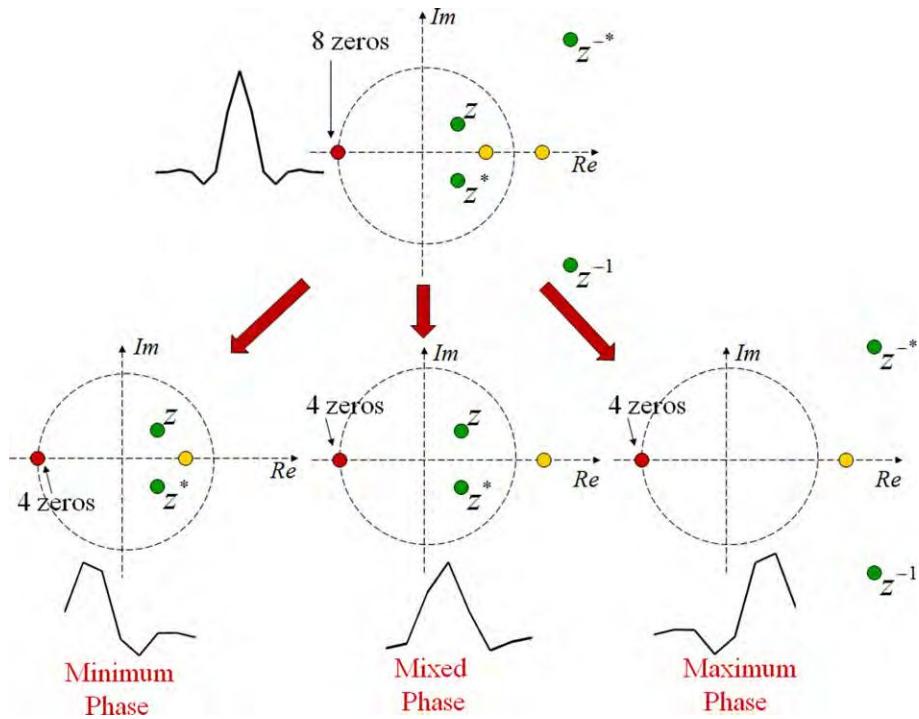

In the bi-orthogonal linear-phase case, there are many more non-trivial possibilities. The best solution in term of attaining the highest theoretical coding gain as well as the highest consistent coding performance in practice is the 9-/7-tap filter pair with  $H_0(z)$  having four roots at  $z = -1$  and four complex roots as depicted in Figure 8.20. This is often referred to as the Daubechies 9/7 wavelet filter pair [32], which is JPEG2000's default for floating-point high performance option [4]. Various interesting properties of these JPEG2000's wavelet filters have been explored in depth in [33].

It is worth noting that sacrificing a few vanishing moments (precisely, reducing the number of roots at  $z = -1$  from eight to six in  $P_0(z)$ ) opens up more flexibility in achieving other desirable properties such as dyadic coefficient. The following 9-/7-tap filter pair is called *binlet*—binary wavelet. The analysis bank now only has two vanishing moments (instead of four as in the Daubechies 9/7 JPEG2000 pair) whereas the synthesis bank still retains four vanishing moments since the vanishing moments—intimately related to the level of smoothness—are more critical in signal reconstruction than in signal decomposition. The 9-/7-tap binlet filter coefficients are tabulated below.

$$\begin{cases} h_0[n] = \frac{1}{64}[1 \ 0 \ -8 \ 16 \ 46 \ 16 \ -8 \ 0 \ 1], \\ h_1[n] = \frac{1}{16}[1 \ 0 \ -9 \ 16 \ -9 \ 0 \ 1]. \end{cases} \quad (8.40)$$

#### 1.8.6.3 Lifting and the wavelet transform

The lifting scheme is originally designed for the wavelet transform and two-channel FB decomposition [19]. Two-channel filter banks implemented with the lifting scheme save roughly half of the computational complexity due to the exploitation of the inter-subband relationship between coefficients. It has

**FIGURE 8.19**

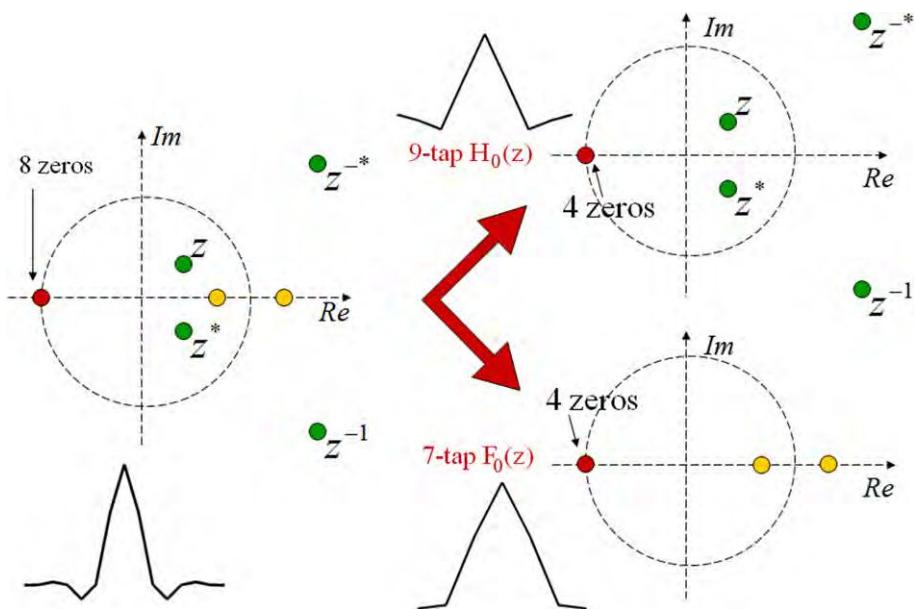

Orthogonal wavelet filter design via spectral factorization.

been proven that any  $2 \times 2$  polyphase matrix  $\mathbf{E}(z)$  with unity determinant can be factored into a cascade of prediction  $\mathbf{P}(z)$ , update  $\mathbf{U}(z)$  lifting steps, and a diagonal scaling matrix as shown in Figure 8.21 [34].

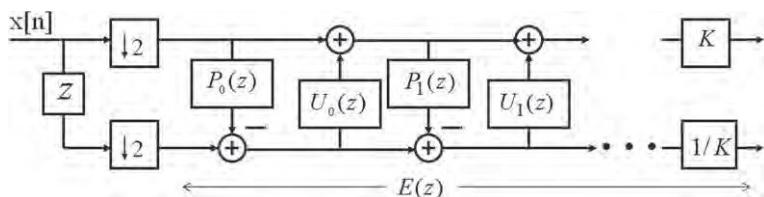

As previously mentioned, one of the most elegant as well as the most popular wavelet filter pair in practice is the Le Gall 5/3 [31] whose polyphase matrix can be constructed with 2 lifting steps:  $P(z) = \frac{1}{2}(1 + z^{-1})$  and  $U(z) = \frac{1}{4}(1 + z)$ . This transform depicted in Figure 8.22 leads to a multiplier-less implementation, and since it can map integers to integers with exact invertibility, it is naturally adopted by JPEG2000 for the lossless (or low cost) compression mode [4]. It has a very intuitive time-domain interpretation: each high-pass detail wavelet coefficient is simply the prediction error between the average of 2 neighboring even-indexed samples and the in-between odd-indexed sample. Figure 8.23 shows the lifting implementation of the irrational-coefficient 9/7 Daubechies wavelet filter pair [32,34] as previously discussed in Section 1.8.6.2.2 (see Figure 8.22).

## 1.8.7 Higher-order design approach via optimization

One major drawback with non-overlapped block transforms such as the DCT and its integer versions as described in the previous section is the existence of annoying blocking artifacts from discontinuities at

**FIGURE 8.20**

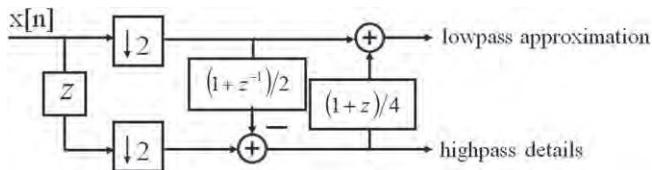

Linear-phase bi-orthogonal wavelet filter design via spectral factorization.

**FIGURE 8.21**

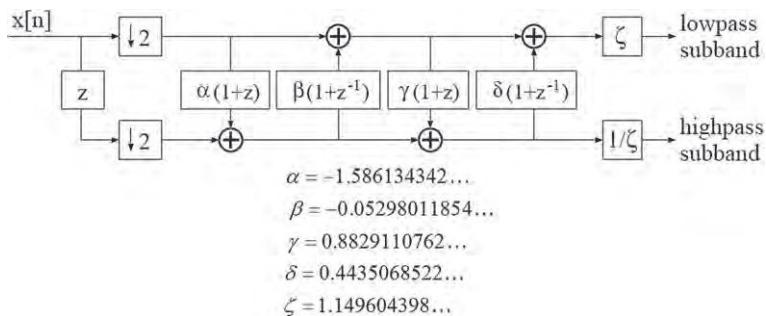

General wavelet construction and implementation with lifting steps.

block boundaries in low bit-rate applications. Transforms with overlapping basis functions such as the wavelet transform, the wavelet packet, and the lapped transform (LT) can elegantly solve the blocking problems, producing much more visually pleasant reconstructed images and video frames.

From a filter bank perspective, higher-order design lengthens the filters, leading to drastic improvement in frequency resolution and hence decorrelation efficiency while still retaining time or space resolution. As aforementioned, from a filter bank perspective, wavelet and lapped transform are simply higher-order systems whose polyphase matrices contain polynomials in  $z$  whereas all examples discussed so far are block transforms whose polyphase matrices are regular scalar matrices of zero order.

**FIGURE 8.22**

The 5/3-tap integer wavelet implementation in lifting.

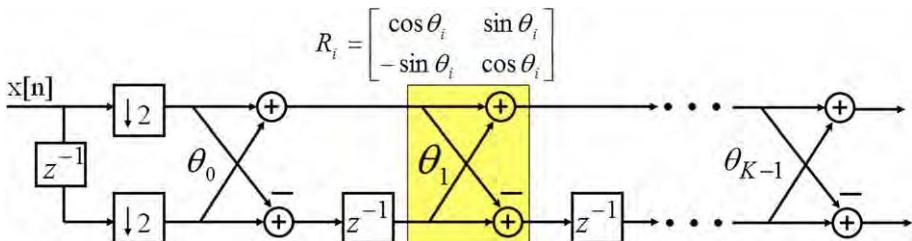

**FIGURE 8.23**

The 9/7-tap double-precision wavelet implementation in lifting.

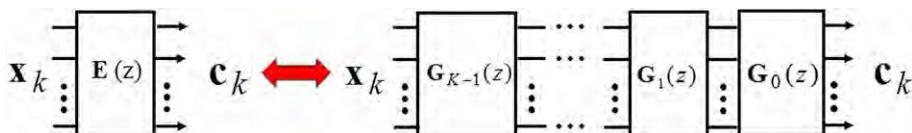

### 1.8.7.1 General modular construction

In the wavelet case where the basic building block is a 2-channel FB, the most general design approach is the spectral factorization of a low-pass half-band filter. The lifting scheme is used mainly for fast and efficient wavelet implementation. When the number of channels  $M$  increases, spectral factorization is not applicable and the most successful design approach is the modular construction from the lattice structure pioneered by Vaidyanathan [7] and Malvar [12]. This first filter bank design based on this philosophy is illustrated in Figure 8.24 where the each modular stage is a rotation angle (coupled with a delay element), propagating the orthogonality property. This simple structure has been proven to utilize the minimum number of delay elements in the resulting implementation since it shares the delays between the two channels. More importantly, the structure in Figure 8.24 covers *all* possible orthogonal solutions in the two channel case. Indeed, when  $K = 2$ , the particular selection of  $\{\theta_0 = 60^\circ, \theta_1 = -15^\circ\}$  generates the D4 orthogonal Daubechies wavelet filters in (8.39). It is a simple exercise for the reader to verify that the resulting polyphase matrix here always satisfy the paraunitary condition in (8.11), i.e.,  $\mathbf{E}^{-1}(z) = z^{-(K-1)} \mathbf{E}^T(z^{-1})$ .

Similarly, in the more general  $M$ -channel case, we can construct the high-order polyphase matrix  $\mathbf{E}(z)$  as in Figure 8.25 from a cascade of many low-order building blocks  $\mathbf{G}_i(z)$ , each propagating certain desirable properties such as symmetry, perfect reconstruction (or more elegantly, orthogonality), and zero DC leakage. The free parameters of the structure within each building block  $\mathbf{G}_i(z)$  are then further optimized to achieve other remaining desirable properties such as coding gain and stop-band attenuation

**FIGURE 8.24**

First 2-channel  $2K$ -tap filter bank design via the lattice structure propagating orthogonality.

**FIGURE 8.25**

Construction of a high-order polyphase matrix  $\mathbf{E}(z)$  from a cascade of low-order building blocks  $\mathbf{G}_i(z)$ .

as discussed in Section 1.8.3. This modular construction design approach yields numerous interesting filter bank solutions, which the reader can learn about in much greater details in two excellent textbooks [6, 7].

### 1.8.7.2 Higher-order design with pre-/post-processing operators

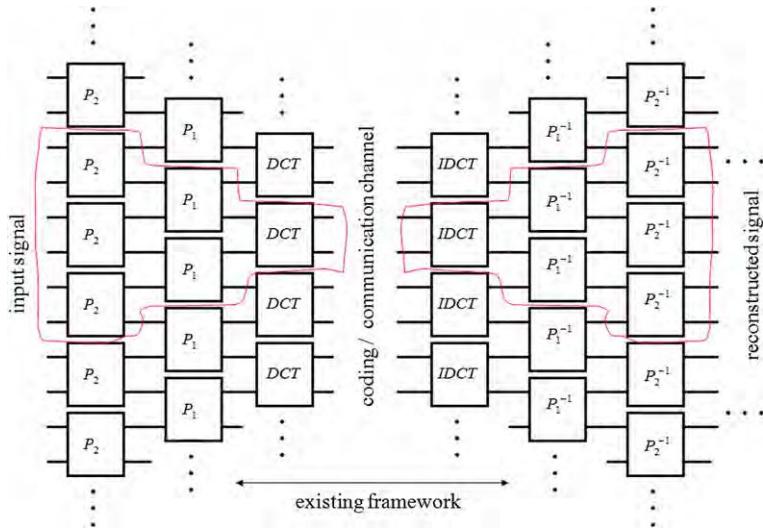

Within the more restrictive constraint of this chapter, let us present in depth a general structure that has an intuitive time-domain interpretation [35] as illustrated in Figure 8.26.

#### 1.8.7.2.1 A simple example

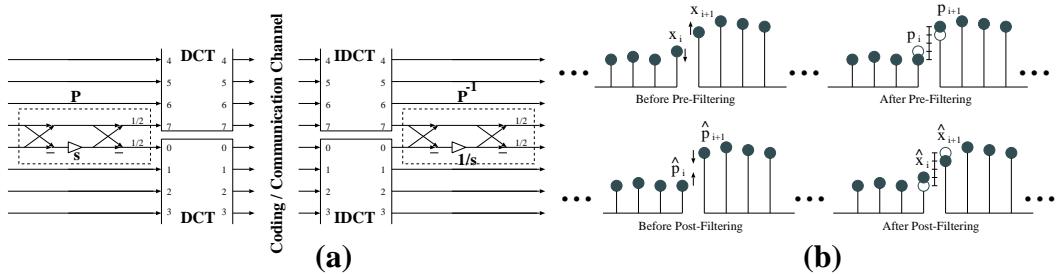

Several basic properties of this design approach are best explained through an almost trivial example—the addition of 2-point pre- and post-processing (or pre-/post-filtering) operators linking any two DCT blocks in traditional block coders such as JPEG [1] depicted in Figure 8.27a. This is a particular pre-processor in the general framework of Figure 8.26 and the post-processor has been chosen to be the exact inverse of the pre-processor’s.

Let  $\{x_i\}$ ,  $\{p_i\}$ ,  $\{\hat{p}_i\}$ , and  $\{\hat{x}_i\}$  be the set of the pre-processor’s input samples, the pre-processor’s output samples, the post-processor’s input samples, and the post-processor’s output samples, respectively. We examine the post-processor first since its operation is slightly more intuitive than the pre-processor’s.

Consider  $\hat{p}_i$  and  $\hat{p}_{i+1}$  in Figure 8.27b—two input samples of the post-processor at the boundary of two neighboring IDCT blocks—and their corresponding output samples,  $\hat{x}_i$  and  $\hat{x}_{i+1}$ . Define a crude measure of blocking artifact  $D$  as the absolute difference between two samples at the block boundary. Without any post-processing,  $D = |\hat{p}_i - \hat{p}_{i+1}|$ . It is intuitive that in order to reduce the blocking artifact

**FIGURE 8.26**

General transformation framework for block coding systems with pre- and post-processing operators.

**FIGURE 8.27**

Basic demonstration of the pre-/post-processing design. (a) Simple  $2 \times 2$  pre-/post-processing operator pair  $\{P, P^{-1}\}$  linking two DCT blocks. (b) Pre-processed and post-processed effects.

$D$ , we simply have to pull  $\hat{p}_i$  and  $\hat{p}_{i+1}$  closer (blurring out the discontinuity at boundary) depending on how far they are apart. One systematic method to achieve this objective is presented in Figure 8.27a where the scaling factor  $s$  is the single degree of freedom.

With  $P^{-1} = \frac{1}{2} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & 1/s \end{bmatrix} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$ , we can easily derive the following relationships

$$\hat{x}_i = \hat{p}_i + \frac{1/s - 1}{2}(\hat{p}_i - \hat{p}_{i+1}) \quad \text{and} \quad \hat{x}_{i+1} = \hat{p}_{i+1} - \frac{1/s - 1}{2}(\hat{p}_i - \hat{p}_{i+1}).$$

Hence, after post-processing,

$$\begin{aligned}\widehat{D} &= |\hat{x}_i - \hat{x}_{i+1}| = |(\hat{p}_i - \hat{p}_{i+1}) + (1/s - 1)(\hat{p}_i - \hat{p}_{i+1})| \\ &= |(\hat{p}_i - \hat{p}_{i+1})/s| = |1/s||\hat{p}_i - \hat{p}_{i+1}|.\end{aligned}\quad (8.41)$$

Choosing  $|1/s| < 1$  (or equivalently  $|s| > 1$ ), guarantees a decrease in blocking artifact. This post-processing effect is demonstrated in Figure 8.27b. For example, if we choose  $s = 2$ , then the post-processing operator partitions the distance  $D = |\hat{p}_i - \hat{p}_{i+1}|$  into four segments of equal length, moves  $\hat{x}_i$  up one segment length from  $\hat{p}_i$ , and moves  $\hat{x}_{i+1}$  down one segment length from  $\hat{p}_{i+1}$ . So, post-processing adaptively reduces the observed discrepancy  $D$  by a factor of two.

The pre-processor modifies the samples in the exact opposite direction. It attempts to “decorrelate” the boundary by lowering the smaller-value sample  $x_i$  while increase the larger-value  $x_{i+1}$  based on a percentage of their difference  $|x_i - x_{i+1}|$ . Again, the choice  $s > 1$  makes intuitive sense. If  $s < 1$ , samples are adjusted in the wrong direction. A good choice of  $s$  in the energy compaction sense for a smooth AR(1) signal model is the *Golden Ratio*  $\frac{1+\sqrt{5}}{2}$  or a close approximation such as  $\frac{8}{5}$  [35] (note that this choice also yields a multiplier-less post-processor).

### 1.8.7.2.2 More general solutions

The seemingly trivial example above actually provides a valuable lesson. When more than two samples are involved, the pre-processing operator should be designed as a *flattening* operator. It should attempt to make the input to the DCT as homogeneous as possible; thus, improving the overall energy compaction of the combined decomposition. This is quite consistent with most pre-processing schemes in practice: smoothing the input signal improves coding efficiency. However, in this framework, perfect reconstruction can be easily maintained (by choosing the post-processor as the inverse of the pre-processor). High-frequency signal components are never eliminated; they are only slightly shifted spatially. In other words, we take full advantage of the block-based framework by *carefully aligning high-frequency components at block boundaries*. Discontinuities between DCT blocks, i.e., actual high-frequency contents, do not affect coding performance whereas, within each block, data samples are smoothed out, enhancing the core block transform’s effectiveness in energy compaction.

The most general higher-order transform as shown in Figure 8.27 is equivalent to an  $M$ -channel critically-sampled filter banks with filters of length  $L = KM$  whose analysis polyphase matrix turns out to be

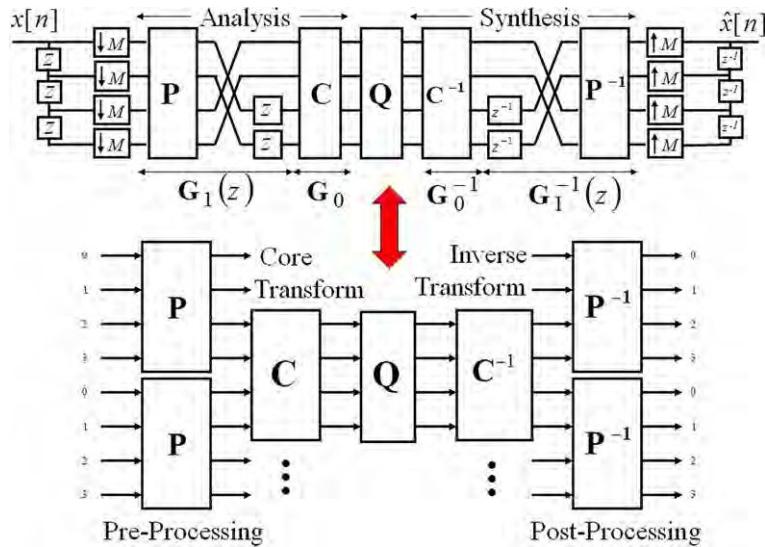

$$\mathbf{E}(z) = \mathbf{G}_0 \mathbf{G}_1(z) \mathbf{G}_1(z) \dots \mathbf{G}_{K-1}(z), \quad (8.42)$$

where each propagating component takes on the form  $\mathbf{G}_i(z) = \mathbf{\Lambda}(z) \mathbf{P}_i$  with

$$\mathbf{\Lambda}(z) \triangleq \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & z\mathbf{I} \end{bmatrix} \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ \mathbf{I} & \mathbf{0} \end{bmatrix} = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ z\mathbf{I} & \mathbf{0} \end{bmatrix} \quad (8.43)$$

being the permuted advance chain. The synthesis polyphase matrix is then

$$\mathbf{R}(z) = \mathbf{G}_{K-1}^{-1}(z) \mathbf{G}_{K-2}^{-1}(z) \dots \mathbf{G}_0^{-1}. \quad (8.44)$$

**FIGURE 8.28**

Construction of an  $M$ -channel filter bank from two  $M \times M$  matrices  $\mathbf{P}$  and  $\mathbf{C}$  (top) and the equivalent time-domain interpretation of pre- and post-processing (bottom).

The more detailed polyphase representation is shown in Figure 8.28 for the case of  $M = 4$  and  $K = 1$ . By choosing the inverse  $\mathbf{G}_i^{-1}(z) = \mathbf{P}_i^{-1} \mathbf{\Lambda}^{-1}(z)$ , we ensure that the resulting filter bank or decomposition has perfect reconstruction. Enforcing the tighter constraint  $\mathbf{P}^{-1} = \mathbf{P}^T$  leads to a paraunitary system, i.e., an orthogonal mapping.

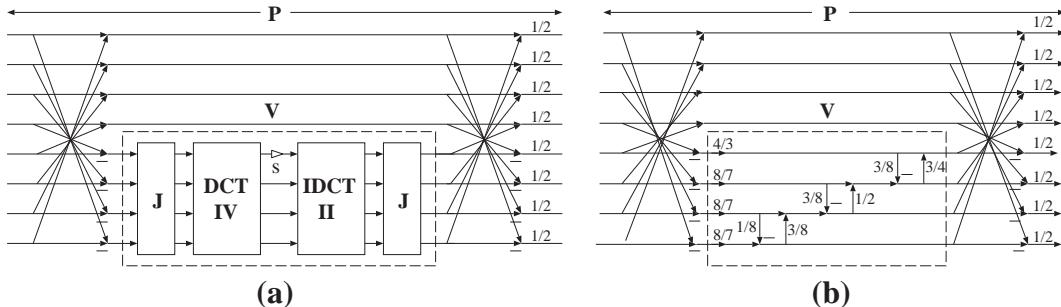

To obtain linear-phase basis functions, further structural constraint has to be imposed on the basic building block  $\mathbf{P}$ . A general closed form  $M$ -point pre-processing operator  $\mathbf{P}$  that works well with DCT of any size  $M$ , generating a linear-phase mapping, is presented in [35]. This general pre-processing block operator is shown in Figure 8.29a and it should be placed squarely between two adjacent DCT blocks as illustrated in Figure 8.28. The linear operator consists of two stages of butterflies and a matrix  $\mathbf{V}$  between them:

$$\mathbf{P} = \frac{1}{2} \begin{bmatrix} \mathbf{I} & \mathbf{J} \\ \mathbf{J} & -\mathbf{I} \end{bmatrix} \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{V} \end{bmatrix} \begin{bmatrix} \mathbf{I} & \mathbf{J} \\ \mathbf{J} & -\mathbf{I} \end{bmatrix}, \quad (8.45)$$

where the reader is reminded that  $\mathbf{I}$ ,  $\mathbf{J}$ , and  $\mathbf{0}$  are the  $\frac{M}{2} \times \frac{M}{2}$  identity matrix, the reversal matrix, and the null matrix, respectively. The matrix  $\mathbf{V}$ , controlling pre- and post-processing behavior, can be further chosen as

$$\mathbf{V} = \mathbf{J} \mathbf{C}_{M/2}^{II^T} \mathbf{S} \mathbf{C}_{M/2}^{IV} \mathbf{J}, \quad (8.46)$$

where  $\mathbf{C}_{M/2}^{II}$  is the  $\frac{M}{2}$ -point type-II DCT matrix in (8.7),  $\mathbf{C}_{M/2}^{IV}$  is the  $\frac{M}{2}$ -point type-IV DCT matrix in (8.8), and  $\mathbf{S}$  is a diagonal matrix that introduces bi-orthogonality. One example of  $\mathbf{S}$  is  $\text{diag}\{\frac{8}{5}, 1, \dots, 1\}$ . The structure produces orthogonal pre-processing linear operator if  $\mathbf{S}$  is chosen to be the identity matrix.

**FIGURE 8.29**

Pre-processors for the DCT. (a) General closed form  $M$ -point pre-filter. (b) Fast 8-point rational-coefficient pre-processing operator.

**FIGURE 8.30**

Pre-processing's block-wise flattening effect with  $8 \times 8$  block size. From left to right: original image; after 2-point, 4-point, 6-point, and 8-point pre-processing, respectively.

In general, it can be straightforwardly proven that any orthogonal matrix  $\mathbf{V}$  would yield a linear-phase orthogonal transform. For the particular case of 8-point pre/post-processing, a fast rational-coefficient approximation of  $\mathbf{P}$  is shown in Figure 8.29b.

It is interesting to note the flattening property of the pre-processing scheme as demonstrated in an image processing example shown in Figure 8.30 where pre-processing is carried out in 2D separably. When the size of the pre-processing operator grows, the pre-processed image (which will then be the input of the traditional block DCT decomposition) becomes more blocky since each  $8 \times 8$  block becomes smoother, less correlated with its neighbors, and more high-frequency components are shifted to the block boundary. The closed-form pre-processor  $\mathbf{P}$  of (8.45) depicted in Figure 8.29a is used to generate this example. At the decoder side, the post-processor—if chosen as the inverse of its counterpart—serves as a *smoothening interpolating operator* placed between block boundaries, mitigating blocking artifacts.

### 1.8.7.2.3 HD photo or JPEG-XR transform

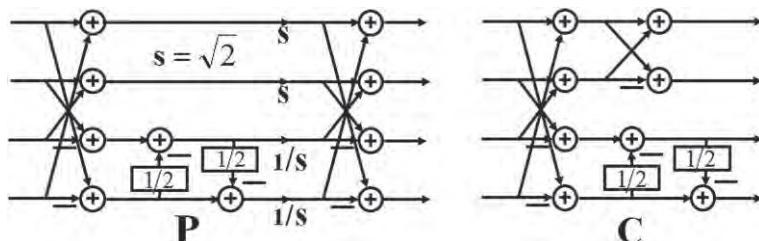

Both concepts of multiplier-less transform design via the lifting scheme as described in Section 1.8.5.4 and pre-/post-processing of Section 1.8.7.2 are on full display in JPEG-XR [27,28]. The still-image compression algorithm/file format JPEG-XR has been widely distributed along with Windows Vista and Windows 7 operating systems and was officially approved as an ISO/IEC International standard in 2010. The entire transformation stage in JPEG-XR (formerly known as Microsoft HD-Photo)—including a base integer transform called Photo Core Transform (PCT) C and an additional pre-processing operator called Photo Overlap Transform (POT) C—is just one particular solution of the much general framework illustrated in Figures 8.26 and 8.28.

Both operators are constructed from cascades of hardware-friendly dyadic-rational lifting steps. In fact, the choice of the two dyadic lifting steps  $\frac{1}{2}$  in the core transform PCT comes from Configuration C5 as shown previously in Table 8.1. In Figure 8.31, two pairs of scaling factors  $\sqrt{2}$  and  $\frac{1}{\sqrt{2}}$  are shown merely to illustrate the conceptual design. The actual implementation in JPEG-XR utilizes dyadic-rational lifting steps to approximate each pair of irrational scaling. Therefore, the entire transformation stage (including both PCT and POT) in JPEG-XR is constructed from a cascade of only dyadic-rational lifting steps [27,28].

### 1.8.7.3 Adaptive decomposition design

Here, by adaptivity, we refer to time-varying adaptable operators that the encoder or the decoder can select on-the-fly based on the local statistical behavior of the input. Adaptivity can lead to significant coding improvements if the amount of side information is cleverly avoided or kept to a minimum. It is clear that long basis functions associated with large operator size are best for representing smooth signal regions. On the other hand, transient signals, abrupt discontinuities, and strong edges are best captured with short high-time-resolution basis. Based on this observation, various adaptive operators are developed to provide a powerful decomposition framework with strong time-frequency localization. Several options are under consideration:

- varying the support of pre- and post-processing operator at each block boundary;
- varying the transform block size;

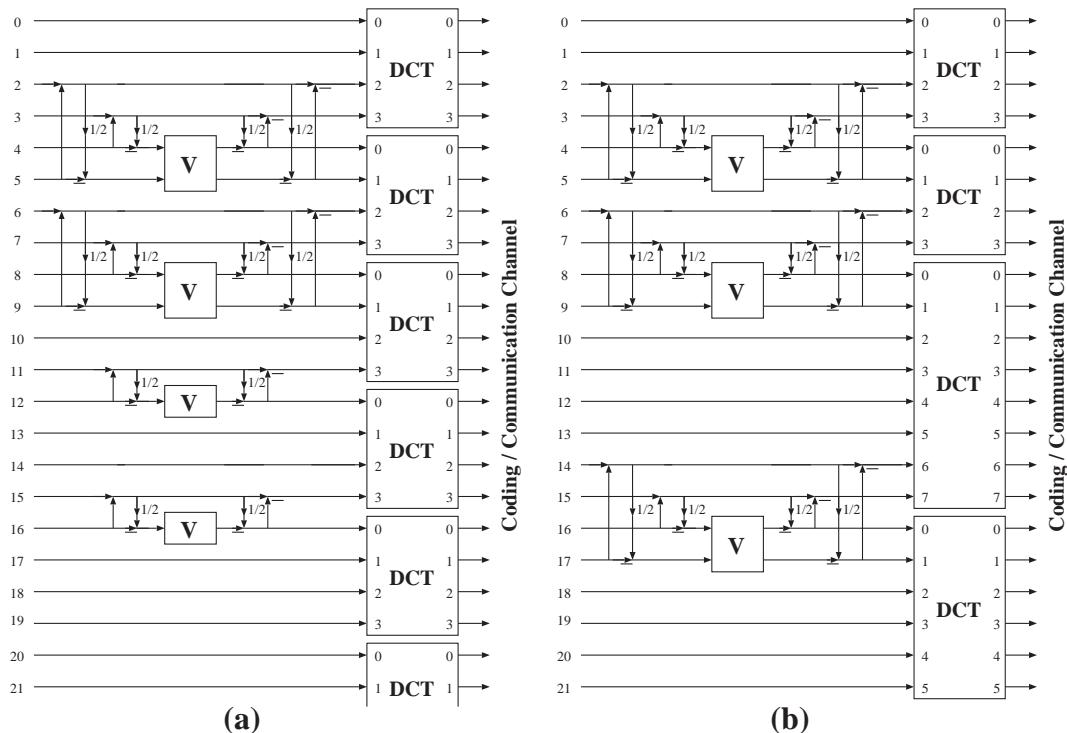

**FIGURE 8.31**

The photo overlap transform **P** (left) and the photo core transform **C** (right) in HD photo or JPEG-XR transformation stage.

- a combination of both of the above;
- allowing every operator's parameters to be time-varying.

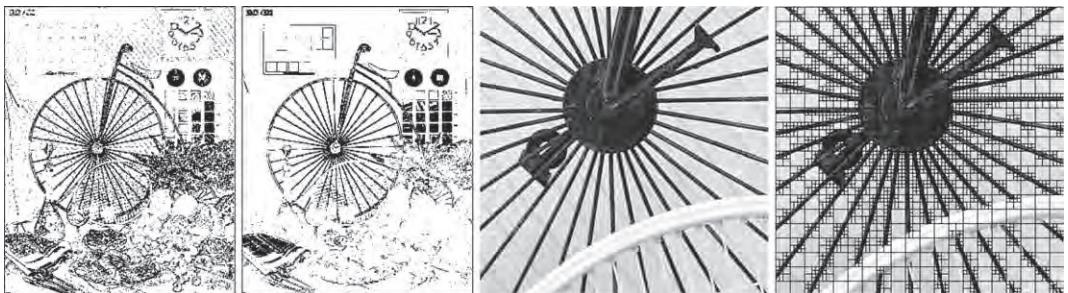

#### 1.8.7.3.1 Adaptive pre-/post-processing support

Within the pre-/post-processing framework in Section 1.8.7.2, based on the energy of the transform coefficients generated, we can decide to turn on or off pre/post-processing. It is just as easy to vary the size of pre-processing support dynamically. This adaptive-borrowing signal decomposition is illustrated in Figure 8.32a where the block size is fixed to  $M = 4$  while the pre-processing operator can be chosen among: no processing,  $2 \times 2$  processing, or  $4 \times 4$  processing. In other words, from top to bottom, we are switching from a  $4 \times 8$  to a  $4 \times 7$  to a  $4 \times 6$  to a  $4 \times 5$  and finally to a  $4 \times 4$  linear mapping. With the transform set to the DCT of a fixed block size (e.g., 8) and the size of the pre-/post-processing operator can be chosen from the set  $\{0, 2, 4, 8\}$ , then the side information for each block boundary is only 2 bits. The side information can be lowered with Huffman or context-based adaptive arithmetic coding.

**FIGURE 8.32**

Examples of adaptive time-varying decomposition. (a) Adaptive pre-processing with fixed DCT block size. (b) Adaptive DCT block size with fixed pre-processing operators.

**FIGURE 8.33**

Visual demonstration of adaptive decomposition algorithms. From left to right: pre-/post-processing mode selection for maximum local coding efficiency via exhaustive search; pre-/post-processing mode selection for fast overflow/underflow criterion; portion of the original *Bike* image; optimal block-size selection based on maximum coding efficiency criterion.

A visual illustration of adaptive pre-/post-processing is depicted in the left-most binary image in Figure 8.33. Here, dark pixels indicate blocks which the coder select the minimum-size  $2 \times 2$  operator whereas light pixels indicate blocks where the maximum-size  $8 \times 8$  pre-processing operator is preferred. The decision is based on the minimum bit-length needed to encode each particular data block and we have employed an exhaustive search [36]. It is clear that pre- and post-processing *should be avoided* at or near strong edges of the input image.

#### 1.8.7.3.2 Adaptive transform block size

Another adaptive decomposition scheme is to employ variable block sizes. In slowly-changing homogeneous part of the signal, a large data block is desirable (higher frequency resolution is needed). On the other hand, in fast-changing transient part of the signal, it is more advantageous to switch to a small block size (higher time resolution is needed). Such a signal-adaptive switching scheme has proven to be very effective in practice. For instance, MPEG-4's Advanced Audio Coder switches back-and-forth between a 256-point high-time-resolution short window and a 2048-point high-frequency-resolution long window to avoid pre-echo and to improve coding efficiency [37]. A variable-block-size decomposition scheme as depicted in Figure 8.32b can be employed where the pre-processing operator is fixed whereas the DCT block size is allowed to vary. The side information, just like in the adaptive-processing case, can be kept manageable as well with a well chosen set of block sizes, e.g.,  $\{4, 8, 16, 32\}$  for image/video applications.

A demonstration of the adaptive block transform algorithm is shown in the right of Figure 8.33. An expensive exhaustive search algorithm is set up to generate this example: pre- and post-processing is fixed to the maximum size allowable based on the size of any two neighboring DCT blocks; block size selection is restricted to  $\{4, 8, 16\}$ ; and the criterion is again the minimum amount of bits required to encode each local  $16 \times 16$  image region. This example vividly confirms that optimally adaptive decomposition algorithm has a tendency to latch onto strong local image features [36].

In the more general case, both adaptive pre-processing with different sizes, with multiple stages, and adaptive variable block size can be combined. This decomposition scheme generates a large library of basis functions that the encoder can choose from depending on the input signal behavior. How to make the right decision quickly and how to minimize the amount of side information involved are two important open research problems.

#### 1.8.7.4 Modulated design

One drawback with the cascading structural approach in (8.42) and illustrated in Figure 8.26 is that the optimization becomes problematic when the application demands or desires a larger number of channels  $M$  and/or a longer filter length  $L = KM$ . In speech and audio coding applications, for example, frequency resolution of the transform is often critical and the number  $M$  of frequency bins (or channels) is typically in the hundreds or even thousands [12,38].

Given that most of the cost function in Section 1.8.3.1 is not convex, the huge number of free parameters in the matrices  $\{\mathbf{G}_0, \mathbf{P}_i\}$ —from  $2K \binom{M/2}{2}$  in the linear-phase orthogonal case to  $K \binom{M}{2}$  in the orthogonal case to  $KM^2$  in the most general case [35]—poses a major challenge to any optimization approach. One particular elegant design that can efficiently deal with this obstacle is the cosine-modulated approach where a low-pass prototype filter is designed and the rest of the filters are obtained from cosine or sine modulation as illustrated in Figure 8.34. Many different cosine-modulation approaches have been developed and the most significant difference among them is the low-pass prototype choice and the phase of the cosine/sine sequence [6,7,12].

For the case  $K = 1$  ( $M \times 2M$  transform), the modulated design with the type-IV DCT in (8.8) is often referred to as the Modified Discrete Cosine Transform (MDCT) [39] or the Modulated Lapped Transform (MLT) [40]. The transform basis functions (or the filter coefficients) are given as

$$h_k[n] = \sqrt{\frac{2}{M}} h[n] \cos \left[ \left( n + \frac{M+1}{2} \right) \left( k + \frac{1}{2} \right) \frac{\pi}{M} \right] \quad (8.47)$$

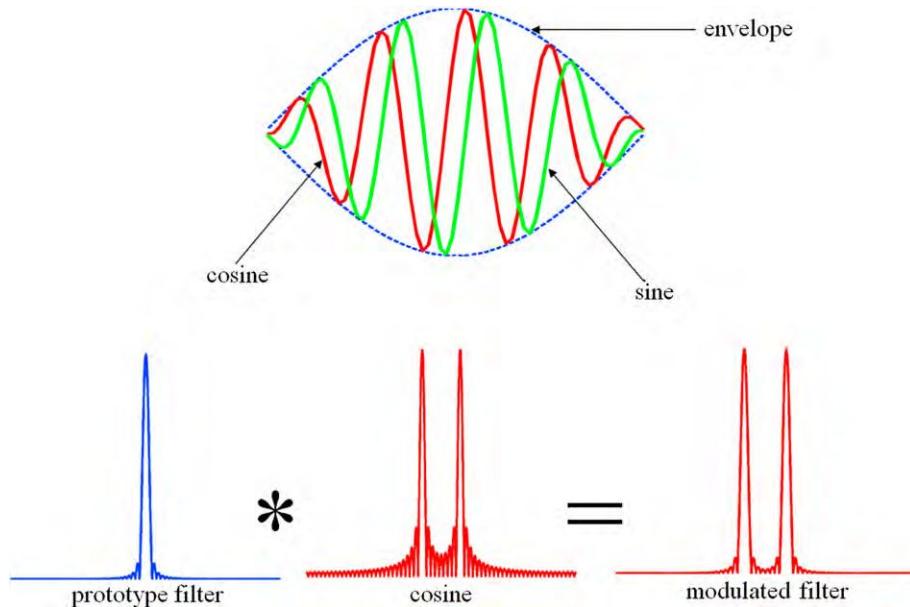

for  $0 \leq k \leq M - 1$ ,  $0 \leq n \leq 2M - 1$  and  $h[n]$  can be thought of as a symmetric window modulating the cosine sequence or the impulse response of a low-pass prototype (with cut-off frequency at  $\frac{\pi}{2M}$ ). It has been shown that as far as perfect reconstruction is concerned, the choice of the prototype window  $h[n]$  is rather flexible: all it has to satisfy is the following two constraints

$$\begin{cases} h[n] = h[2M - 1 - n], \\ h^2[n] + h^2[M - 1 - n] = 1. \end{cases} \quad (8.48)$$

A nice choice with a closed-form expression for the prototype filter  $h[n]$  is

$$h[n] = -\sin \left[ \left( n + \frac{1}{2} \right) \frac{\pi}{2M} \right], \quad (8.49)$$

which the reader can easily verify that it does not only satisfy both conditions in (8.48) but it also produces a smooth symmetric low-pass filter.

**FIGURE 8.34**

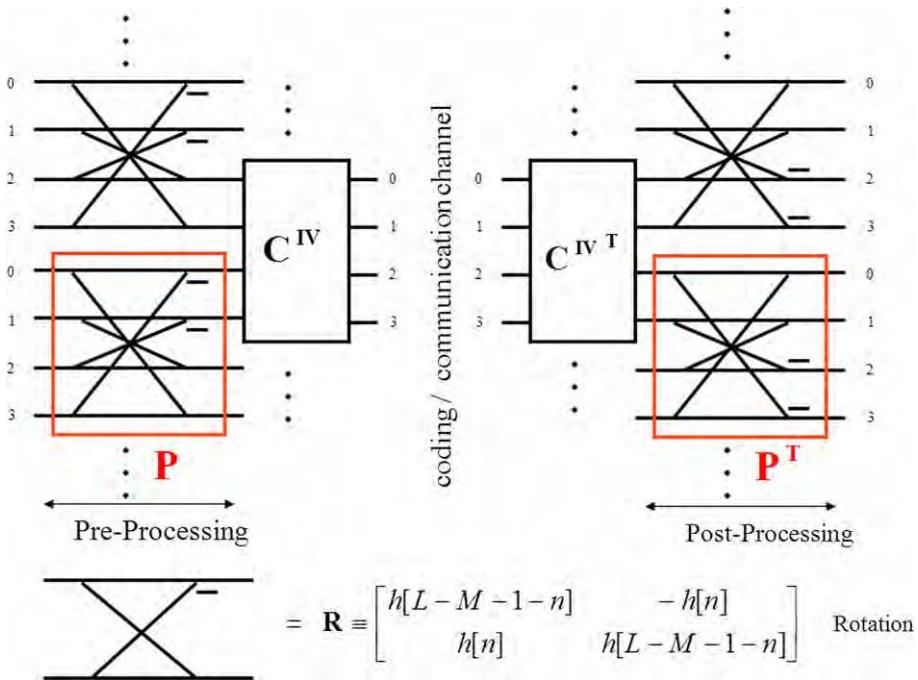

Construction via cosine/sine modulation.

It is interesting to note that the MDCT/MLT as defined in (8.47) and (8.49) also fits the pre- and post-processing framework in Figure 8.28. In this interpretation, the prototype window is completely governed by the pre-processing operator  $\mathbf{P}$  while the orthogonal core transform  $\mathbf{C}^{IV}$  takes care of the cosine-modulation part. The particular window choice in (8.49) leads to a series of  $\frac{M}{2}$  pairwise rotation angles, which yields an overall orthogonal transform. Unfortunately, we did have to give up the linear-phase property. However, for speech and audio applications, that is not a critical property. The MDCT/MLT as depicted in Figure 8.35 still has a very efficient implementation. Finally, as discussed in Section 1.8.5.2, the MDCT can easily be approximated with dyadic lifting steps, rendering a multiplier-less transformation with exact integer-to-integer mapping [41].

Both MP3 and MPEG-2 AAC employs the choice of window in (8.49). However, this is not the only choice. In fact, the open-source Vorbis codec selects a slightly different sine window

$$h[n] = \sin \left\{ \frac{\pi}{2} \sin^2 \left[ \left( n + \frac{1}{2} \right) \frac{\pi}{2M} \right] \right\}. \quad (8.50)$$

MP3 utilizes a hybrid adaptive decomposition approach: the MDCT/MLT is applied to the output of a 32-channel 512-tap near-perfect-reconstruction filter bank. MP3's hybrid filter bank adapts to the signal characteristics via the block switching technique similarly to the adaptive mechanism shown in Figure 8.32: the codec adaptively selects either a  $6 \times 12$  MDCT (labeled short block for higher time resolution)

**FIGURE 8.35**

Modulated lapped transform or MDCT implementation with pre-/post-processing operators.

or a  $18 \times 36$  MDCT (labeled long block for higher frequency resolution). On the other hand, MPEG-4 AAC dynamically switches between a  $128 \times 256$  MDCT (short blocks) and a  $1024 \times 2048$  MDCT (long blocks) [38]. The long block's frequency resolution is rather high, offering improved coding efficiency for stationary signals whereas the shorter blocks provide optimized coding capability for transient signals. The transform choice in MP3 and AAC clearly indicates the importance of adaptivity in state-of-the-art compression systems.

Finally, if the application requires even higher frequency resolution, the reader should consider the extended version of the MDCT/MLT, namely the extended lapped transform (ELT) [12, 42] whose basis functions are

$$h_k[n] = h[n] \cos \left\{ \left[ k + \frac{1}{2} \right] \left[ \left( n - \frac{L-1}{2} \right) \frac{\pi}{M} + (N+1) \frac{\pi}{2} \right] \right\} \quad (8.51)$$

for  $0 \leq k \leq M-1$ ,  $0 \leq n \leq L-1$ , and  $h[n]$  is again the impulse response of the prototype low-pass window. A major advantage of the ELT is the existence of various fast implementation algorithms which still rely on the DCT type-IV as the modulation engine but employ more layers of pre-processing operators (similarly to the overall framework shown in Figure 8.26).

---

## 1.8.8 Conclusion

In this chapter, we first briefly review the deep and rich history of transform design and then present a general systematic approach for modern transform design: the structural construction of high-order transforms from low-order basic building blocks: butterflies, lifting steps, and possibly scaling factors. We concentrate on the integer or dyadic-rational coefficient case which yields powerful integer invertible transforms. Numerous key examples in mainstream audio, image, and video applications are also presented.

## 1.09.1 Introduction

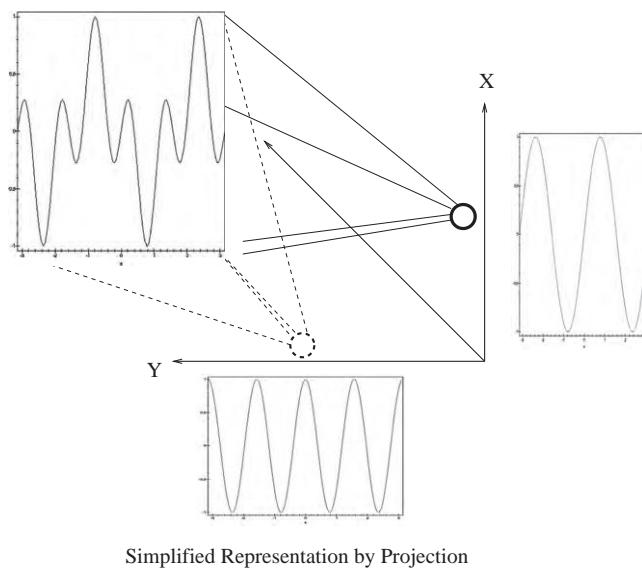

### 1.09.1.1 A overview of multiscale transforms

One's first and most natural reflex when presented with an unfamiliar object is to carefully look it over, and hold it up to the light to inspect its different facets in the hope of recognizing it, or of at least relating any of its aspects to a more familiar and well known entity. This almost innate strategy pervades all science and engineering disciplines.

Physical phenomena (e.g., earth vibrations) are monitored and observed by way of measurements in a form of temporal and/or spatial data sequences. Analyzing such data is tantamount to extracting information which is useful to further understanding of the underlying process (e.g., frequency and amplitude of vibrations may be an indicator for an imminent earthquake). Visual or manual analysis of typically massive amounts of acquired data (e.g., in remote sensing) are impractical, making one resort to adapted mathematical tools and analysis techniques to better cope with potential intricacies and complex structure of the data. Among these tools, figure a variety of functional transforms (e.g., Fourier Transform) which in many cases, may facilitate and simplify an analytical track of a problem, and frequently (and just as importantly) provide an alternative view of, and a better insight into, the problem (this, in some sense, is analogous to exploring and inspecting data under a “different light”). An illustration of such a “simplification” is shown in Figure 9.1, where a rather intricate signal  $x(t)$  shown in the leftmost figure may be displayed/viewed in a different space as two elementary tones. In Figure 9.2, a real bird chirp is similarly displayed as a fairly rich signal which, when considered in an appropriate space, is reduced and “summarized” to a few “atoms” in the Time-Frequency representation (TF). Transformed signals may formally be viewed as *convenient* representations in a different domain which is itself described by a set of vectors/functions  $\{\phi_i(t)\}_{i=\{1,2,\dots,N\}}$ . A contribution of a signal  $x(t)$  along a direction “ $\phi_i(t)$ ” (its projection) is given by the following inner product

$$C_i(x) = \langle x(t), \phi_i(t) \rangle = \int_{-\infty}^{\infty} x(t) \phi_i(t) dt, \quad (9.1)$$

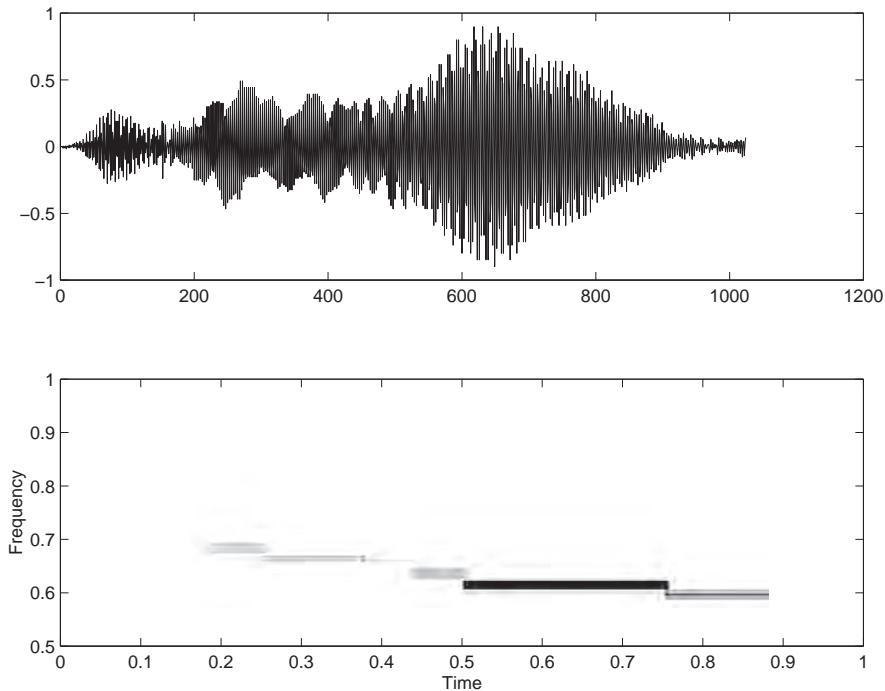

where the compact notation “ $\langle \cdot, \cdot \rangle$ ” for an inner product is used. The choice of functions in the set is usually intimately tied to the nature of information that we are seeking to extract from the signal of

**FIGURE 9.1**

A canonical function-based projection to simplify a representation.

interest. A Fourier function for example, is specified by a complex exponential “ $e^{j\omega t}$ ,” and reflects the harmonic nature of a signal, and provides it with a simple and an intuitively appealing interpretation as a “tone.” Its spectral (frequency) representation is a Dirac impulse which is well localized in frequency. A Fourier function is hence well adapted to represent a class of signals with a fairly well localized “spectrum,” and is highly inadequate for a transient signal which, in contrast, tends to be temporally well localized. This thus calls for a different class of analyzing functions, namely those with good temporal compactness. The wavelet transform, by virtue of its mathematical properties, indeed provides such an analysis framework which in many ways is complementary to that of the Fourier Transform.

The success of classical wavelets has motived the active research in the multiscale analysis field where multidisciplinary researchers pursue the best multiscale basis/frame in order to efficiently approximate a function that has singularities across scales. Although the classical wavelets can reach the optimal approximation for one-dimensional (1-D) functions, it has problems in generating sparse coefficients to approximate a two-dimensional (2-D) function with discontinuities. The classical wavelets locate singularities of a 2-D function in isotropic and multiscale representations. The Fourier frequency plane is partitioned with scaled square windows that are only in the horizontal/vertical directions. The band pass wavelet atoms, in general, are conceptually equivalent to applying differential operators (such as calculating the gradient difference) to an image to measure the regularities in localized areas along the horizontal/vertical directions. This isotropic measurement lacks flexibility, and therefore, although the classical wavelets can identify discontinuities efficiently, they can not efficiently detect the direction oriented curves in an image even at fine scales. Even though some improvements has been introduced to adopt anisotropic dilation in different directions, the problems still persist.

**FIGURE 9.2**

Bird Chirp with a simplified representation in an appropriate basis.

A 2-D signal, visually represented as an image, typically contains spatially distributed geometrical shapes that can be characterized by edges that signal the transients from one object to other objects. The edges are the discontinuities in an image intensity function along curves, contours, or lines that are directional oriented. Scientists have acknowledged [1–3] the instinct of a human eye in recognizing objects in a multiscale manner. The eye can quickly zoom into the most important isotropic or anisotropic features. Researchers in mathematics and engineering fields have extended this vision natural to the new era anisotropic wavelets. These new transformations have allowed researchers to selectively capture edges, which are important features in image processing.

The recently developed curvelets [4–7], contourlets [8,9], and shearlets [10–13] aim to mathematically animate the eye's function in order to catch the anisotropic curve features. We generally refer them to the anisotropic wavelets. The beauty with the anisotropic wavelets is their flexibility in partitioning the Fourier plane into a collection of atoms with varied scales and orientations. One advantage with the anisotropic wavelets is that, when a two dimensional function is projected into these wedge shaped atoms, the energy of singularities can be confined to only a sparse number of atoms, resulting only a small amount of significant coefficients across scales. They are more efficient tools than the classical wavelets in capturing the direction oriented curve features. Another advantage with the anisotropic wavelets is that many nice features of the classical wavelets are retained under the anisotropic wavelets. Some essential results are parallel to the classical wavelets, for example, the exact reconstruction and

energy conservation formula. This has not only made the anisotropic wavelets more attractive tools, but also allows fast development of the anisotropic wavelets using the classical wavelets as guidelines.

The goal of this chapter being of a tutorial nature, we cannot help but provide a somewhat high level exposition of the theoretical frameworks of the classical wavelets and the anisotropic wavelets, while our focus will be to provide a working knowledge of the tools as well as their potential for applications in information sciences in general. Some of the MATLAB code for the pictures used in this paper can be downloaded in [14]. Before we get into introduction of the various wavelets, we will introduce some classical Fourier transform related topics in this remaining section.

### 1.09.1.2 Signal representation in functional bases

As noted above, a proper selection of a set of analyzing functions heavily impacts the resulting representation of an observed signal in the dual space, and hence the resulting insight as well.

When considering finite energy signals (these are also said to be  $L^2(\mathcal{R}^d)$ ), i.e.,

$$\int_{\mathcal{R}^d} |x(t)|^2 dt < \infty, \quad (9.2)$$

a convenient functional vector space is that which is endowed with a norm inducing inner product, namely a Hilbert space, which will also be our assumed space throughout.

**Definition 1.** A vector space endowed with an inner product, which in turn induces a norm, and such that every sequence of functions  $x_n(t)$  whose elements are asymptotically close is convergent (this convergence is in the Cauchy sense whose technical details are deliberately left out to help the flow of the chapter), is called a Hilbert space.

**Remark.** An  $L^2(\mathcal{R}^d)$ ,  $d = 1, 2$  space is a Hilbert space.

**Definition 2.** Given  $\alpha > 0$ , a function  $x(t)$  is said to be Lipschitz- $\alpha$  at  $t_0 \in \mathcal{R}^d$ , if there exists a positive constant  $K$  and a polynomial  $p_{n,t_0}$  with degree  $n = [\alpha]$  such that, for all  $t$  in a neighborhood of  $t_0$ , we have

$$|x(t) - p_{n,t_0}(t)| \leq K|t - t_0|^\alpha. \quad (9.3)$$

It is shown that function  $x(t)$  is necessarily  $m$  times differentiable at point  $t_0$  if  $x(t)$  is uniformly Lipschitz with  $\alpha > m$  in a neighborhood of  $t_0$ . Further, if  $x(t)$  is Lipschitz  $\alpha$  with  $\alpha < 1$  at  $t_0$ , then  $f$  is not differentiable at  $t_0$ .

**Definition 3.** A set of vectors or functions  $\{\phi_i(t)\}$ ,  $i = 1, \dots$ , which are linearly independent and which span a vector space, is called a *basis*. If in addition these elements are orthonormal, then the basis is said to be an orthonormal basis.

Among the desirable properties of a selected basis in such a space are *adaptivity* and a *capacity* to preserve and reflect some key signal characteristics (e.g., signal smoothness). Fourier bases have in the past been at the center of all science and engineering applications. They have in addition, provided an efficient framework for analyzing periodic as well as non-periodic signals with dominant modes.

### 1.09.1.3 The continuous Fourier transform

The Fourier transform is a powerful tool in understanding features of signals/images through a basis. A Fourier Transform essentially measures the spectral content of a signal  $x(t)$  across all frequencies “ $\omega$ ,” view as row vector, and is defined as the decomposition of the signal over a basis  $\{e^{-j\omega t}\}$  as.

**Definition 4.** For a signal  $x(t), t \in \mathbb{R}^d$  viewed as a column vector, that is an absolutely integrable function, its Fourier transform is defined as

$$X(\omega) = \int_{\mathbb{R}^d} x(t) e^{-j\omega t} dt. \quad (9.4)$$

The formula is also referred to as the Fourier integral. The signal  $x(t)$  can be recovered by its inverse Fourier transform that is defined as

$$x(t) = \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} X(\omega) e^{j\omega t} d\omega. \quad (9.5)$$

As an orthonormal transform, the FT enjoys a number of interesting properties [15]. To simplify, we are constrained to 1-D function  $f(t)$  in the following until we get to the sections of anisotropic wavelets. If we use  $FT(f)(\omega) = F(\omega)$  to represent the Fourier transform of  $f(t)$ , we can list some of its important properties as follows,

- *Linearity:*

$$FT(f + g)(\omega) = F(\omega) + G(\omega).$$

- *Convolution:*

$$FT(f \star g)(\omega) = F(\omega)G(\omega).$$

- *Multiplication:*

$$FT(fg)(\omega) = F(\omega) \star G(\omega).$$

- *Shifting:*

$$FT(x(t - s))(\omega) = e^{-js\omega} X(\omega).$$

- *Scaling:*

$$FT(x(at))(\omega) = |a|^{-1} X(a^{-1}\omega).$$

- *Differentiation:*

$$FT\left(\frac{\partial^n x(t)}{\partial t^n}\right)(\omega) = (j\omega)^n X(\omega).$$

Throughout, and unless otherwise specified, the  $\star$  symbol between two functions usually indicates a convolution between the two functions, and as a superscript denotes a complex conjugate. Furthermore, a useful property of 1-D the Fourier transform is its energy preservation in the dual space (transform domain),

$$\int_{\mathbb{R}} |x(t)|^2 dt = \int_{\mathbb{R}} |X(\omega)|^2 d\omega.$$

This is also true for signals in  $\mathbb{R}^d$ , and is referred to as the Plancherel/Parseval property [15].

### 1.09.1.4 Fourier series

If a canonical function of a selected basis is  $\phi(t) = e^{j\omega t}$ , where  $\omega \in \mathbb{R}$ , then we speak of a Fourier basis which yields a Fourier Series (FS) for periodic signals and a Fourier Transform (FT) for aperiodic signals.

The Fourier Transform is defined for a broad class of signals [16], and may also be specialized to derive the Fourier Series (FS) of a periodic signal. This is easily achieved by noting that a periodic signal  $\tilde{x}(t)$  may be evaluated over a period  $T$ , which in turn leads to,

$$\tilde{x}(t) = x(t + T) = \sum_{n=-\infty}^{\infty} \alpha_n^x e^{jn\omega_0 t}, \quad (9.6)$$

with  $\omega_0 = 2\pi/T$  and  $\alpha_n^x = 1/T \int_0^T x(t) e^{-jn\omega_0 t} dt$ .

In applications, however,  $x(t)$  is measured and sampled at discrete times, requiring that the aforementioned transform be extended to obtain a spectral representation which closely approximates the theoretical truth and which remains just as informative. Towards that end, we proceed to define a Discrete Time Fourier Transform (DTFT) as

$$X(e^{j\omega}) = \sum_{i=-\infty}^{\infty} x(i) e^{-j\omega i}. \quad (9.7)$$

This expression may also be extended for finite observation (finite dimensional) signals via the Fast Fourier Transform [15]. While these transforms have been, and remain crucial in many applications, they show limitations in problems requiring a good “time-frequency” localization as often encountered in transient analysis. This may easily be understood by reinterpreting Eq. (9.7) as a weighted transform where each of the time samples is equally weighted in the summation for  $X(e^{j\omega})$ . Prior to introducing alternatives to uniform weighting in the Fourier space, we first discuss the practical implementation and exploitation of the DTFT.

### 1.09.1.5 The discrete Fourier transform

In application, the Discrete Fourier Transform is the computational surrogate for the continuous Fourier Transform and a natural extension of the DTFT. It results in a periodic sequence of numbers that is mapped to discretely sampled values of an analog signal (viewed as a time function). The sampling is performed over a  $N$ -long window which is extended periodically. The discrete Fourier transform (DFT) also views a finite length signal,  $x(n)$ , as a periodic signal, and is defined as

$$X(k) = \sum_{n=0}^{N-1} x(n) e^{-j\frac{2\pi}{N} kn}.$$

The original signal may be recovered by applying an inverse transform

$$x(n) = \frac{1}{N} \sum_{k=0}^{N-1} X(k) e^{\frac{j2\pi}{N} kn}.$$

The Discrete Fourier transform decomposes a signal into an orthonormal basis. The energy is preserved by the Plancherel formula described earlier and written as

$$\|f\|^2 = \sum_{n=0}^{N-1} |x(n)|^2 = \frac{1}{N} \sum_{k=0}^{N-1} |X(k)|^2.$$

The discrete Fourier transform of a two-dimensional signal (image) is correspondingly defined as

$$X(k_1, k_2) = \sum_{n_1, n_2=0}^{N-1} x(n_1, n_2) e^{-j2\pi(k_1 n_1 + k_2 n_2)/N}.$$

The original signal may also be recovered by applying an inverse transform

$$x(n_1, n_2) = \frac{1}{N^2} \sum_{k_1, k_2=0}^{N-1} X(k_1, k_2) e^{j2\pi(k_1 n_1 + k_2 n_2)/N}.$$

Since the DFT is based on the sampling taken over a certain length, the frequency content of the original function may not be adequately represented by the DFT when the sampling rate is insufficiently low. This will cause the high frequency content to fold back into the lower frequency content and yield aliasing.

To overcome some of the limitations of the uniform weighting of a function of a classical FT, Gabor [17] first proposed to use a different weighting window leading to the so-called windowed FT which served well in many practical applications [18] and is discussed next.

### 1.09.1.6 Windowed Fourier transform

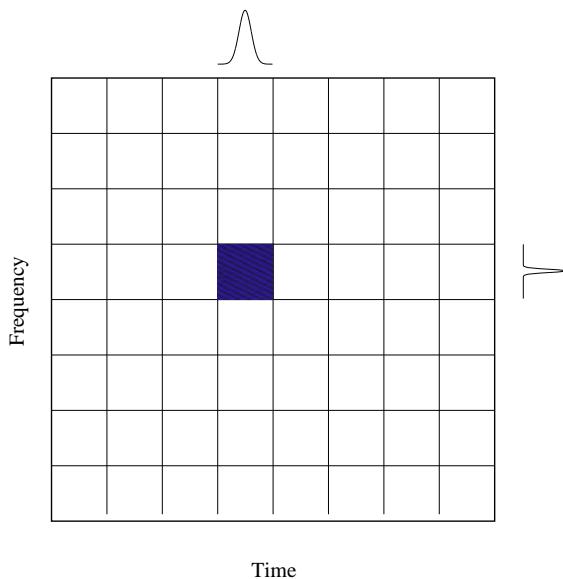

As just mentioned, when our goal is to analyze very local features, such as those present in transient signals for instance, it then makes sense to introduce a focusing window as follows:

$$W_{\mu, \omega}(t) = e^{j\omega t} W(t - \mu),$$

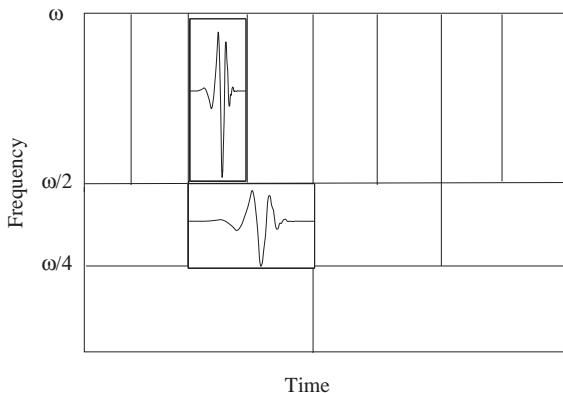

where  $\|W_{(\mu, \omega)}\| = 1 \forall (\mu, \omega) \in \mathbb{R}^2$  and where  $W(\cdot)$  is typically a smooth function with a compact support. This yields the following parameterized transform:

$$\hat{X}_W(\omega, \mu) = \langle x(t), W_{\mu, \omega}(t) \rangle. \quad (9.8)$$

The selection of a proper window is problem-dependent and is ultimately resolved by the desired spectro-temporal trade-off which is itself constrained by the Heisenberg uncertainty principle [18, 19]. From the T-F distribution perspective, and as discussed by Gabor [17] and displayed in Figure 9.3, the Gaussian window may be shown to have minimal temporal as well as spectral support of any other function. It hence represents the best compromise between the temporal and spectral resolution. Its numerical implementation entails a discretization of the modulation and translation parameters, and results in a uniform partitioning of the T-F plane as illustrated in Figure 9.4. Different windows result in various T-F distributions of elementary atoms, favoring either temporal or spectral resolution as may be seen for the different windows in Figure 9.5. While representing an optimal time-frequency compromise, the uniform coverage of the T-F plane by the Gabor transform falls short of adequately resolving a signal whose components are spectrally far apart. This may easily and convincingly be illustrated by the study case in Figure 9.6, where we note the number of cycles which may be enumerated within a window of fixed time width. It is readily seen that while the selected window (shown grid) may be adequate for one fixed frequency component, it is inadequate for another lower frequency component. An analysis of a spectrum exhibiting such a time-varying behavior is ideally performed by way of a frequency-dependent

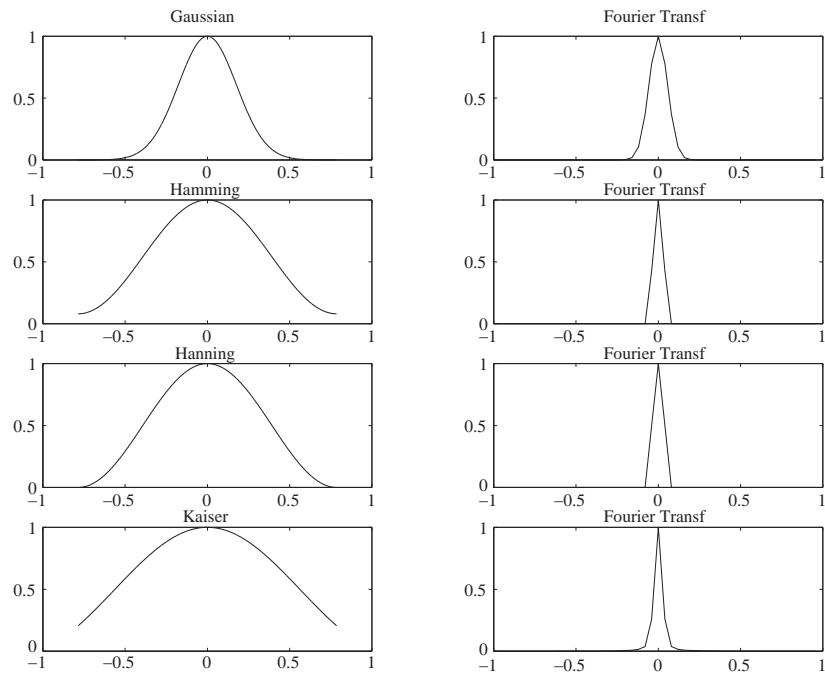

**FIGURE 9.3**

A Gaussian waveform results in a uniform analysis in the time-frequency plane.

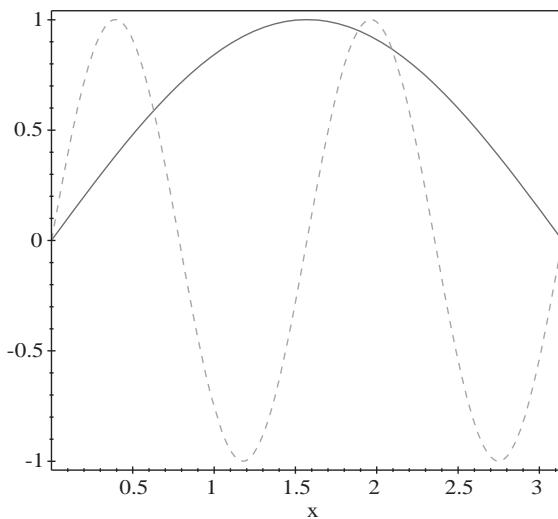

**FIGURE 9.4**

A time frequency tiling of dyadic wavelet basis by a proper sub-sampling of a wavelet frame.

time window in different designs as we elaborate in the next several sections. The wavelet transform described next, offers a highly adaptive window which is of compact support, and which, by virtue of its dilations and translations covers different spectral bands at all instants of time. The anisotropic wavelets using different windows, such as the curvelet transform, the contourlet transform, and the shearlet transform, will be introduced following the discussion of wavelet transform and wavelet decomposition.

**FIGURE 9.5**

Trade-off resulting from windows.

**FIGURE 9.6**

Time windows and frequency trade-off.

## 1.09.2 Wavelets: a multiscale analysis tool

This section is organized as follows: In Section 1.09.2.1, we define a multiscale analysis based on a wavelet basis and elaborate on their properties and their implications, as well as on their applications. In Section 1.09.2.2, we discuss a specific estimation technique which is believed to be sufficiently generic and general to be useful in a number of different applications of information sciences in general, and of signal processing and communications in particular.

### 1.09.2.1 Wavelet transform

Much like the FT, the WT is based on an elementary function, which is well localized in time and frequency. In addition to a compactness property, this function has to satisfy a set of properties to be admissible as a wavelet. The first fundamental property is stated next,

**Definition 5.** [18,20,21] A wavelet is a finite energy function  $\psi(\cdot)$  (i.e.,  $\psi(\cdot) \in L^2(\mathcal{R})$ ) with zero mean,

$$\int_{-\infty}^{\infty} \psi(t) dt = 0. \quad (9.9)$$

Commonly normalized so that  $\|\psi\| = \int |\psi|^2 dt = 1$ , it also constitutes a fundamental building block in the construction of functions (atoms) spanning the time-scale plane by way of dilation and translation parameters. We hence write,

$$\psi_{\mu,\xi}(t) = \frac{1}{\sqrt{\xi}} \psi\left(\frac{t - \mu}{\xi}\right),$$

where the scaling factor  $\xi^{\frac{1}{2}}$  ensures an energy invariance of  $\psi_{\mu,\xi}(t)$  over all dilations “ $\xi$ ”  $\in \mathcal{R}^+$  and translations “ $\mu$ ”  $\in \mathcal{R}$ . With such a function in hand, and towards mitigating the limitation of a windowed FT, we proceed to define a Wavelet Transform (WT) with such a capacity. A scale-dependent window with good time localization properties as shown in Figure 9.7, yields a transform for  $x(t)$  given by

$$\mathcal{W}_x(\mu, \xi) = \int_{-\infty}^{\infty} x(t) \frac{1}{\sqrt{\xi}} \psi^*\left(\frac{t - \mu}{\xi}\right) dt, \quad (9.10)$$

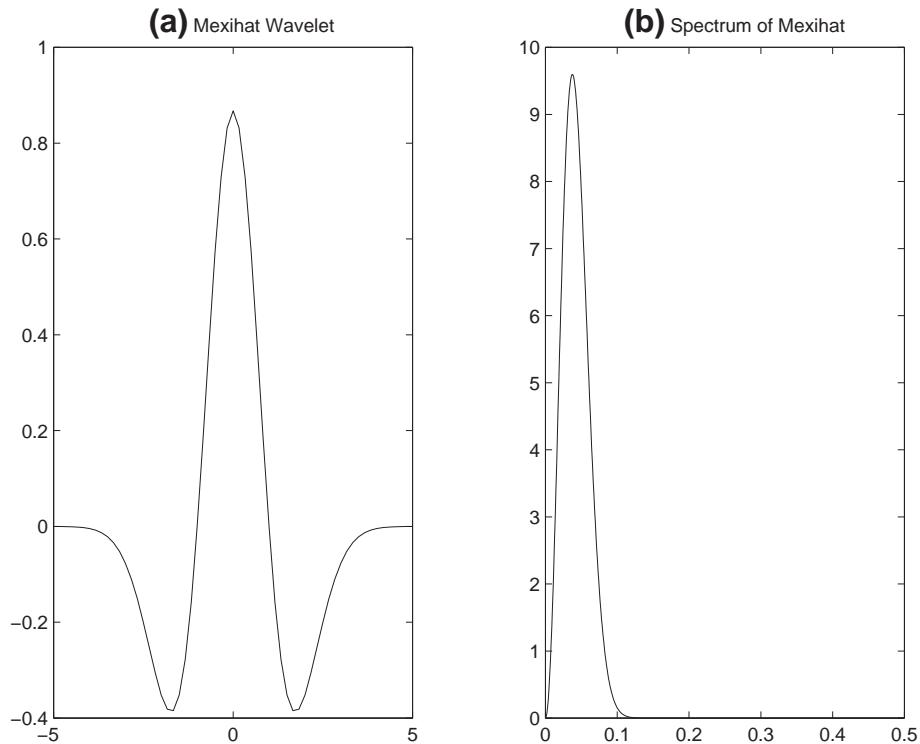

where “\*” denotes complex conjugate. This is of course in contrast to the Gabor transform whose window width remains constant throughout. A time-frequency plot of a continuous wavelet transform is shown in Figure 9.8 for a corresponding  $x(t)$ .

### 1.09.2.2 Inverting the wavelet transform

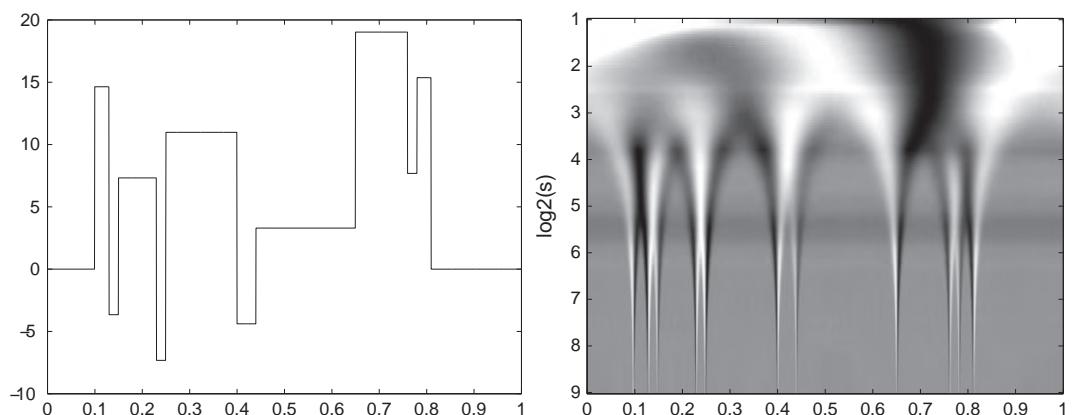

Similarly to the weighted FT, the WT is a redundant representation, which with a proper normalization factor, leads to a reconstruction formula,

$$x(t) = \frac{1}{C_\psi} \int_0^\infty \int_{-\infty}^\infty \mathcal{W}_x(\mu, \xi) \frac{1}{\sqrt{\xi}} \psi\left(\frac{t - \mu}{\xi}\right) \frac{d\xi}{\xi^2} d\mu, \quad (9.11)$$

with  $C_\psi = \int_0^{+\infty} \frac{\hat{\Psi}^2(\omega)}{\omega} d\omega$ .

**FIGURE 9.7**

Admissible Mexican hat wavelet.

**FIGURE 9.8**

Continuous signal with corresponding wavelet transform with cones of influence around singularities.

While the direct and inverse WT have been successfully applied in a number of different problems [18], their computational cost due to their continuous/redundant nature is considered as a serious drawback. An immediate and natural question arises about a potential reduction in the computational complexity, and hence in the WT redundancy. This has clearly to be carefully carried out to guarantee a sufficient coverage of the T-F plane, and thereby ensure a proper reconstruction of a transformed signal. Upon discretizing the scale and dilation parameters, a dimension reduction relative to a continuous transform is achieved. The desired adaptivity of the window width with varying frequency naturally results by selecting a geometric variation of the dilation parameter  $\xi = \xi_0^m, m \in \mathbb{Z}$  (*set of all positive and negative integers*). To obtain a systematic and consistent coverage of the T-F plane, our choice of the translation parameter “ $\mu$ ” should be in congruence with the fact that at any scale “ $m$ ,” the coverage of the whole line  $\mathcal{R}$  (for instance) is complete, and the translation parameter be in step with the chosen wavelet  $\psi(t)$ , i.e.,  $\mu = n\mu_0\xi_0^m$  with  $n \in \mathbb{Z}$ . This hence gives the following scale and translation adaptive wavelet:

$$\psi(t)_{m,n} = \xi_0^{-m/2} \psi \left( \frac{t}{\xi_0^m} - n\mu_0 \right), \quad (9.12)$$

where the factor “ $\xi_0^{-m/2}$ ,” ensures a unit energy function. This reduction in dimensionality yields a redundant discrete wavelet transform endowed with a structure which lends itself to an iterative and fast inversion/reconstruction of a transformed signal  $x(t)$ .

**Definition 6.** The set of resulting wavelet coefficients  $\{\langle x(t), \psi_{mn}(t) \rangle\}_{(m,n) \in \mathbb{Z}^2}$  completely characterizes  $x(t)$ , and hence leads to a stable reconstruction [18, 19] if  $\forall x(t) \in L^2(\mathcal{R})$  (or finite energy signal) the following condition on the energy holds,

$$A \|x(t)\|^2 \leq \sum_{m,n} |\langle x(t), \psi_{mn}(t) \rangle|^2 \leq B \|x(t)\|^2. \quad (9.13)$$

Such a set of functions  $\{\psi_{mn}(t)\}_{(m,n) \in \mathbb{Z}^2}$  then constitutes a frame.

The energy inequality condition intuitively suggests that the redundancy should be controlled to avoid instabilities in the reconstruction (i.e., too much redundancy makes it more likely that any perturbation of coefficients will yield an unstable/inconsistent reconstruction). If the frame bounds “ $A$ ” and “ $B$ ” are equal, the corresponding frame is said to be tight, and if furthermore  $A = B = 1$ , it is an orthonormal basis. Note, however, that for any  $A \neq 1$  a frame is not a basis. In some cases, the frame bounds specify a redundancy ratio which may help guide one in inverting a frame representation of a signal, since a unique inverse does not exist. An efficient computation of an inverse (for reconstruction), or more precisely of a pseudo-inverse, may only be obtained by a judicious manipulation of the reconstruction formula [18, 19]. This is, in a finite dimensional setting, similar to a linear system of equations with a rank deficient matrix whose column space has an orthogonal complement (the union of the two subspaces yields all of the Hilbert space), and hence whose inversion is ill conditioned. The size of this space is determined by the order of the deficiency (number of linearly dependent columns), and explains the potential for instability in a frame projection-based signal reconstruction [18]. This type of “effective rank” utilization is encountered in numerical linear algebra applications (e.g., signal subspace methods [22], model order identification, etc.). The close connection between the redundancy of a frame and the rank deficiency of a matrix, suggests that solutions available in linear algebra [23] may provide

insight in solving our frame-based reconstruction problem. A well known iterative solution to a linear system and based on a gradient search solution is described in [24], (and in fact coincides with a popular iterative solution to the frame algorithm for reconstructing a signal) for solving

$$\mathbf{f} = \mathbf{L}^{-1}\mathbf{b},$$

where “ $\mathbf{L}$ ” is a matrix operating on  $\mathbf{f}$ , and  $\mathbf{b}$  is the data vector. Starting with an initial guess  $\mathbf{f}_0$  and iterating on it leads to

$$\mathbf{f}_n = \mathbf{f}_{n-1} + \alpha(\mathbf{b} - \mathbf{L}\mathbf{f}_{n-1}). \quad (9.14)$$

When  $\alpha$  is appropriately selected, the latter iteration may be shown to yield [18]

$$\lim_{n \rightarrow +\infty} \mathbf{f}_n = \mathbf{f}. \quad (9.15)$$

Numerous other good solutions have also been proposed in the literature and their detailed descriptions are given in [18, 19, 25, 26].

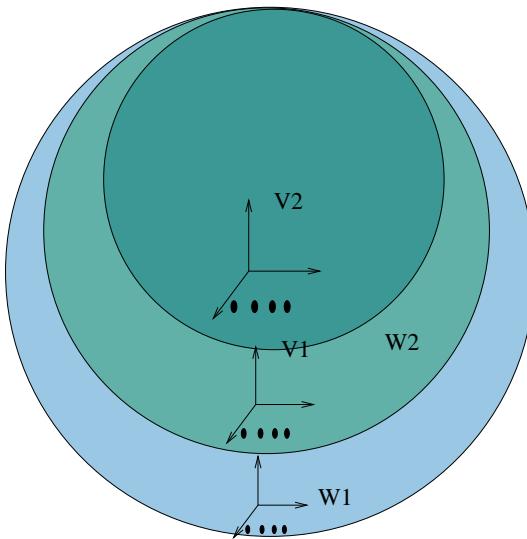

### 1.09.2.3 Wavelets and multiresolution analysis

While a frame representation of a signal is of lower dimension than that of its continuous counterpart, a complete elimination of redundancy is only possible by orthonormalizing a basis. A proper construction of such a basis ensures orthogonality within scales as well as across scales. The existence of such a basis with a dyadic scale progression was first shown, and an explicit construction was given by Meyer [27] and Daubechies et al. [19]. The connection to subband coding discovered by Mallat [28] resulted in a numerically stable and efficient implementation which helped propel wavelet analysis at the forefront of computational sciences (see Ref. [29] for a comprehensive historical as well technical development [19] which also led to Daubechies celebrated orthonormal wavelet bases).

To help maintain a smooth flow of this chapter, and achieve the goal of endowing an advanced undergraduate with a working knowledge of the Multiresolution Analysis (MRA) framework, we give a high level introduction, albeit comprehensive, and defer most of the technical details to the sources in the bibliography. For example, the trade-off in time-frequency resolution advocated earlier, lies at the heart of the often technical wavelet design and construction. The balance between the spectral and temporal decay which constitutes one of the key design criteria, has led to a wealth of new functional bases, and this upon the introduction of the now classical multiresolution analysis framework [18, 30]. The pursuit of a more refined analysis arsenal resulted in the recently introduced nonlinear multiresolution analysis in [31–33].

#### 1.09.2.3.1 Multiresolution analysis

The Multiresolution Analysis theory (MRA) developed by Mallat [34] and Meyer [27], may be viewed as a functional analytic approach to subband signal analysis, which had previously been introduced in and applied to engineering problems [35, 36]. The clever connection between an orthonormal wavelet decomposition of a signal and its filtering by a bank of corresponding filters led to an axiomatic formalization of the theory and subsequent equivalence. This as a result, opened up a new wide avenue of research in the development and construction of new functional bases as well as filter banks [21, 37–39]. The construction of a telescopic set of nested approximation and detail subspaces  $\{V_j\}_{j \in \mathbb{Z}}$  and  $\{W_j\}_{j \in \mathbb{Z}}$

**FIGURE 9.9**

Hierarchy of wavelet bases.

each endowed with an orthonormal basis, as shown in Figure 9.9, is a key step of the analysis. An inter and intra scale orthogonality of the wavelet functions, as noted above, is preserved, with the inter-scale orthogonality expressed as

$$W_i \perp W_j \quad \forall i \neq j. \quad (9.16)$$

By replacing the discrete parameter wavelet  $\psi_{ij}(t)$  where  $(i, j) \in \mathbb{Z}^2$  (*set of all positive and negative 2-tuple integers*) respectively denote the translation and the scale parameters, in Eq. (9.10) (i.e.,  $\mu = 2^j i$ ,  $\xi = 2^j$ ), we obtain the orthonormal wavelet coefficients as [18],

$$c_j^i(x) = \langle x(t), \psi_{ij}(t) \rangle. \quad (9.17)$$

The orthogonal complementarity of the scaling subspace and that of the residuals/details amount to synthesizing the higher resolution subspace

$$V_i \oplus W_i = V_{i-1}.$$

Iterating this property, leads to a reconstruction of the original space where the observed signal lies, and which in practice, is taken to be  $V_0$ . That is, the observed signal at its first and finest resolution (this may be viewed as implicitly accepting the samples of a given signal as the coefficients in an approximation space with a scaling function corresponding to that which the subsequent analysis is based on). The dyadic scale progression has been thoroughly investigated, and its wide acceptance/popularity is due to its tight connection with subband coding, whose practical implementation is fast and simple. Other nondyadic developments have also been explored (see for e.g., [21]).

The qualitative characteristics of the MRA we have thus far discussed, may be succinctly stated as follows,

**Definition 7.** [18] A sequence  $\{V_i\}_{i \in \mathcal{Z}}$  of closed subspaces of  $L^2(\mathcal{R})$  is a multiresolution approximation if the following properties hold:

- $\forall (j, k) \in \mathcal{Z}^2, x(t) \in V_j \Leftrightarrow x(t - 2^j k) \in V_j$ ,
- $\forall j \in \mathcal{Z}, V_{j+1} \subset V_j$ ,
- $\forall j \in \mathcal{Z}, x(t) \in V_j \Leftrightarrow x\left(\frac{t}{2}\right) \in V_{j+1}$ ,
- $\lim_{j \rightarrow -\infty} V_j = \overline{\bigcap_{j=-\infty}^{\infty} V_j} = \{0\}$ ,
- $\lim_{j \rightarrow -\infty} \overline{\bigcup_{j=-\infty}^{\infty} V_j} = L^2(\mathcal{R})$ ,
- There exists a function  $\phi(t)$  such that  $\{\phi(t - n)\}_{n \in \mathcal{Z}}$  is a Riesz basis of  $V_0$ , where the “overbar” denotes closure of the space.

### 1.09.2.3.2 Properties of wavelets

A wavelet analysis of a signal assumes a judiciously preselected wavelet, and hence a prior knowledge about the signal itself. As stated earlier, the properties of an analyzing wavelet have a direct impact on the resulting multiscale signal representation. Carrying out a useful and meaningful analysis is hence facilitated by a good understanding of some fundamental wavelet properties.

### 1.09.2.3.3 Vanishing moments

Recall that one of the fundamental admissibility conditions of a wavelet is that its first moment be zero. This is intuitively understood in the sense that a wavelet focuses on residuals or oscillating features of a signal. This property may in fact be further exploited by constructing a wavelet with an arbitrary number of vanishing moments. We say that a wavelet has  $n$  vanishing moments if

$$\int \psi(t)t^i dt = 0, \quad i = \{0, 1, \dots, n-1\}. \quad (9.18)$$

Reflecting a bit on the properties of a Fourier Transform of a function [15], it is easy to note that the number of zero moments of a wavelet reflects the behavior of its Fourier Transform around zero. This property is also useful in applications like compression, where it is highly desirable to maximize the number of small/negligible coefficients, and only preserve a minimal number of large coefficients. The associated cost with increasing the number of vanishing moments is that of an increased support size for the wavelet, hence that of the corresponding filter [18, 19], and hence of some of its localizing potential.

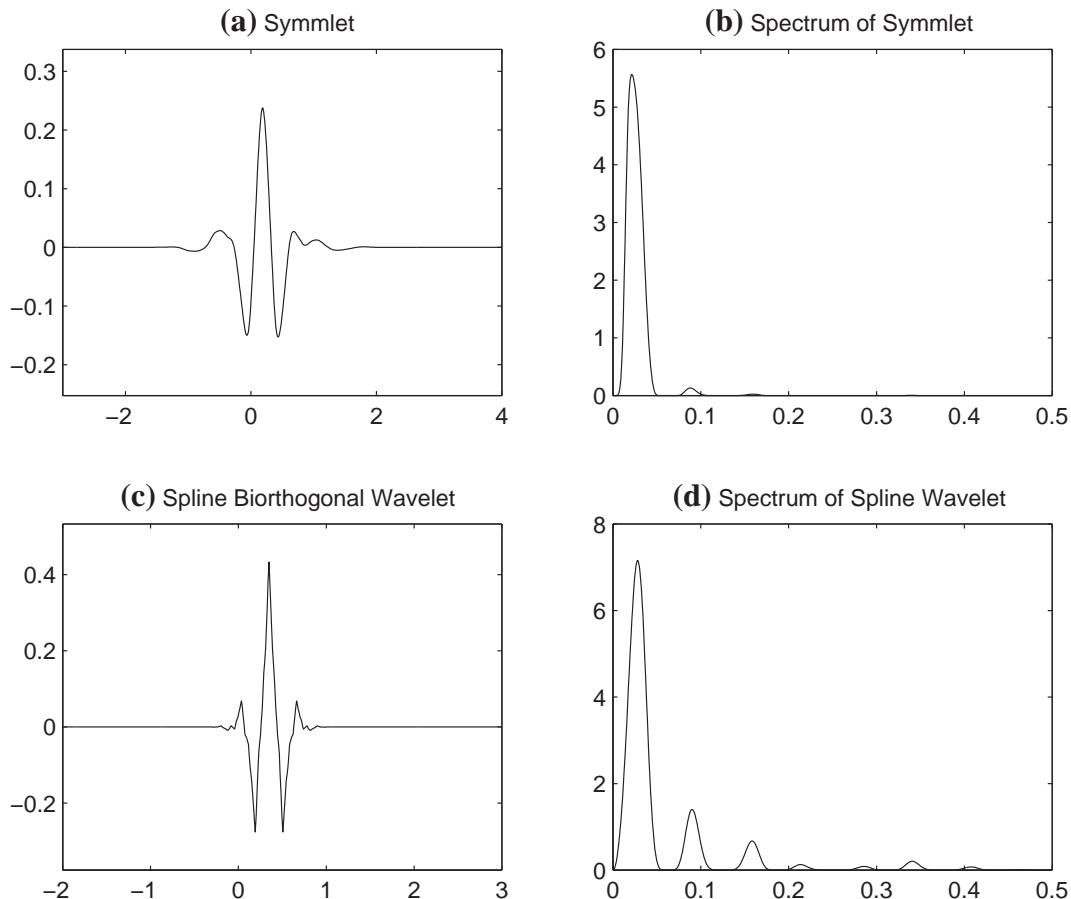

### 1.09.2.3.4 Regularity/smoothness

The smoothness of a wavelet “ $\psi(t)$ ” is important for an accurate and parsimonious signal approximation. For a large class of wavelets (those relevant to applications), the smoothness (or regularity) property of a wavelet, which may also be measured by its degree of differentiability ( $d^\alpha \psi(t)/dt^\alpha$ ) or equivalently by its Lipschitzity “ $\gamma$ ,” is also reflected by its number of vanishing moments [18]. The larger the number of vanishing moments, the smoother the function. In applications, such as image coding, a smooth analyzing wavelet is useful for not only compressing the image, but for controlling the visual distortion due to errors as well. The associated cost (i.e., some trade-off is in order) is again a size increase in the

wavelet support, which may in turn make it more difficult to capture local features, such as important transient phenomena.

#### 1.09.2.3.5 Wavelet symmetry

At the exception of a Haar wavelet, compactly supported real wavelets are asymmetric around their center point. A symmetric wavelet clearly corresponds to a symmetric filter which is characterized by a linear phase. The symmetry property is important for certain applications where symmetric features are crucial (e.g., symmetric error in image coding is better perceived). In many applications, however, it is generally viewed as a property secondary to those described above. When such a property is desired, truly symmetric biorthogonal wavelets have been proposed and constructed [19, 40], with the slight disadvantage of using different analysis and synthesis mother wavelets. In Figure 9.10, we show some

**FIGURE 9.10**

Biorthogonal wavelets preserve symmetry and symlets nearly do.

illustrative cases of symmetric wavelets. Other nearly symmetric functions (referred to as symlets) have also been proposed, and a detailed discussion of the pros and cons of each, is deferred to Daubechies [19].

#### 1.09.2.3.6 A filter bank view: implementation

As noted earlier, the connection between a MRA of a signal and its processing by a filter bank was not only of intellectual interest, but was of breakthrough proportion for general applications as well. It indeed provided a highly efficient numerical implementation for a theoretically very powerful methodology. Such a connection is most easily established by invoking the nestedness property of MR subspaces. Specifically, it implies that if  $\phi(2^{-j}t) \in V_j$  and  $V_j \subset V_{j-1}$ , and we can hence write,

$$\frac{1}{2^{j/2}}\phi(2^{-j}t) = \frac{1}{2^{\frac{j-1}{2}}} \sum_{k=-\infty}^{\infty} h(k)\phi(2^{-j+1}t - k), \quad (9.19)$$

where  $h(k) = \langle \phi(2^{-j}t), \phi(2^{-j+1}t - k) \rangle$ , i.e., the expansion coefficient at time shift  $k$ . By taking the FT of Eq. (9.19), we obtain

$$\Phi(2^j\omega) = \frac{1}{2^{1/2}} H(2^{j-1}\omega) \Phi(2^{j-1}\omega), \quad (9.20)$$

which when iterated through scales leads to

$$\Phi(\omega) = \prod_{p=-\infty}^{\infty} \frac{h(2^{-p}\omega)}{\sqrt{2}} \Phi(0). \quad (9.21)$$

The complementarity of scaling and detail subspaces noted earlier stipulates that any function in subspace  $W_j$  may also be expressed in terms of  $V_{j-1} = \text{Span}\{\phi_{j-1,k}(t)\}_{(j,k) \in \mathcal{Z}^2}$ , or

$$\frac{1}{2^{j/2}}\psi(2^{-j}t) = \sum_{i=-\infty}^{\infty} \frac{1}{2^{(j-1)/2}} g(i)\phi(2^{-j+1}t - i). \quad (9.22)$$

In the Fourier domain, this leads to

$$\Psi(2^j\omega) = \frac{1}{\sqrt{2}} G(2^{j-1}\omega) \Phi(2^{j-1}\omega), \quad (9.23)$$

whose iteration also leads to an expression of the wavelet FT in terms of the transfer function  $G(\omega)$ , as previously given for  $\Phi(\omega)$  in Eq. (9.21). In light of these equations it is clear that the filters  $\{G(\omega), H(\omega)\}$  may be used to compute functions at successive scales. This in turn implies that the coefficients of any function  $x(t)$  may be similarly obtained as they are merely the result of an inner product of the signal of interest  $x(t)$  with a basis function,

$$\begin{aligned} \langle x(t), \psi_{ij}(t) \rangle &= \sum \langle x(t), g(k) \frac{1}{2^{(j-1)/2}} \phi(2^{-j+1}(t - 2^{-j}i) - k) \rangle \\ &= m_k g(k) \mathcal{A}_{i-k}^{j+1}(x). \end{aligned} \quad (9.24)$$

To complete the construction of the filter pair  $\{H(\cdot), G(\cdot)\}$ , the properties between the approximation subspaces ( $\{V_j\}_{j \in \mathcal{Z}}$ ) and detail subspaces ( $\{W_j\}_{j \in \mathcal{Z}}$ ) are exploited to derive the design criteria for

the discrete filters. Specifically, the same scale orthogonality property between the scaling and detail subspaces in

$$\sum_{k \in \mathcal{Z}} \Phi(2^j \omega + 2k\pi) \Psi(2^j \omega + 2k\pi) = 0, \quad \forall j, \quad (9.25)$$

is the first property that the resulting filters should satisfy. For the sake of illustration, fix  $j = 1$  and use

$$\sqrt{2}\Phi(2\omega) = H(\omega)\Phi(\omega). \quad (9.26)$$

Using Eq. (9.26) together with the orthonormality property of  $j$ th scale basis functions  $\{\Phi_{jk}(t)\}$  [18], i.e.,  $\sum |\Phi(\omega + 2k\pi)|^2 = 1$ , where we separate even and odd terms, yields the first property of one of the so-called conjugate mirror filters,

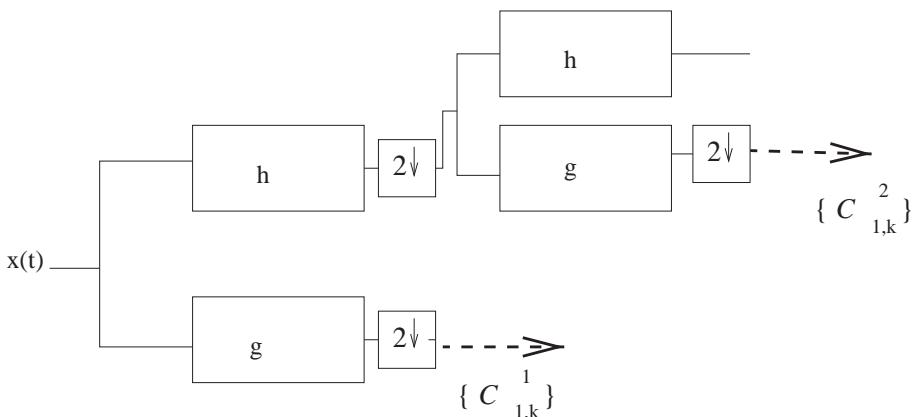

$$|H(\omega)|^2 + |H(\omega + \pi)|^2 = 1. \quad (9.27)$$

Using the non-overlapping property expressed in Eq. (9.25), together with the evaluations of  $\Psi(2\omega)$  and  $\Phi(2\omega)$ , and making a similar argument as in the preceding equation, yield the second property of conjugate mirror filters,

$$H(\omega)G^*(\omega) + H(\omega + \pi)G^*(\omega + \pi) = 0. \quad (9.28)$$

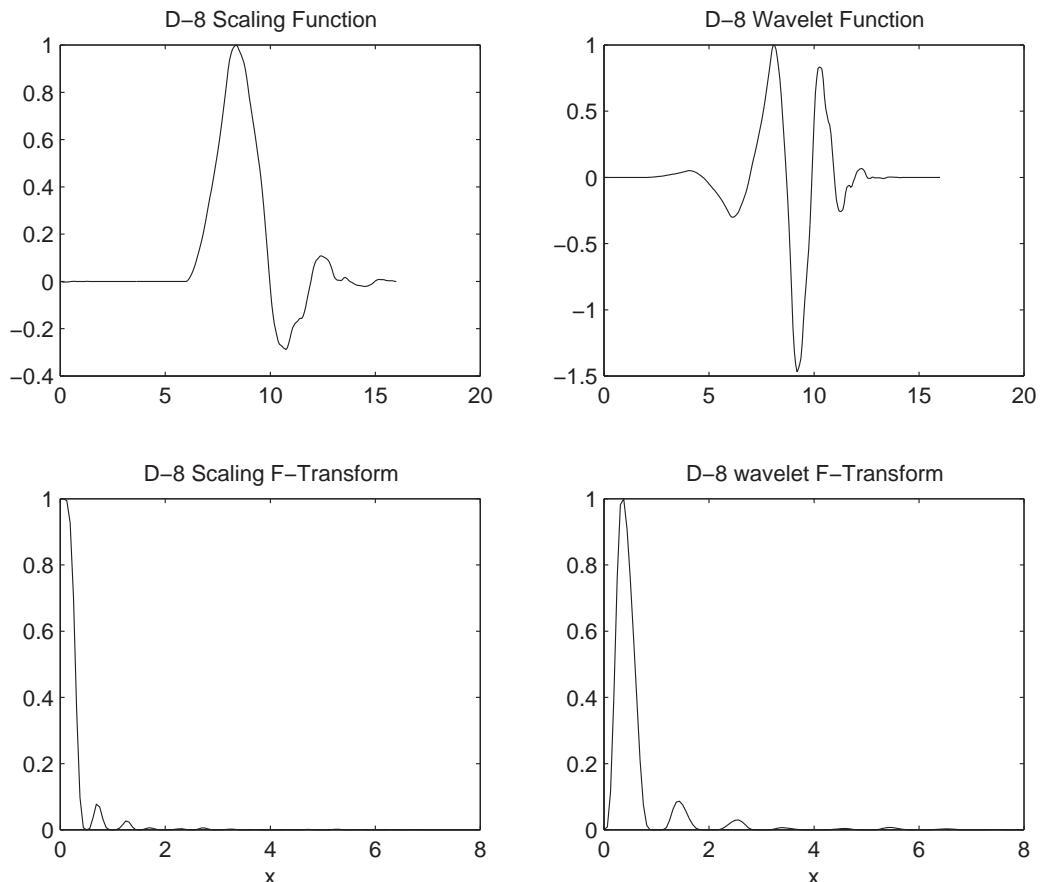

The combined structure of the two filters is referred to as “a conjugate mirror filter bank,” and their respective impulse responses completely specify the corresponding wavelets (see numerous references, e.g., [20] for additional technical details). Note that the literature in the MR studies tends to follow one of two possible strategies:

- A more functional analytic approach, which is mostly followed by applied mathematicians/mathematicians and scientists [18, 19, 30] (we could not possibly do justice to the numerous good texts now available, the author cites what he is most familiar with).
- A more filtering oriented approach widely popular among engineers and some applied mathematicians [21, 38, 41], see Figures 9.11 and 9.12.

**FIGURE 9.11**

#### 1.09.2.3.7 Refining a wavelet basis: wavelet packet and local cosine bases

A selected analysis wavelet is not necessarily well adapted to any observed signal. This is particularly the case when the signal is time varying and has a rich spectral structure.

One approach is to then partition the signal into homogeneous spectral segments and by the same token find it an adapted basis. This is tantamount to further refining the wavelet basis, and resulting in what is referred to as a wavelet packet basis. A similar adapted partitioning may be carried out in the time domain by way of an orthogonal local trigonometric basis (sine or cosine). The two formulations are very similar, and the solution to the search for an adapted basis in both cases is resolved in precisely the same way. In the interest of space, we focus in the following development on only wavelet packets.

### 1.09.2.3.8 Wavelet packets

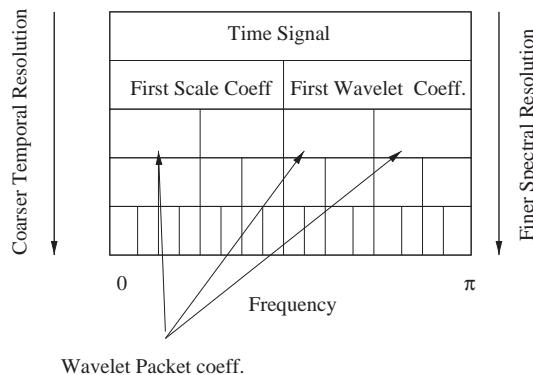

We maintained above that a selection of an analysis wavelet function should be carried out in function of the signal of interest. This of course assumes that we have some prior knowledge about the signal at hand. While plausible in some cases, this assumption is very unlikely in most practical cases. Yet it is highly desirable to select a basis which might still lead to an adapted representation of an apriority “unknown” signal. Coifman and Meyer [42] proposed to refine the standard wavelet decomposition. Intuitively, they proposed to further partition the spectral region of the details (i.e., wavelet coefficients) in addition to partitioning the coarse/scaling portion as ordinarily performed for a wavelet representation. This as shown in Figure 9.13 yields an overcomplete representation of a signal, in other words a dictionary of bases with a tree structure. The binary nature of the tree as further discussed below, affords a very efficient search for a basis which is best adapted to a given signal in the set.

Formally, we accomplish a partition refinement of say a subspace  $U_j$  by way of a new wavelet basis which includes both its approximation and its details, as shown in Figure 9.13. This construction due to Coifman and Meyer [42] may be simply understood as one’s ability to find a basis for all the subspaces  $\{V_j\}_{j \in \mathbb{Z}}$  and  $\{W_j\}_{j \in \mathbb{Z}}$  by iterating the nestedness property. This then amounts to expressing two new functions  $\tilde{\psi}_j^0(t)$  and  $\tilde{\psi}_j^1(t)$  in terms of  $\{\tilde{\psi}_{j-1,k}\}_{(j,k) \in \mathbb{Z}^2}$ , an orthonormal basis of a generic subspace  $U_{j-1}$  (which in our case may be either  $V_{j-1}$  or  $W_{j-1}$ ),

$$\tilde{\psi}_j^0(t) = \sum_{k=-\infty}^{\infty} h(k) \tilde{\psi}_{j-1}(t - 2^{j-1}k), \quad (9.29)$$

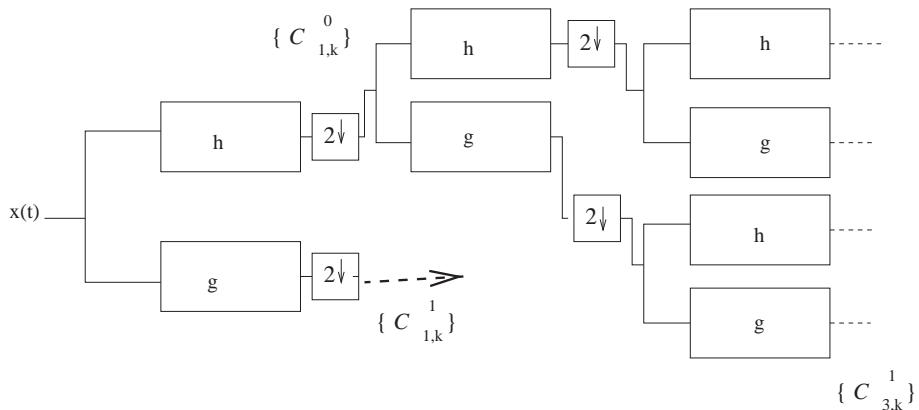

$$\tilde{\psi}_j^1(t) = \sum_{k=-\infty}^{\infty} g(k) \tilde{\psi}_{j-1}(t - 2^{j-1}k), \quad (9.30)$$

where  $h(\cdot)$  and  $g(\cdot)$  are the impulse responses of the filters in a corresponding filter bank, and the combined family  $\{\tilde{\psi}_j^0(t - 2^j k), \tilde{\psi}_j^1(t - 2^j k)\}_{(j,k) \in \mathbb{Z}^2}$  is an orthonormal basis of  $U_j$ . This, as illustrated in Figure 9.13, is graphically represented by a binary tree where, at each of the nodes reside the

**FIGURE 9.13**

Wavelet packet bases structure.

**FIGURE 9.14**

Wavelet packet filter bank realization.

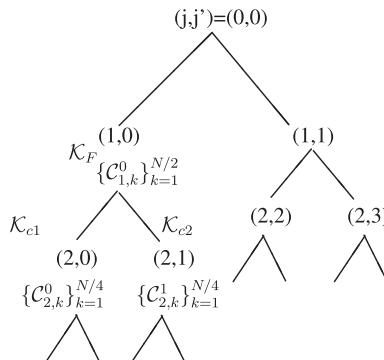

corresponding wavelet packet coefficients. The implementation of a wavelet packet decomposition is a straightforward extension of that of a wavelet decomposition, and consists of an iteration of both  $H(\cdot)$  and  $G(\cdot)$  bands (see Figure 9.14) to naturally lead to an overcomplete representation. This is reflected on the tree by the fact that, at the exception of the root and bottom nodes which only have respectively two children nodes and one ancestor node, each node bears two children nodes and one ancestor node.

#### 1.09.2.3.9 Basis search

To identify the best adapted basis in an overcomplete signal representation, as just noted above, we first construct a criterion which when optimized, will reflect desired properties intrinsic to the signal being analyzed. The earliest proposed criterion applied to a wavelet packet basis search is the so-called entropy criterion [43]. Unlike Shannon's information theoretic criterion, this is additive and makes use of the coefficients residing at each node of the tree in lieu of computed probabilities. The presence of more complex features in a signal necessitates such an adapted basis to ultimately achieve an ideally more parsimonious/succinct representation. As pointed out earlier, when searching for a wavelet packet or local cosine best basis, we typically have a dictionary  $\mathcal{D}$  of possible bases with a binary tree structure. Each node  $(j, j')$  (where  $j \in \{0, \dots, J\}$  represents the depth and  $j' \in \{0, \dots, 2^j - 1\}$  represents the branches on the  $j$ th level) of the tree then corresponds to a given orthonormal basis  $\mathcal{B}_{j,j'}$  of a vector subspace of  $\ell^2(\{1, \dots, N\})$  ( $\ell^2(\{1, \dots, N\})$  is a Hilbert space of finite energy sequences). Since a particular partition  $p \in \mathcal{P}$  of  $[0, 1]$  is composed of intervals  $I_{j,j'} = [2^{-j}j', 2^{-j}(j'+1)[$ , an orthonormal basis of  $\ell^2(\{1, \dots, N\})$  is given by  $\mathcal{B}^p = \bigcup_{\{(j,j')|I_{j,j'} \in \mathcal{P}\}} \mathcal{B}_{j,j'}$ . By taking advantage of the property

$$\text{Span}\{\mathcal{B}_{j,j'}\} = \text{Span}\{\mathcal{B}_{j+1,2j'}\} \overset{\perp}{\oplus} \text{Span}\{\mathcal{B}_{j+1,2j'+1}\}, \quad (9.31)$$

where  $\oplus$  denotes a subspace direct sum, we associate to each node a cost  $\mathcal{C}(\cdot)$ . We can then perform a bottom-up comparison of children versus parent costs (this in effect will eliminate the redundant/inadequate leaves of the tree) and ultimately prune the tree.

**FIGURE 9.15**

Tree pruning in search for a best-basis.

Our goal is to then choose the basis which leads to the *best* approximation of  $\{x[t]\}$  among a collection of orthonormal bases  $\{\mathcal{B}^p = \{\Psi x_i p\}_{1 \leq i \leq N} | p \in \mathcal{P}\}$ , where the subscript  $x_i$  emphasizes that it is adapted to  $\{x[t]\}$ . Trees of wavelet packet bases studied by Coifman and Wickerhauser [44] are constructed by quadrature mirror filter banks and comprise functions that are well-localized in time and frequency. This family of orthonormal bases partitions the frequency axis into intervals of different sizes, with each set corresponding to a specific wavelet packet basis. Another family of orthonormal bases studied by Malvar [45], and Coifman and Meyer [42], can be constructed with a tree of windowed cosine functions, and correspond to a division of the time axis into intervals of dyadically varying sizes.

For a discrete signal of size  $N$  (e.g., the size of the WP tableau shown in Figure 9.13), one can show that a tree of wavelet packet bases or local cosine bases has  $P = N(1 + \log_2 N)$  distinct vectors but includes more than  $2^{N/2}$  different orthogonal bases. One can also show that the signal expansion in these bases is computed with algorithms that require  $O(N \log_2 N)$  operations. Coifman and Wickerhauser [43] proposed that for any signal  $\{x[m]\}$  and an appropriate functional  $\mathcal{K}(\cdot)$ , one finds the best basis  $\mathcal{B}^{p_0}$  by minimizing an “additive” cost function

$$\text{Cost}(\mathbf{x}, \mathcal{B}^p) = \sum_{i=1}^N \mathcal{K}(|\langle \mathbf{x}, \Psi x_i p \rangle|^2) \quad (9.32)$$

over all bases. As a result, the basis which results from minimizing this cost function corresponds to the “best” representation of the observed signal. The resulting pruned tree of Figure 9.15 bears the coefficients at the remaining leaves/nodes.

#### 1.09.2.4 MR applications in estimation problems

The computational efficiency of a wavelet decomposition together with all of its properties have triggered unprecedented interest in their application in the area of information sciences (see e.g., [46–51]). Specific applications have ranged from compression [52–55] to signal/image modeling [56–59], and from signal/image enhancement to communications [60–67]. The literature in statistical applications as a whole has seen an explosive growth in recent years, and in the interest of space, we will focus

our discussion on a somewhat broader perspective which may in essence, be usefully reinterpreted in a number of different instances.

#### 1.09.2.4.1 Signal estimation/denoising and modeling

Denoising may be heuristically interpreted as a quest for parsimony of a representation of a signal. Wavelets as described above, have a great capacity for energy compaction, particularly at or near singularities. Given a particular wavelet, its corresponding basis as noted above, is not universally optimal for all signals and particularly not for a noisy one; this difficulty may be lifted by adapting the representation to the signal in a “best” way possible and according to some criterion. The first of the two possible ways, is to pick an optimal basis in a wavelet packet dictionary and discard the negligible coefficients [68]. The second which focuses on reconstruction of a signal in noise, and which we discuss here, accounts for the underlying noise statistics in the multiscale domain to separate the “mostly” signal part from the “mostly” noise part [69–71]. We opt here to discuss a more general setting which assumes unknown noise statistics and where a signal reconstruction is still sought in some optimal way, as we elaborate below. This approach is particularly appealing in that it may be reduced to the setting in earlier developments.

#### 1.09.2.4.2 Problem statement

Consider an additive noise model

$$x(t) = s(t) + n(t), \quad (9.33)$$

where  $s(t)$  is an unknown but deterministic signal corrupted by a zero-mean noise process  $n(t)$ , and  $x(t)$  is the observed, i.e., noisy, signal. The objective is to recover the signal  $\{s(t)\}$  based on the observations  $\{x(t)\}$ .

The underlying signal is modeled with an orthonormal basis representation,

$$s(t) = \sum_i C_i^s \psi_i(t),$$

and similarly the noise is represented as

$$n(t) = \sum_i C_i^n \psi_i(t).$$

By linearity, the observed signal can also be represented in the same fashion, its coefficients given by

$$C_i^x = C_i^s + C_i^n.$$

A key assumption we make is that for certain values of  $i$ ,  $C_i^s = 0$ ; in other words, the corresponding observation coefficients  $C_i^x$  represent “pure noise,” rather than signal corrupted by noise. As shown by Krim and Pesquet [72], this is a reasonable assumption in view of the spectral and structural differences between the underlying signal  $s(t)$  and the noise  $n(t)$  across scales. Given this assumption, wavelet-based denoising consists of determining which wavelet coefficients represent primarily signal, and which mostly capture noise. The goal is to then localize and isolate the “mostly signal” coefficients. This may be achieved by defining an information measure as a function of the wavelet coefficients. It identifies the “useful” coefficients as those whose inclusion improves the data explanation. One such measure is Rissanen’s information-theoretic approach (or Minimum Description Length (MDL)) [73]. In other words, the MDL criterion is utilized for resolving the tradeoff between model complexity (each

retained coefficient increases the number of model parameters) and goodness-of-fit (each truncated coefficient decreases the fit between the received—i.e., noisy—signal and its reconstruction).

#### 1.09.2.4.3 The coding length criterion

Wavelet thresholding is essentially an order estimation problem, one of balancing model accuracy against overfitting, and one of capturing as much of the “signal” as possible, while leaving out as much of the “noise” as possible. One approach to this estimation problem is to account for any prior knowledge available on the signal of interest, which usually is of probabilistic nature. This leads to a Bayesian estimation approach as developed in [74, 75]. While generally more complex, it does provide a regularization capacity which is much needed in low Signal to Noise Ratio environments.

A parsimony-driven strategy which we expound on here, addresses the problem of modeling in general, and that of compression in particular. It provides in addition a fairly general and interesting framework where the signal is assumed deterministic and unknown, and results in some intuitively sensible and mathematically tractable techniques [68]. Specifically, it brings together Rissanen’s work on stochastic complexity and coding length [73, 76], and Huber’s work on minimax statistical robustness [77, 78].

Following Rissanen, we seek the data representation that results in the shortest encoding of both observations and complexity constraints. As a departure from the commonly assumed Gaussian likelihood, we rather assume that the noise distribution  $f$  of our observed sequence is a (possibly) scaled version of an unknown member of the family of  $\varepsilon$ -contaminated normal distributions,

$$\mathcal{P}_\varepsilon = \{(1 - \varepsilon)\Phi + \varepsilon G : G \in \mathcal{F}\},$$

where  $\Phi$  is the standard normal distribution,  $\mathcal{F}$  is the set of all suitably smooth distribution functions, and  $\varepsilon \in (0, 1)$  is the known fraction of contamination (this is no loss of generality, since  $\varepsilon$  may always be estimated if unknown). Note that this study straightforwardly reduces to the additive Gaussian noise case, by setting the mixture parameter  $\varepsilon = 0$ , and is in that sense more general.

For fixed model order, the expectation of the MDL criterion is the entropy, plus a penalty term which is independent of both the distribution and the functional form of the estimator. In accordance with the minimax principle, we seek the least favorable noise distribution and evaluate the MDL criterion for that distribution. In other words, we solve a minimax problem where the entropy is maximized over all distributions in  $\mathcal{P}_\varepsilon$ , and the description length is minimized over all estimators in  $\mathcal{S}$ . The saddle-point (provided its existence) yields a minimax robust version of MDL, which we call the Minimax Description Length (MMDL) criterion.

In [68], it is shown that the least favorable distribution in  $\mathcal{P}_\varepsilon$ , which also maximizes the entropy, is one which is Gaussian in the center and Laplacian (“double exponential”) in the tails, and switches from one to the other at a point whose value depends on the fraction of contamination  $\varepsilon$ .

**Proposition 1.** *The distribution  $f_H \in \mathcal{P}_\varepsilon$  that minimizes the negentropy is*

$$f_H(c) = \begin{cases} (1 - \varepsilon)\phi_\sigma(a)e^{\frac{1}{\sigma^2}(ac+a^2)} & c \leq -a, \\ (1 - \varepsilon)\phi_\sigma(c) & -a \leq c \leq a, \\ (1 - \varepsilon)\phi_\sigma(a)e^{\frac{1}{\sigma^2}(-ac+a^2)} & a \leq c, \end{cases} \quad (9.34)$$

where  $\phi_\sigma$  is the normal density with mean zero and variance  $\sigma^2$ , and  $a$  is related to  $\varepsilon$  by the equation

$$2 \left( \frac{\phi_\sigma(a)}{a/\sigma^2} - \Phi_\sigma(-a) \right) = \frac{\varepsilon}{1-\varepsilon}. \quad (9.35)$$

#### 1.09.2.4.4 Coding for worst case noise

Let the set of wavelet coefficients obtained from the observed signal be denoted by  $\mathcal{C}^N = \{C_1^x, C_2^x, \dots, C_N^x\}$  as a time series without regards to the scale, and where the superscript indicates the corresponding process. Let exactly  $K$  of these coefficients contain signal information, while the remainder only contain noise. If necessary, we re-index these coefficients so that

$$C_i^x = \begin{cases} C_i^s + C_i^n & i = 1, 2, \dots, K, \\ C_i^n & \text{otherwise.} \end{cases} \quad (9.36)$$

By assumption, the set of noise coefficients  $\{C_i^n\}$  is a sample of independent, identically distributed random variates drawn from Huber's distribution  $f_H$ . It follows, by Eq. (9.36), that the observed coefficients  $C_i^x$  obey the distribution  $f_H(c - C_i^s)$  when  $i = 1, 2, \dots, K$ , and  $f_H(c)$  otherwise. Thus, the likelihood function is given by

$$\ell(\mathcal{C}^N; K) = \prod_{i \leq K} f_H(C_i^x - C_i^s) \prod_{i > K} f_H(C_i^x).$$

Since  $f_H$  is symmetric and unimodal with a maximum at the origin, the above expression is maximized (with respect to the signal coefficient estimates  $\{\widehat{C}_i^s\}$ ) by setting

$$\widehat{C}_i^s = C_i^x$$

for  $i = 1, 2, \dots, K$ . It follows that the maximized likelihood (given  $K$ ) is

$$\ell^*(\mathcal{C}^N; K) = \prod_{i \leq K} f_H(0) \prod_{i > K} f_H(C_i^x).$$

Thus, the problem is reduced to choosing the optimal value of  $K$ , in the sense of minimizing the MDL criterion,

$$\mathcal{L}(\mathcal{C}^N; K) = -\log \ell^*(\mathcal{C}^N; K) + K \log N = -\sum_{i \leq K} \log f_H(0) - \sum_{i > K} \log f_H(C_i^x) + K \log N. \quad (9.37)$$

Neglecting terms independent of  $K$ , this is equivalent to minimizing

$$\tilde{\mathcal{L}}(\mathcal{C}^N; K) = \frac{1}{2\sigma^2} \sum_{i > K} \eta(C_i^x) + K \log N,$$

where

$$\eta(c) = \begin{cases} c^2 & \text{if } |c| < a, \\ a|c| - a^2 & \text{otherwise} \end{cases}$$

is proportional to the exponent in Huber's distribution  $f_H$ . This can simply be achieved by a thresholding scheme [68].

**Proposition 2.**

1. When  $\log N > \frac{a^2}{2\sigma^2}$ , the coefficient  $|C_i^x|$  is truncated if

$$|C_i^x| < \frac{a}{2} + \frac{\sigma^2}{a} \log N.$$

2. When  $\log N \leq \frac{a^2}{2\sigma^2}$ , the coefficient  $|C_i^x|$  is truncated if

$$|C_i^x| < \sigma \sqrt{2 \log N}.$$

**Remarks.** More ample details may be found in [68].

When  $\sigma^2 \rightarrow 0$ , the thresholding scheme reduces to Case 2, and  $C_i^x$  is never truncated; since this represents the no-noise case, it is reasonable that all coefficients should be retained in the reconstruction. On the other hand, for large  $\sigma^2$ , the thresholding scheme reduces to Case 1, which is more conservative. For  $\sigma^2 \rightarrow \infty$ , the signal-to-noise ratio becomes zero and the best one can do is to estimate the signal as identically zero.

Similarly, when  $a \rightarrow \infty$ , the noise distribution becomes purely Gaussian, and the thresholding scheme reduces to Case 2, as expected. The resulting threshold of this particular noise case coincides with the results of [69, 70] and is qualitatively similar to that derived in [71]. On the other hand, when  $a \rightarrow 0$ , the noise distribution becomes purely Laplacian, and the thresholding scheme reduces to Case 1.

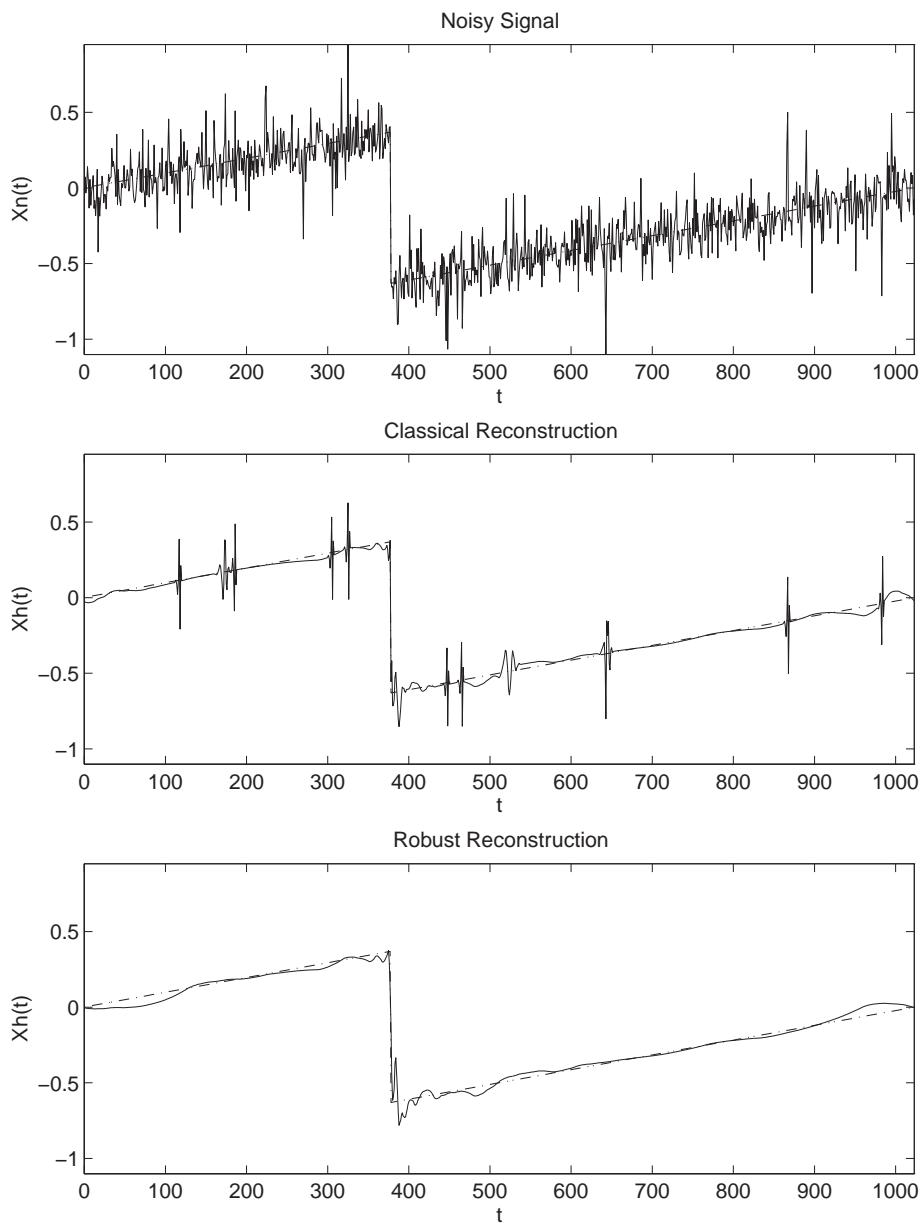

Finally, when  $N \rightarrow 1$ , the thresholding scheme reduces to Case 2, suggesting that outliers are unlikely to occur in a small sample, and it is hence more reasonable to assume purely Gaussian noise. On the other hand, for large  $N$ , the thresholding scheme reduces to Case 1, since outliers are highly likely to occur in a large sample.

It is important to distinguish the minimax error result obtained in [69] which was achieved over a signal smoothness class, from those discussed here and derived in [68] which are obtained over a family of noise distributions.

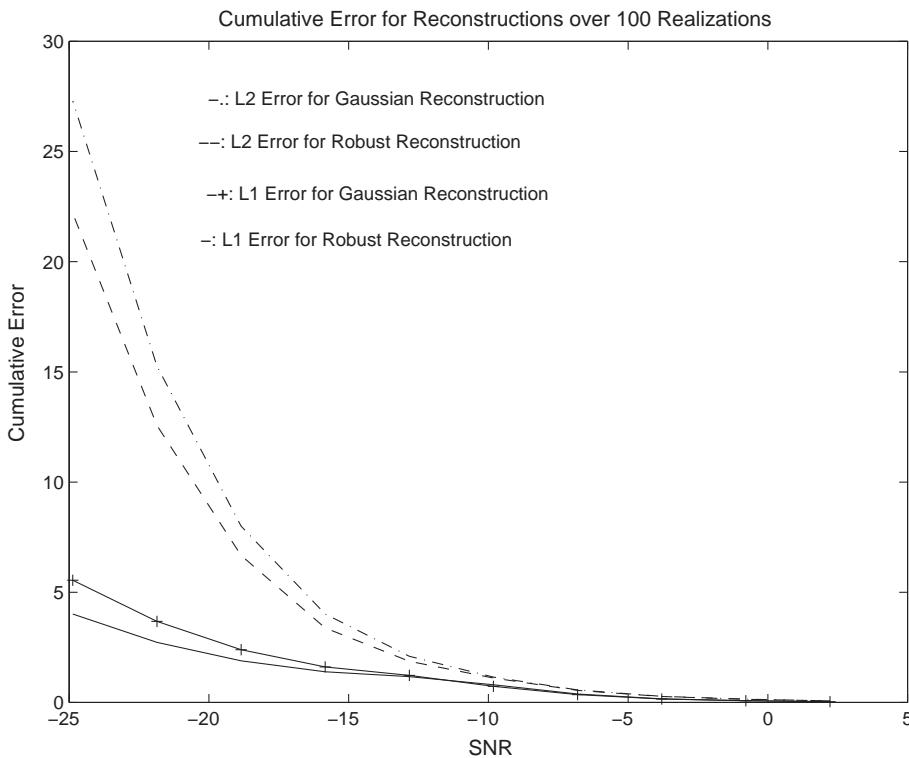

#### 1.09.2.4.5 Numerical experiments

In the examples that follow, we demonstrate the performance of the robust thresholding procedure described above, and compare it with that of the thresholding scheme based upon the assumption of normally distributed noise.

**Example I.** Using WAVELET (available from the Stanford Statistics Department, courtesy of D. L. Donoho and I. M. Johnstone), we synthesized a broken ramp signal of length  $N = 1024$ . This signal admits an efficient representation in a wavelet basis, i.e., one with very few non-zero coefficients. The noise was additive and i.i.d., obeying a  $N(0, \sigma^2)$  distribution contaminated by a fraction  $\varepsilon = 10\%$  of white Gaussian noise with distribution  $N(0, 9\sigma^2)$ . The overall Signal-to-Noise Ratio (SNR) was maintained at 10 dB (see Figure 9.16, top).

**FIGURE 9.16**

Noisy ramp signal, and its Gaussian and robust reconstructions.

**FIGURE 9.17**

$L_1$  and  $L_2$  error performance versus SNR, for the Gaussian and robust estimators.

We implemented two estimators, the first one of which is based on a purely Gaussian noise assumption (i.e.,  $\varepsilon = 0$ ), and where the thresholding scheme due to [72, 79] was used. The second was the MMDL robust estimator described above. The reconstructions based on each estimator appear in Figure 9.16. As may easily be observed, and in contrast to the MMDL technique, the Gaussian assumption induces a high susceptibility to outliers.

Monte-Carlo simulations were carried out to evaluate the reconstruction performance over a range of SNRs. At each value of the SNR, 100 experiments were conducted, and the cumulative reconstruction error is displayed in Figure 9.17. The robust estimator uniformly outperforms the *classic* estimator in both  $L_1$  and  $L_2$  errors over a wide range of SNRs. Furthermore, the performances of the Gaussian and robust estimators become indistinguishable at high SNRs, i.e., small noise variance, showing that robustness does not come at the cost of reduced efficiency.

#### Bounding the reconstruction error.

Although the robust estimator-based reconstruction error is much improved it is still potentially unbounded. As further discussed in [68], and due to the compactness of wavelets, unbounded noise will still result in unbounded reconstruction error, a property that may be considered undesirable.

This problem may be circumvented by making the assumption that the signal has bounded energy; in that case, one of at least two alternatives is possible:

1. In practice, the signal is known to be bounded, and prior knowledge of the physical properties of the signal may be used to determine the  $\|\cdot\|_\infty$  of the sequence of signal wavelet coefficients  $\{C_i^s\}$ . This information may be used to truncate observed coefficients  $\{C_i^x\}$  not only below, as discussed earlier, but also above.
2. In the absence of such prior knowledge, it may still be possible to bound the reconstruction error through an adaptive supremum–secondary thresholding scheme based upon some representation criterion, e.g., entropy.

The first of these approaches uses the following modified thresholding: let  $\alpha > 0$  be an upper bound on the magnitude of the signal coefficients; then,

$$\tilde{C}_i^s = \begin{cases} 0 & \text{if } |C_i^x| \leq \frac{a}{2} + \frac{\sigma^2}{a} \log N, \\ \hat{C}_i^s = C_i^x & \text{if } \frac{a}{2} + \frac{\sigma^2}{a} \log K \leq |C_i^x| \leq \alpha, \\ \alpha \operatorname{sgn}(C_i^x) & \text{if } \alpha \leq |C_i^x| \end{cases}$$

provided that  $\log N > a^2/2\sigma^2$  and  $\alpha > (a/2) + (\sigma^2/a) \log N$ . The graph shows that although the robust estimator's reconstruction error initially grows more slowly than that of the Gaussian estimator, the two errors soon converge as the variance of the outliers grows. The reconstruction error for the bounded-error estimator, however, levels off past a certain magnitude of the outlier, as expected.

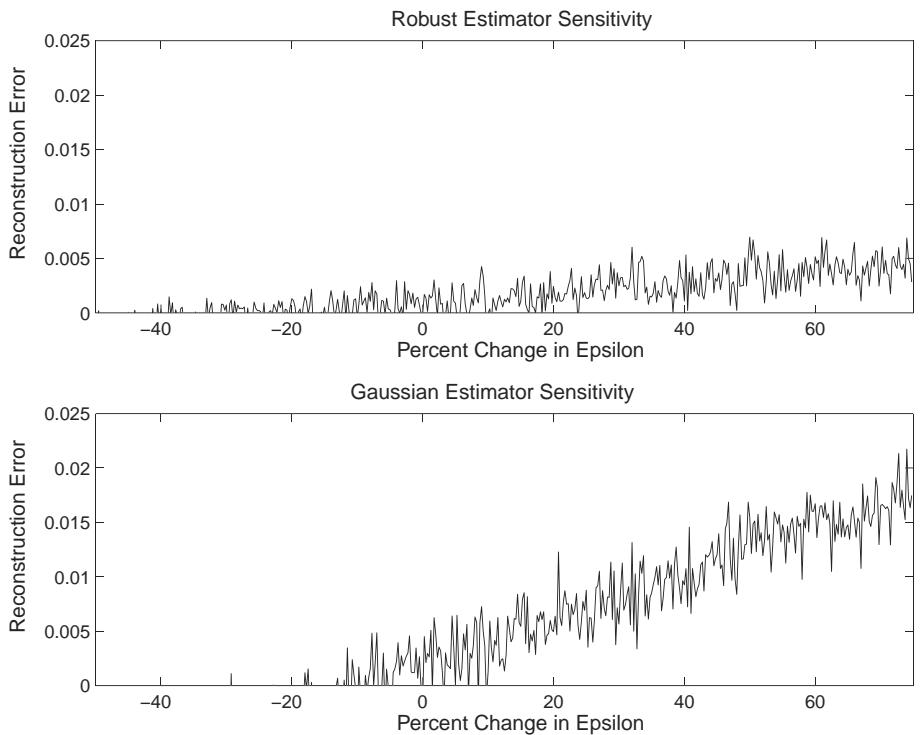

*Sensitivity analysis for the fraction of contamination.*

Although such crucial assumptions as the normality of the noise or exact knowledge of its variance  $\sigma^2$  usually go unremarked, it is often thought that Huber-like approaches are limited on account of the assumption of known  $\varepsilon$ . We demonstrate the resilience and robustness of the approach by studying the sensitivity of the estimator to changes in the assumed value of  $\varepsilon$ .

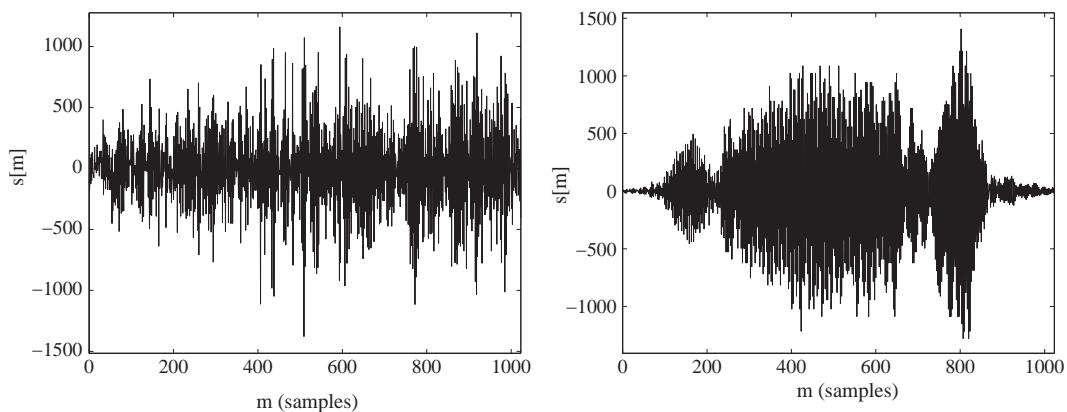

Figure 9.18 shows the total reconstruction error as a function of variation in the true fraction of contamination  $\varepsilon$ . In other words, an abscissa of “0” corresponds to an assumed fraction of contamination equal to the true fraction; larger abscissas correspond to outliers of larger magnitude than assumed by the robust estimator, and vice versa. Clearly, the Gaussian estimator assumes zero contamination throughout. The figure shows that the reconstruction error for the Gaussian estimator grows very rapidly as the true fraction of contamination increases, whereas that of the robust estimator is nearly flat over a broad range. This should not come as a surprise: outliers are, by definition, rare events, and for a localized procedure such as wavelet expansion, the precise frequency of outliers is much less important than their existence at all.

**Example II.** The example above assumed a fixed wavelet basis. As discussed above, however, highly non-stationary signals can be represented most efficiently by using an adaptive basis that automatically chooses resolutions as the behavior of the signal varies over time. Using an  $L^2$  error criterion we search for the best basis of a chirp and show the reconstruction in Figure 9.19 (see [80] for more details).

The separability property of most carefully designed wavelets, and their inability to achieve fine tuned directional analysis has led to seeking alternative wavelets which are more sensitive to arbitrary curves

**FIGURE 9.18**

Error stability vs. variation in the mixture parameter  $\varepsilon$ .

**FIGURE 9.19**

A noisy chirp reconstructed from its best basis and denoised as shown in the figure on the right.

and image edges. These include the introduction of curvelets, contourlets (an efficient implementation of curvelets) and to shearlets, which are respectively discussed in more detail, in the next three sections.

### 1.09.3 Curvelets and their applications

In this section, we introduce the 2D curvelet transform developed by Candès and Donoho around 2000 [4]. Initially, they proposed the ridgelet transform in Cartesian Fourier plane [81] in order to locate segmented curve features in an image. Soon, they discovered that multi-scale partition of the Fourier plane using polar coordinate parameters can provide much simpler structures. This led to their development of the current continuous curvelet transform. This is closely related to Smith's parabolic scaling based transform using the Fourier Integral Operators [82]. The convenience in using polar coordinates in defining the continuous curvelet transform indeed has a cost in implementing it in the digital world. Candès, Donoho, and their collaborators have also introduced the discretized curvelet transform, in which, the discrete Fourier transform involving polar coordinates has been resampled using Cartesian coordinates [83].

It is worth to point out that the varying numbers of wedge-shaped atoms are used across scales when the anisotropic curvelets are used to partition the Fourier plane. This is very different from the classical wavelets, in which only a fixed number of isotropic squares are used. In 2-D spatial plane, the curvelet atoms effective impact is similar to applying differential operators to an image along selected directions to measure the regularities in localized areas that can be contained inside rotated rectangles. Large coefficients can be obtained when a differential operator is applied across the discontinuities along a curve, and thus can be used to characterize salient features in an image.

To start, we first review the conversion between polar coordinates and Cartesian coordinates. In the Fourier frequency plane, a point  $\Omega = (\Omega_x, \Omega_y)$  with Cartesian coordinates, can be converted to polar coordinates  $(r, \sigma)$  by

$$r = \pm|\Omega| = \pm\sqrt{\Omega_x^2 + \Omega_y^2}, \quad \sigma = \arctan(\Omega_y / \Omega_x),$$

assume we confine the angle  $\sigma$  to  $(-\pi/2, \pi/2)$  (the angle between the polar axis and the ray from the pole to the point). Meanwhile, the polar coordinates  $(r, \sigma)$  can be converted to the Cartesian coordinates  $(\Omega_x, \Omega_y)$ , see Figure 9.20, by

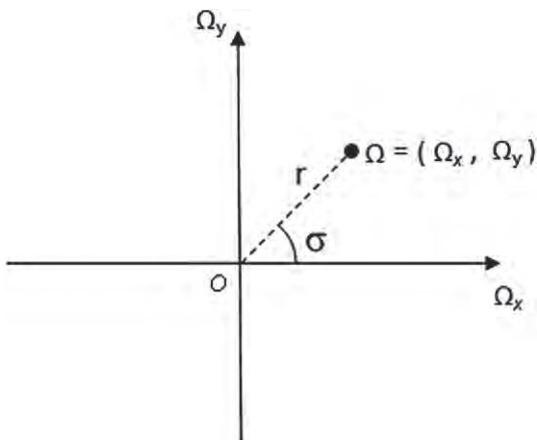

$$\Omega_x = r \cos \sigma, \quad \Omega_y = r \sin \sigma. \quad (9.38)$$

Let  $R_\theta$  be the operator that rotates a point  $\Omega$  in the counter clockwise (ccw) direction around the origin by an angle of  $\theta$  radians, the end point in polar coordinates will be  $R_\theta(\Omega) = (r, \sigma + \theta)$ . In Cartesian coordinates, the operator can be written as a matrix

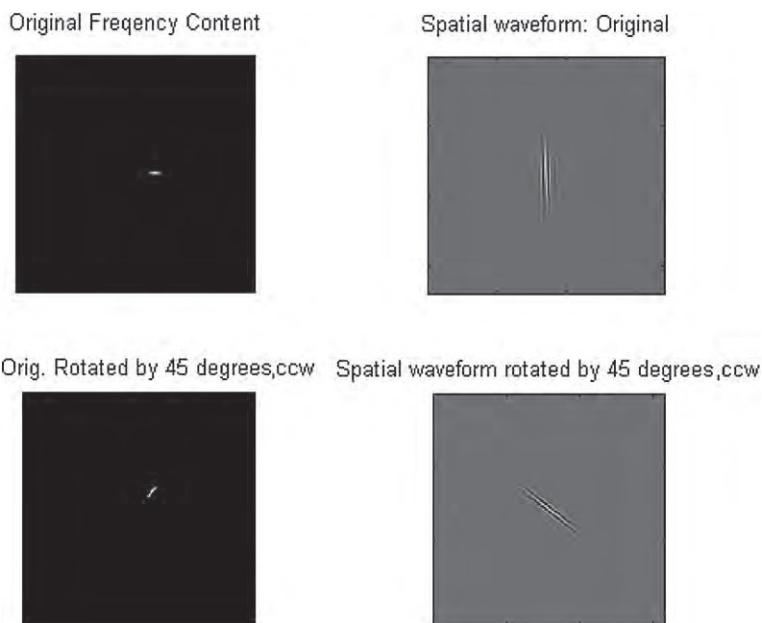

$$R_\theta = \begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix},$$

and the end point of the rotation,  $R_\theta(\Omega) = R_\theta \cdot \Omega$ , is the multiplication of the rotating matrix and the vector  $\Omega$  ( $\Omega$  can be viewed as a column vector).

The following proposition states that, when the input of a function is rotated by  $\theta$  radians in the ccw direction, its Fourier transform is also rotated by  $\theta$  radians in the Fourier plane, see Figure 9.21.

**FIGURE 9.20**

The polar and rectangle coordinates.

**FIGURE 9.21**

First row, left, the selected Fourier content of an image, right, its corresponding spatial waveform. Second row, left, the Fourier content is rotate ccw by 45°, right, its corresponding spatial waveform is also rotated ccw by 45°.

**Proposition 3.** Let the Fourier transform of  $f(\mathbf{x}) \in L^2(\mathcal{R}^2)$  be  $F(\Omega)$ , we have

$$F(R_\theta(\Omega)) = \int_{\mathcal{R}^2} f(R_\theta(\mathbf{x})) d\mathbf{x}. \quad (9.39)$$

### 1.09.3.1 The continuous curvelet transform

The continuous curvelet transform is defined as the inner product of a function with curvelet atoms at various dilating scales, rotating angles, and translating locations. It calculates the energy of the function correlated to each curvelet atom so that the frequency content of the function can be examined separately in each localized subband. At each scale, the curvelet atoms are generated from rotating a smooth 2-D window with compact support in its Frequency domain, and shifting its waveform in spatial domain to various locations. This window is called the mother curvelet at scale  $a$ , see Figure 9.22.

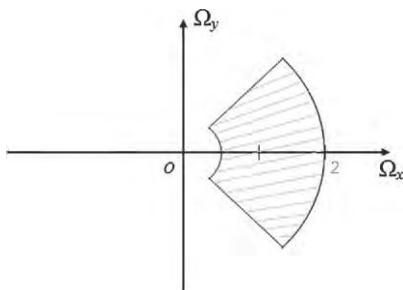

#### 1.09.3.1.1 The mother curvelets

At scale  $a$ , the Fourier transform of a mother curvelet is written as  $\Psi_a(\Omega_x, \Omega_y)$  in Cartesian coordinates, or  $\Psi_a(r, \sigma)$  in the polar coordinates. It is defined using two 1-D windows, along the radial and angular directions, and is given by

$$\Psi_a(r, \sigma) = a^{3/4} \Psi_1(ar) \Psi_2\left(\frac{\sigma}{\sqrt{a}}\right), \quad 0 < a \leq 1, \quad (9.40)$$

where the radial (or amplitude) window,  $\Psi_1(r)$ , is a smooth, bandpass, and non-negative real-valued function that has its support  $r \in [1/2, 2]$ . This interval is chosen for the convenience of using dyadic intervals for discretization. The angular (or phase) window,  $\Psi_2(\sigma)$ , is a smooth, lowpass, and non-negative real-valued even function that has its support  $\sigma \in [-1, 1]$ .

At scale  $a$ , the mother curvelet  $\Psi_a(r, \sigma)$  is constructed by scaling the two window functions,  $\Psi_1$  and  $\Psi_2$ , in two different ways. The support of this mother curvelet is a single polar wedge with an area of  $Const. \cdot a^{-3/2}$ , and is located inside  $\{(r, \sigma) : \frac{1}{2a} < r < \frac{2}{a}, |\sigma| < \sqrt{a}\}$ . It is symmetric with respect to the polar axis. The length of the wedge in the polar axis direction is at the same order as  $a^{-1}$ , and the larger arc length in the angular direction is at the same order as  $a^{-1/2}$ , see Figure 9.22. Approximately,

**FIGURE 9.22**

A mother curvelet window  $\Psi_a(\Omega)$  at scale  $a = 1$ .

the wedge has  $\text{width} \approx \text{length}^2$ . It can be observed that the mother curvelets at two different scales  $a, a'$ , with  $a \neq a'$ , have no scaling relation between them, so they differ slightly at various scales.

#### 1.09.3.1.2 The amplitude and angular windows

The choice of the amplitude and angular windows not only decides the properties of the mother curvelets, but also decides the properties of the curvelet atoms. The above construction shows that the curvelet windows have compact supports in the Fourier plane because both  $\Psi_1$  and  $\Psi_2$  have compact supports. Further, the following Proposition 4 [84] implies that their corresponding spatial waveforms  $\psi_1(x), \psi_2(t) \in C^\infty$ . Hence the mother curvelets are  $C^\infty$  in the spatial plane.

**Proposition 4.** *A function  $\psi(x)$  is bounded and  $n$  times continuously differentiable with bounded derivatives if its Fourier transform  $\Psi(\Omega_x)$  satisfies*

$$\int_{-\infty}^{+\infty} |\Psi(\Omega_x)|(1 + |\Omega_x|^n) d\Omega_x < +\infty. \quad (9.41)$$

The compact support of a mother curvelet in the Fourier plane indicates that the spatial waveform of the mother curvelet does not have a compact support in the spatial plane. Its waveform spreads out and is known as the side robe effects. To allow the curvelets to focus on localized areas in the spatial domain for detecting the singularities, the windows  $\Psi_1$  and  $\Psi_2$  should be chosen as smooth as possible in the Fourier plane so that their spatial waveforms decay rapidly. The rapid decay of a function is defined as, there exists a constant  $M_n$  such that, the following is true for all integer  $n > 0$  for  $f(\mathbf{x})$ ,

$$|f(\mathbf{x})| \leq \frac{M_n}{(1 + |\mathbf{x}|^n)}, \quad \forall \mathbf{x}. \quad (9.42)$$

Proposition 4 is also true for the inverse Fourier transform. If the spatial waveform of a mother curvelet decays fast, then it indicates that Fourier windows  $\Psi_1(r)$  and  $\Psi_2(\sigma)$  should be  $C^n$ . Therefore, the windows  $\Psi_1$  and  $\Psi_2$  should be smooth so they be  $n$  times continuously differentiable. In the literature, the windows are often required to be  $C^\infty$  to ensure the spatial functions decay rapidly.

At scale  $a$ , the mother waveform oscillates along the horizontal direction with most of its support located inside an ellipsoid shaped area along a ridge in the vertical direction. The ridge is defined as the (line) locations where the amplitude of a function reaches its maximum amplitude. This ellipsoid shape becomes “needle-like” shape when the scale  $a$  gets smaller. Namely, the area becomes longer and narrower.

Finally, the amplitude and angular windows  $\Psi_1$  and  $\Psi_2$  should satisfy the following admissibility conditions:

$$\int_0^\infty \frac{\Psi_1^2(r)}{r} dr = C_{\Psi_1}, \quad (9.43)$$

$$\int_{-1}^1 \Psi_2^2(\sigma) d\sigma = C_{\Psi_2}. \quad (9.44)$$

The admissibility conditions in Eqs. (9.43) and (9.44) can be normalized such that  $C_{\Psi_1} = 1$ , and  $C_{\Psi_2} = 1$ . Equation (9.43) indicates that  $\Psi_1(0) = 0$ , namely,  $\Psi_1(r)$  is the transfer function of a bandpass filter.

A continuously differentiable Fourier transfer function,  $\Psi_1$ , that satisfies  $\Psi_1(0) = 0$ , is sufficient to ensure that  $\Psi_1$  satisfies the admissibility condition in Eq. (9.43) [84]. The selection of the windows for constructing the curvelets will be further discussed in detail in the discrete case.

### 1.09.3.1.3 The curvelet atoms

**Definition 8.** A curvelet atom is referred to an element in the set  $\{\psi_{a,\theta,b}(x), x \in \mathcal{R}^2, a \in (0, 1], \theta \in [0, 2\pi), b \in \mathcal{R}^2\}$ . It can be defined as the inverse Fourier transform of a function,  $\Psi_{a,\theta,b}(\Omega)$ , as following

$$\Psi_{a,\theta,b}(\Omega) = \exp(-j \langle b, \Omega \rangle) \Psi_a(R_\theta \Omega), \quad (9.45)$$

where  $\Psi_a(\Omega)$  is a mother curvelet. The polar coordinate format of  $\Psi_a(R_\theta \Omega)$  is equal to  $\Psi_a(r, \sigma + \theta)$ .

Specifically, at scale  $a$ , the curvelet atom at  $\theta = 0, b = (0, 0)$  (we usually use  $\mathbf{0} = (0, 0)$ ) is the mother curvelet because

$$\Psi_{a,0,\mathbf{0}}(\Omega) = \Psi_a(\Omega). \quad (9.46)$$

The spatial waveform of the curvelet atom,  $\psi_{a,\theta,b}(x)$ , takes a complex value, and can be written in terms of a mother curvelet as,

$$\psi_{a,\theta,b}(x) = \psi_{a,0,\mathbf{0}}(x)(R_\theta(x - b)), \quad a \in (0, 1], \theta \in [0, 2\pi), b \in \mathcal{R}^2. \quad (9.47)$$

Figure 9.21 shows two curvelet atoms (in both Fourier and spatial planes) at different orientations. Although complex valued curvelet atoms are capable of separating the amplitude and the phase information contained in a 2-D function, in many situations the real-valued curvelet atoms can be built by modifying the mother curvelet windows, namely, replacing the radial window  $\Psi_1(r)$  with  $\Psi_{R,1}(r) = \Psi_1(r) + \Psi_1(-r)$ , or replacing the angular window  $\Psi_2(\sigma)$  with  $\Psi_{R,2}(\sigma) = \Psi_2(\sigma) + \Psi_2(\sigma + \pi)$ . It results in mother curvelets supported on two polar wedges that are symmetric with respect to the  $x, y$  axes in the rectangle coordinates. Figure 9.23 shows the frequency support (the gray area) of a mother curvelet that generates complex-valued curvelet atoms in spatial domain, while Figure 9.24 shows the frequency support of a mother curvelet that generates real-valued curvelet atoms.

The curvelet atoms generated by the mother curvelets dissect the Fourier plane into localized subbands so that the Fourier plane is packed redundantly with all the dilated and rotated curvelet atoms. Note that shifting in the spatial plane has no effect on the amplitude of the content in the Fourier plane.

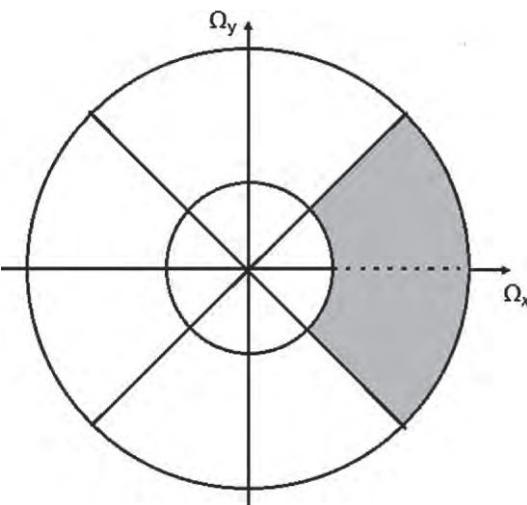

### 1.09.3.1.4 The definition of continuous curvelet transform

**Definition 9.** Let  $f(x) \in L^2(\mathcal{R}^2)$ , and let  $\{\psi_{a,\theta,b}(x)\}_{a \in (0, 1], \theta \in [0, 2\pi), b \in \mathcal{R}^2}$  be the families of curvelet atoms defined above. The continuous curvelet transform, see Figure 9.25, is defined as

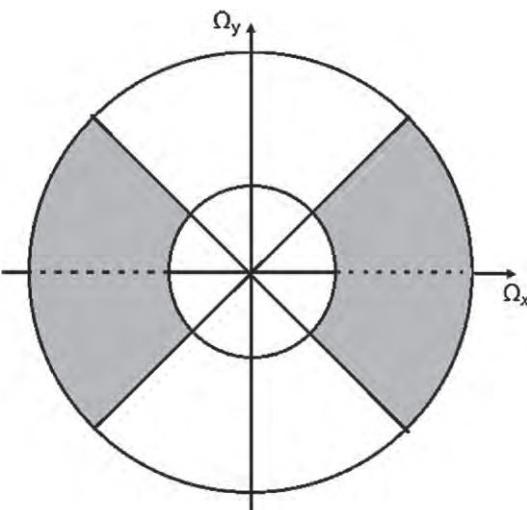

$$C_f(a, \theta, b) = \langle f, \psi_{a,\theta,b} \rangle = \int_{\mathcal{R}^2} f(x) \psi_{a,\theta,b}^*(x) dx, \quad (9.48)$$

where  $\{C_f(a, \theta, b), a \in (0, 1], \theta \in [0, 2\pi), b \in \mathcal{R}^2\}$  are called the curvelet coefficients of the function  $f(x)$ .

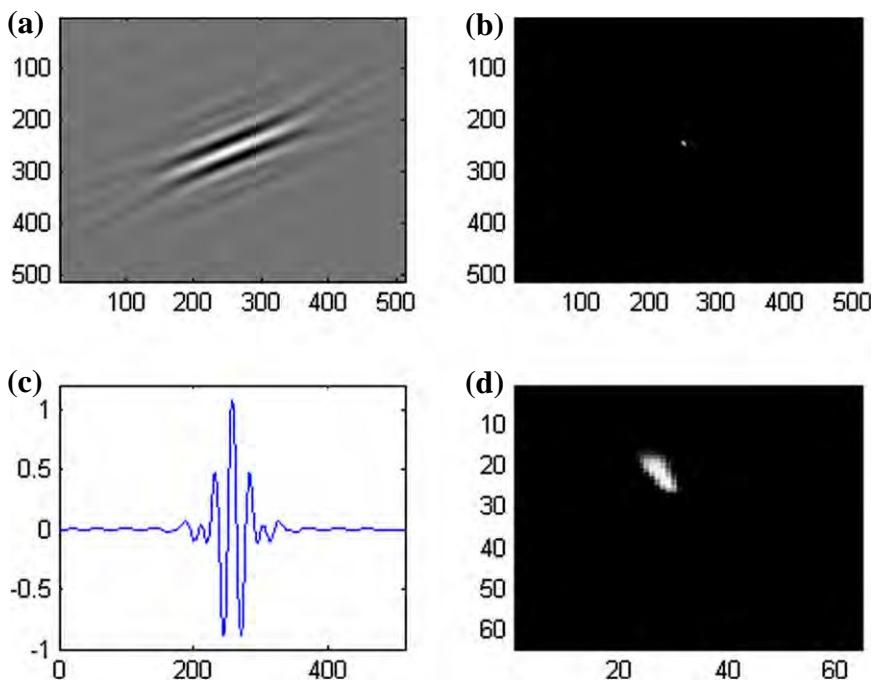

Note that here we mentioned the families of curvelet atoms. This is because each mother curvelet at scale  $a$  generates a family of curvelet atoms. The curvelet transform projects a 2-D function into the

**FIGURE 9.23**

Shown here is a mother curvelet that generates a family of complex valued curvelets. The mother curvelet has its frequency content supported in a single wedge, represented by the gray area.

**FIGURE 9.24**

Shown here is a mother curvelet that generates a family of real-valued curvelets. The mother curvelet has its frequency content supported in a pair of symmetric wedge, represented by the gray area.

**FIGURE 9.25**

(a) The real part of a wavelet atom in the spatial space. (b) The Fourier transform of the wavelet atom shown. (c) The graph of oscillatory function along  $\theta$  direction taken from the real part of the wavelet atom. In this picture, the horizontal direction is the pixel location along  $\theta$ , the vertical direction is the function's value. (d) The Fourier transform from (b) is zoomed to the center  $64 \times 64$  pixels for a better view of the content. The pixels size is shown in (a, b, d).

families of curvelet atoms to receive a series of decomposed coefficients. Each coefficient reflects the correlation between the function and a curvelet atom focusing inside a localized area. Typically, the curvelet coefficients are calculated in the Fourier plane using the following result, which is the Parseval's formula.

**Proposition 5.** *The curvelet transform can be calculated in the Fourier plane as,*

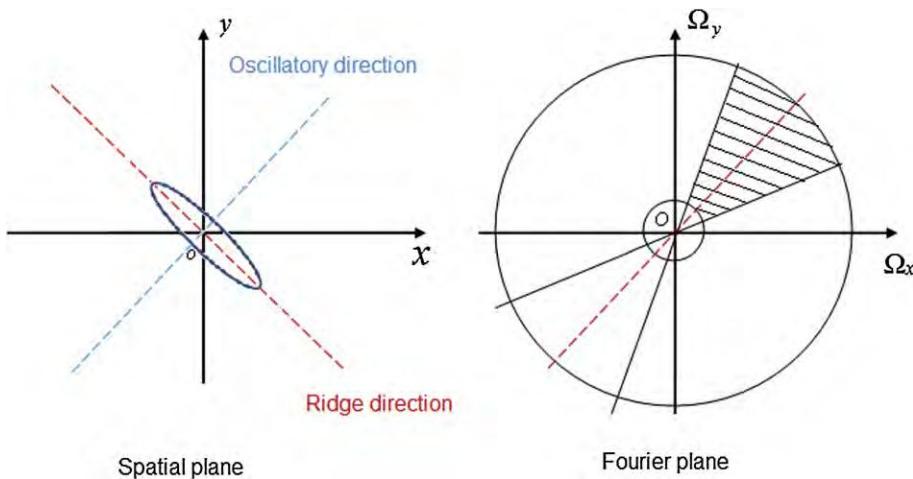

$$C_f(a, \theta, \mathbf{b}) = \langle F, \Psi_{a,\theta,\mathbf{b}} \rangle = \frac{1}{(2\pi)^2} \int_{\mathcal{R}^2} F(\Omega_x, \Omega_y) \Psi_{a,\theta,\mathbf{b}}^*(\Omega_x, \Omega_y) d\Omega_x d\Omega_y, \quad (9.49)$$

for  $a \in (0, 1]$ ,  $\theta \in [0, 2\pi)$ ,  $\mathbf{b} \in \mathcal{R}^2$ .

#### 1.09.3.1.5 The properties of the curvelet transform

The vanishing moments and the oscillatory behavior

In the classical wavelet theory, a wavelet with  $n$  vanishing moments has been interpreted as a multiscale differential operator of order  $n$ . A similar concept can be extended to the curvelets in parallel. A mother

**FIGURE 9.26**

A curvelet atom in its spatial plane and Fourier plane.

curvelet  $\psi_{a,0,\mathbf{0}}$  is said to have  $q$  vanishing moments if its waveform in spatial plane satisfies

$$\int_{-\infty}^{\infty} \psi_{a,0,\mathbf{0}}(x, y) x^n dx = 0, \quad \text{for all } 0 < n \leq q. \quad (9.50)$$

The curvelet windows we selected can have infinitely many vanishing moments as Eq. (9.50) is satisfied for any  $q$ .

The curvelet window that has infinitely many vanishing moments ensures that the coefficients of a smooth image function tend to zero when a mother curvelet is centered at  $\mathbf{x}$ . In the spatial plane, a rotated curvelet atom with oscillatory direction at  $\theta$  radians, if shifted to the spatial location  $\mathbf{b} \in \mathbb{R}^2$ , plays the role of an angular differential operator in a localized area centered at  $\mathbf{b}$ , to measure the regularity along the orientation, see Figure 9.26. This area is referred to as the ellipse support area. If an image function satisfies a localized Lipschitz regularity along the radial direction at location  $\mathbf{x}$ , then a polynomial can be used to approximate the image function in a localized area. The aforementioned infinitely many vanishing moments of the curvelet windows will therefore lead to many curvelet coefficients tending to zero.

### The decay rate of the curvelet coefficients

As we mentioned above, the requirement for infinitely many vanishing moments ensures that the curvelets decay rapidly in the spatial domain. A curvelet coefficient therefore measures the correlation between a function and a curvelet atom focusing in its ellipse support area over the spatial support. The resulting coefficients may be classified into the following three cases [7]:

1. The magnitude of a curvelet coefficient tends to zero if the ellipse support of the curvelet atom does not intersect with a singularity of the function.
2. The magnitude of a curvelet coefficient tends to zero if the ellipse support of the curvelet atom intersects with a singularity, but its ridge direction is not oriented at the tangential direction of a curve.

3. The magnitude of a curvelet coefficient decays slowly if the ellipse support of the curvelet atom intersects with a discontinuity, and it is ridge is oriented along the tangential direction of the curve where the singularities are located. More precisely, the curvelet oscillates along the normal direction of the curve to measure the regularities in a local area centered at  $\mathbf{b}$ .

#### 1.09.3.1.6 The reproducing formula

Similarly to the classical wavelets, the admissibility conditions, Eqs. (9.43) and (9.44), ensure that all the curvelet atoms cover the Fourier plane completely, so the curvelet transform is a redundant representation of a function that can be perfectly reconstructed.

**Theorem 1.** *If the Fourier Transform of a highpass function  $f \in L^2(\mathcal{R}^2)$  vanishes (equal to 0) for  $|\Omega| < 2/a_0$ , this function can be perfectly reconstructed from the curvelet coefficients according to the following Calderon-like reproducing formula:*

$$f(\mathbf{x}) = \int_0^{2\pi} \int_0^{a_0} \int_{\mathcal{R}^2} C_f(a, \theta, \mathbf{b}) \psi_{a, \theta, \mathbf{b}}(\mathbf{x}) \frac{d\mathbf{b}}{a^{1/2}} \frac{da}{a^{3/2}} \frac{d\theta}{a}. \quad (9.51)$$

The proof of this theorem is deferred to [7].

This reproducing formula can be extended to reconstruct any function  $f \in L^2(\mathcal{R}^2)$  that includes both low frequency and high frequency components. To do so, we can introduce a scaling function,  $\phi(\mathbf{x})$ , the so-called father curvelet, through its Fourier Transform,  $\Phi(\Omega)$ , given by,

$$\Phi^2(\Omega) = 1 - \Psi^2(\Omega), \quad \text{where } \Psi^2(\Omega) = \int_0^{a_0|\Omega|} |\Psi_1(r)|^2 \frac{dr}{r}. \quad (9.52)$$

The function  $\Phi(\Omega)$  can be viewed as an aggregation of curvelets at scales greater than  $a_0$ , written as

$$\Phi(\Omega) = \int_{a_0}^{+\infty} \frac{|\Psi_1(r|\Omega)|^2}{r} dr = \int_{a_0|\Omega|}^{+\infty} \frac{|\Psi_1(r)|^2}{r} dr \quad (9.53)$$

and may further be written as

$$\Phi(\Omega) = \begin{cases} 1 & |\Omega| \leq 1/(2a_0), \\ (1 - \Psi^2(\Omega))^{1/2} & 1/(2a_0) < |\Omega| < 2/a_0, \\ 0 & |\Omega| \geq 2/a_0. \end{cases}$$

Note that  $a_0$  is limited to  $0 < a_0 \leq 1$ , it is typically set to  $a_0 = 1$  as in the following.

The high frequency content in  $\Phi(\Omega)$  equaling zero indicates that the father curvelet is the impulse response of a lowpass frequency filter. Shifting the father curvelet  $\phi(\mathbf{x})$  builds the shifting atoms  $\phi_b(\mathbf{x}) = \phi(\mathbf{x} - \mathbf{b})$ ,  $\mathbf{b} \in \mathcal{R}^2$ . It can be seen that the father curvelet is isotropic and is not scaled. It only produces an atom that is shifted to spatial location  $\mathbf{b}$ .

**Theorem 2.** *Any  $f \in L^2(\mathcal{R}^2)$  can be reproduced as*

$$f(\mathbf{x}) = \int_{\mathcal{R}^2} \langle \phi_b, f \rangle \phi_b(\mathbf{x}) d\mathbf{b} + \int_0^1 \int_0^{2\pi} \int_{\mathcal{R}^2} C_f(a, \theta, \mathbf{b}) \psi_{a, \theta, \mathbf{b}}(\mathbf{x}) \frac{d\mathbf{b}}{a^{3/2}} \frac{da}{a} \frac{d\theta}{a^{1/2}} \quad (9.54)$$

and it satisfies the Plancherel's formula

$$\|f(\mathbf{x})\|_2^2 = \int_{\mathcal{R}^2} \langle \phi_b, f \rangle^2 d\mathbf{b} + \int_0^1 \int_0^{2\pi} \int_{\mathcal{R}^2} |C_f(a, \theta, \mathbf{b})|^2 \frac{d\mathbf{b}}{a^{3/2}} \frac{da}{a} \frac{d\theta}{a^{1/2}}. \quad (9.55)$$

The term  $\frac{d\mathbf{b}}{a^{3/2}} \frac{da}{a} \frac{d\theta}{a^{1/2}}$  may be viewed as the reference measure in the parameter space of  $(a, \theta, \mathbf{b})$ . It suggests that the curvelets use anisotropic measuring of the unit cell in the space of  $(a, \theta, \mathbf{b})$ . This theorem ensures that both the curvelets and the classical wavelets can be decomposed into a low frequency component and a combination of detail components. The polar wedge shaped curvelet windows in the frequency domain outperform the classical wavelet in 2-D case, as it allows one to study 2-D functions by measuring the energy inside the windows oriented along selective orientations to efficiently identify the regularities.

### 1.09.3.2 The discrete curvelet transform

The continuous curvelets can be sampled along its scale, rotation, and translation parameters to form a pyramid of discrete curvelets for numerical computation. A tight frame can be adopted for efficiency so that a 2-D function may be projected onto the discrete curvelet frame with the least number of large coefficients. Here only one tight frame is introduced. First we introduce the window functions to be used in generating the curvelets.

#### 1.09.3.2.1 The selection of windows

As we mentioned earlier, the mother curvelets are primarily defined by two window functions,  $\Psi_1$  and  $\Psi_2$ . A good choice is the Meyer wavelet windows in the Fourier domain. Figure 9.27 shows the highpass and lowpass windows that are orthogonal and overlapping. The lowpass window in the 1-D Fourier domain may be used as the angular window,  $\Psi_2(\sigma)$ , and is defined as

$$\Psi_2(\sigma) = \begin{cases} 1 & |\sigma| \leq 1/3, \\ \cos\left(\frac{\pi}{2}\beta(3|\sigma| - 1)\right) & 1/3 < |\sigma| \leq 2/3, \\ 0 & |\sigma| > 2/3. \end{cases} \quad (9.56)$$

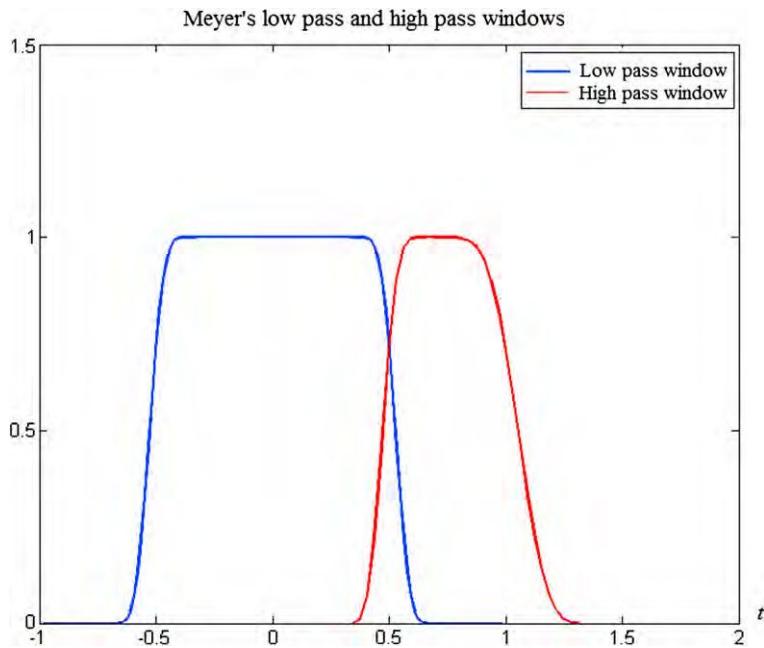

The highpass window in the 1-D Fourier domain may also be used as the radial window  $\Psi_1(r)$  and is defined as

$$\Psi_1(r) = \begin{cases} 0 & |r| \leq 2/3, \text{ and } |r| \geq 8/3, \\ \sin\left(\frac{\pi}{2}\beta\left(\frac{3|r|}{2} - 1\right)\right) & 2/3 < |r| \leq 4/3, \\ \cos\left(\frac{\pi}{2}\beta\left(\frac{3|r|}{4} - 1\right)\right) & 4/3 < |r| < 8/3, \end{cases}$$

where  $\beta(x)$  is any smooth function that defines the transition bands. It is defined on  $[0, 1]$  and satisfies

$$\beta(x) + \beta(1 - x) = 1, \quad x \in \mathcal{R}. \quad (9.57)$$

The following admissibility conditions ensure that the discretized curvelet atoms generated from these windows can completely cover the Fourier plane.

**FIGURE 9.27**

The Meyer's wavelet windows: lowpass  $\Psi_2(t)$ , in blue color, and highpass  $\Psi_1(t)$ , in red color, only its component in the positive axis is shown here. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this book.)

**Proposition 6.** *On a discrete scale, the two windows,  $\Psi_1$  and  $\Psi_2$  selected above, satisfy the following admissibility conditions,*

$$\sum_{k=-\infty}^{\infty} |\Psi_1(2^{-k}r)|^2 = 1, \quad r > 0, \quad (9.58)$$

$$\sum_{l=-\infty}^{\infty} |\Psi_2(\sigma - l)|^2 = 1, \quad \sigma \in \mathcal{R}. \quad (9.59)$$

The proof of the proposition only needs to be shown in the overlapped regions between two adjacent windows; for example, for  $\Psi_1(r)$ , when  $r \in (2/3, 3/4)$ , we have

$$\begin{aligned} \sum_{k=-\infty}^{\infty} |\Psi_1(2^{-k}r)|^2 &= |\Psi_1(r)|^2 + |\Psi_1(2r)|^2 = \sin^2\left(\frac{\pi}{2}\beta\left(\frac{3|r|}{2} - 1\right)\right) \\ &\quad + \cos^2\left(\frac{\pi}{2}\beta\left(\frac{3|2r|}{4} - 1\right)\right) = 1. \end{aligned} \quad (9.60)$$

Refer to [85] for details of the proof for a different set of window functions. Note that Eq. (9.59) is the same as Eq. (9.44), while Eq. (9.58) is similar to Eq. (9.43) for the continuous case when  $C_{\Psi_1} = \ln 2$ . The selected windows can be scaled to fit  $\text{supp}\{\Psi_1(r)\} = [1/2, 2]$ , and  $\text{supp} \Psi_2(\sigma) = [-1, 1]$ .

The discretized windows are used in the following to build the discrete curvelet atoms. Meanwhile, the coarse scale father curvelet window can be defined as the lowpass window  $\Phi(r)$  in the radial direction which satisfies

$$|\Phi(r)|^2 + \sum_{k \geq 0} |\Psi_1(2^{-k}r)|^2 = 1. \quad (9.61)$$

The choice of  $\beta(x)$  determines the transition band of the Meyer window. The definition of the  $\beta(x)$ , for example, can be chosen as

$$\beta(x) = x^4(35 - 84x + 70x^2 - 20x^3), \quad (9.62)$$

the resulting windows  $\Psi_1$  and  $\Psi_2$  are  $C^3$ . **Or**

$$\beta(x) = x^3(5 - 5x + x^2), \quad (9.63)$$

the resulting windows  $\Psi_1$  and  $\Psi_2$  are  $C^2$ . **Or**

$$\beta(x) = x^2(3 - 2x), \quad (9.64)$$

the resulting windows  $\Psi_1$  and  $\Psi_2$  are  $C^1$ . The 1-D window  $\Psi_1$  has infinitely many vanishing moments in the parameter  $r$  because  $\Psi_1(r) = 0$  for  $|r| < 2/3$ . The mother curvelets constructed from the windows  $\Psi_1$  and  $\Psi_2$  should have infinitely many moments too [83, 85].

### 1.09.3.2.2 Constructing a tight frame of curvelet atoms

Now we are to construct a tight Parseval curvelet frame by sampling the continuous curvelets. With a tight frame, the whole Fourier plane can be covered with discrete curvelet atoms with minimum overlap, and the following equation is satisfied,

$$\sum_{n \in \Gamma} |\langle f, \psi_n \rangle|^2 = C \|f\|_2^2. \quad (9.65)$$

The three parameters  $(a, \theta, b)$  will be sampled in order to obtain a tight frame. First, at each scale  $k$ , the radial scale is sampled on a dyadic interval at  $a_k = 2^{-k}$ ,  $k \geq 0$ , resulting in the selection of the mother curvelet,  $\psi_{k,0,0}$ , defined as the inverse Fourier transform of  $\Psi_{k,0,0}(r, \sigma)$ .  $\Psi_{k,0,0}(r, \sigma)$  is defined using the polar coordinates as,

$$\Psi_{k,0,0}(r, \sigma) = \begin{cases} \Psi_1(2^{-k} \cdot r) \Psi_2\left(\frac{2^{(k+2)/2}\sigma}{\pi}\right) 2^{-3k/4}, & k \text{ is an even integer,} \\ \Psi_1(2^{-k} \cdot r) \Psi_2\left(\frac{2^{(k+1)/2}\sigma}{\pi}\right) 2^{-3k/4}, & k \text{ is an odd integer.} \end{cases}$$

Second, the rotation angular parameter is sampled at  $\theta_{k,l}$ , given as

$$\theta_{k,l} = \begin{cases} \pi l 2^{-(k+2)/2}, & k \text{ is an even integer, } 0 \leq l \leq 2^{\frac{(k+2)}{2}+1} - 1, \\ \pi l 2^{-(k+1)/2}, & k \text{ is an odd integer, } 0 \leq l \leq 2^{\frac{(k+1)}{2}+1} - 1. \end{cases}$$

For example, at  $k = 0$  and  $k = 1$ ,  $\theta_{k,l} = \frac{\pi}{2}l$ ,  $l = 0, 1, 2, 3$ ; at  $k = 2$  and  $k = 3$ ,  $\theta_{k,l} = \frac{\pi}{4}l$ ,  $l = 0, 1, 2, \dots, 7$ . It can be deduced that

$$\sum_{l=0}^{2^{\frac{(k+2)}{2}+1}-1} \left| \Psi_2 \left( \frac{2^{(k+2)/2}(\sigma + \theta_{k,l})}{\pi} \right) \right|^2 = 1, \quad \text{for } k \text{ is an even integer} \quad (9.66)$$

and

$$\sum_{l=0}^{2^{\frac{(k+1)}{2}+1}-1} \left| \Psi_2 \left( \frac{2^{(k+1)/2}(\sigma + \theta_{k,l})}{\pi} \right) \right|^2 = 1, \quad \text{for } k \text{ is an odd integer.} \quad (9.67)$$

This results in the discrete curvelet atoms,

$$\psi_{k,l,b}(\mathbf{x}) = \psi_{k,0,0}(R_{\theta_{k,l}}(\mathbf{x} - \mathbf{b})) \quad (9.68)$$

Finally, the parameter  $\mathbf{b}$  is sampled at

$$\mathbf{b}_s^{k,l} = R_{\theta_{k,l}}^{-1}(s_1 2^{-k}, s_2 2^{-k/2}),$$

where the  $\mathbf{b}_s^{k,l}$  is the grids defined by rotating the dyadic points by an angle  $\theta_{k,l}$ . The discrete curvelet atoms are given as,

$$\psi_{k,l,s}(\mathbf{x}) = \psi_{k,0,0}(R_{\theta_{k,l}}(\mathbf{x} - \mathbf{b}_s^{k,l})), \quad s = (s_1, s_2). \quad (9.69)$$

This curvelet frame consists of interleaved curvelet atoms, separately selected from the samplings of two adjacent scales, the even and odd scales. Under this tight frame, the discrete curvelet transform coefficients are given by

$$Cf_{k,l,s} = \langle f, \psi_{k,l,s} \rangle. \quad (9.70)$$

The coefficients are calculated in the Fourier plane using the following formula based on the mother curvelet:

$$Cf_{k,l,s} = \frac{1}{(2\pi)^2} \int_{\mathcal{R}^2} F(\Omega) \Psi_k^*(R_{\theta_{k,l}}(\Omega)) e^{j\langle \mathbf{b}_s^{k,l}, \Omega \rangle} d\Omega. \quad (9.71)$$

**Theorem 3.** For a highpass function  $f \in L^2(\mathcal{R}^2)$ , Eqs. (9.58), (9.66), (9.67) guarantee that a reproducing formula can be obtained by

$$f = \sum_k \sum_l \sum_{s=(s_1,s_2) \in \mathcal{R}^2} Cf_{k,l,s} \psi_{k,l,s}, \quad (9.72)$$

and the energy conservation is maintained.

$$\|f\|_2^2 = \sum_k \sum_l \sum_{s=(s_1,s_2) \in \mathcal{R}^2} |Cf_{k,l,s}|^2. \quad (9.73)$$

Meanwhile, if we add the father curvelet  $\phi_b(x)$  into the frame, calculate the father curvelet coefficients from the inner product between functions  $\phi_b(x)$  and  $f$ , and put both with the curvelet coefficients, and we still write them as  $Cf_{k,l,s}$ , then, any function in  $L^2(\mathcal{R}^2)$  can be reconstructed from the integrated families of the curvelet atoms, and resulting in the same formulas of Eqs. (9.72) and (9.73).

Under this curvelet tight frame, Candès and Donoho [5] have proved the following theorem, which estimates the approximation error under the curvelets coefficients. It shows a faster convergence rate than that using the classical wavelets in 2-D.

**Theorem 4.** *Let  $f(x)$  be a twice differentiable function in  $\mathcal{R}^2$  except at discontinuities along a  $C^2$  curve. Let  $f_N^C$  be the  $N$ -term approximation of  $f$  reconstructed from using the  $n$  largest curvelet coefficients obtained by simple thresholding. The approximation error follows:*

$$\left\| f - f_N^C \right\|_2^2 \leq CN^{-2}(\log N)^3.$$

The proof can be found in [5].

#### 1.09.3.2.3 Implementation procedure for discrete curvelet transform

The discrete curvelet transform is implemented using a lowpass filter  $P_0$ , together with a set of passband filters  $\Delta_1, \Delta_2, \dots, \Delta_s$ . This bank of filters partition the whole frequency plane into  $s+1$  decompositions that are concentrated, and are located near certain frequencies in a sequence of dyadic intervals. Indeed, in the digital curvelet implementation, this bank of filters are generated using concentric squares instead of concentric circles.

To generate the concentric squares, see Figure 9.28, a lowpass filter at scale  $k$  is first generated using a smooth Meyer window,  $\Phi(r)$ , following Eq. (9.56), as

$$\Phi_k(\Omega_x, \Omega_y) = \Phi(2^{-k}\Omega_x)\Phi(2^{-k}\Omega_y). \quad (9.74)$$

The  $P_0$  refers to the window when  $k = 0$ . Then the bandpass filters  $\Delta_k$  corresponding to bandpass window functions,  $\Psi_{1,k}(\Omega_x, \Omega_y)$ , are defined as

$$\Psi_{1,k}(\Omega_x, \Omega_y) = \sqrt{\Phi_{k+1}^2(\Omega_x, \Omega_y) - \Phi_k^2(\Omega_x, \Omega_y)}, \quad k \geq 0.$$

The angular window  $\Psi_{2,k}(\Omega_x, \Omega_y)$  in the Cartesian plane is also defined using the function  $\Psi_2(\sigma)$  in Eq. (9.56),

$$\Psi_{2,k}(\Omega_x, \Omega_y) = \begin{cases} \Psi_2\left(\frac{2^{k/2}\Omega_y}{\Omega_x}\right) & k \text{ is an even integer,} \\ \Psi_2\left(\frac{2^{(k-1)/2}\Omega_y}{\Omega_x}\right) & k \text{ is an odd integer.} \end{cases}$$

The mother curvelet at scale  $k$  can be obtained in the Fourier domain as,

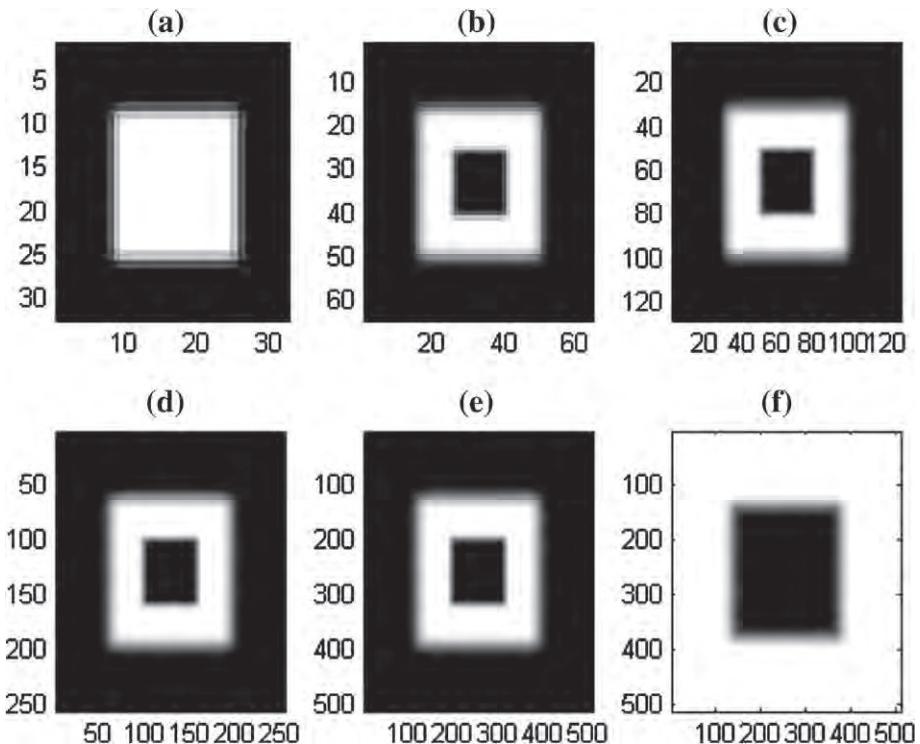

$$\Psi_k(\Omega) = 2^{-3k/4}\Psi_{1,k}(\Omega)\Psi_{2,k}(\Omega), \quad \Omega = (\Omega_x, \Omega_y).$$

The curvelet atoms at  $b = 0$  can be obtained in the Fourier domain as,

$$\Psi_{k,l}(\Omega) = \Psi_k(S_{\theta_{k,l}}^{-1}\Omega) = 2^{-3k/4}\Psi_{1,k}(\Omega)\Psi_{2,k}\left(S_{\theta_{k,l}}^{-1}(\Omega)\right), \quad \Omega = (\Omega_x, \Omega_y),$$

where  $S_{\theta_{k,l}}$ , is the shear matrix, with its inverse  $S_{\theta_{k,l}}^{-1}$ . Both matrices are given as

$$S_{\theta_{k,l}} = \begin{pmatrix} 1 & 0 \\ -\tan(\theta_{k,l}) & 1 \end{pmatrix} \quad \text{and} \quad S_{\theta_{k,l}}^{-1} = \begin{pmatrix} 1 & 0 \\ \tan(\theta_{k,l}) & 1 \end{pmatrix}.$$

**FIGURE 9.28**

Shown here are windows at several scales, namely the window at (a) The low frequency level. (b)  $k = 1$  level. (c)  $k = 2$  level. (d)  $k = 3$  level. (e)  $k = 4$  level. (f) The remaining high frequency at  $k = 4$  level. Note that number of pixels in  $x, y$  direction is shown for each image because of the different size of the window at different scale.

The selection of  $\theta_{k,l}$  is defined through

$$\tan(\theta_{k,l}) = \begin{cases} l \cdot 2^{-k/2} & k \text{ is an even integer, } l = -2^{k/2}, \dots, 2^{k/2} - 1, \\ l \cdot 2^{-(k-1)/2} & k \text{ is an odd integer, } l = -2^{(k-1)/2}, \dots, 2^{(k-1)/2} - 1. \end{cases}$$

The  $\Psi_{k,l}(\Omega_x, \Omega_y)$  indeed defines the Cartesian approximation of the curvelet atoms in the polar Fourier plane along the horizontal cone direction. Rotating this system by  $\pi/2$  defines the Cartesian approximation along the vertical cone direction. The two systems together define the Cartesian approximation of the curvelet atoms [83, 86, 87]. Using the discretized curvelet atoms, the Curvelab software [88] calculates the discrete curvelet coefficients using two different approaches, the unequispaced FFTs (USFFT), and the Wrapping methods. It is believed that the Wrapping method is simpler to understand. Here we summarize the two implementation procedures in the following.

### The unequispaced FFTs (USFFT) method

The USFFT implements the method that carries out the operation of shearing a curvelet atom to shearing  $F$  according to the following formula:

$$\begin{aligned} C_f(k, l, s) &= \frac{1}{(2\pi)^2} \int_{\mathcal{R}^2} F(\Omega) \Psi_k(S_\theta^{-1}\Omega) \exp\left(j \langle S_\theta^{-T} \mathbf{b}, \Omega \rangle\right) d\Omega_x d\Omega_y \\ &= \frac{1}{(2\pi)^2} \int_{\mathcal{R}^2} F(S_\theta \Omega) \Psi_k(\Omega) \exp(j \langle \mathbf{b}, \Omega \rangle) d\Omega_x d\Omega_y \end{aligned} \quad (9.75)$$

with  $\theta = \theta_{k,l}$ ,  $\mathbf{b} \simeq (s_1 2^{-k}, s_2 2^{-k/2})$ . Note that  $\Psi_k(\Omega)$  is a real valued function, therefore  $\Psi_k^*(\Omega) = \Psi_k(\Omega)$  is used in Eq. (9.75). The procedure for implementing the USFFT to calculate the discrete curvelet coefficients is summarized in the following, for more details, refer to [83, 86].

1. Apply a 2-D FFT to a function  $f(\mathbf{x})$ , and obtain its discrete Fourier samples  $F(n_1, n_2)$ ,  $0 < n_1, n_2 \leq N$ , where  $N$  is the sample size.
2. For each scale/angle pair  $(k, l)$ , resample (or interpolate)  $F(n_1, n_2)$  to obtain sheared sample values, written as  $F(n_1, n_2 - n_1 \tan \theta_{k,l})$  for  $(n_1, n_2) \in R_k$ . The  $R_k$  is a rectangle of  $Length = 2^k$ ,  $Width = 2^{k/2}$ , that is at the center of the bandpass content of the mother curvelet at scale  $k$ .
3. Multiply the resampled  $F$  with the mother curvelet window  $\Psi_{k,l}$ , we have  $Cf_{k,l}(n_1, n_2) = F(n_1, n_2 - n_1 \tan \theta_{k,l}) \Psi_{k,l}(n_1, n_2)$ .
4. Apply an inverse 2-D FFT to each  $Cf_{k,l}(n_1, n_2)$  obtained in the previous step to calculate the discrete curvelet coefficients  $C_f(k, l, s)$ .

In Curveletlab [88], the following package in MATLAB is used to decompose the original image into curvelet coefficients:

```
% is_real      Type of the transform
%           0: complex-valued curvelets
%           1: real-valued curvelets
Curveletcoef = fdct_usfft (X,is_real);
```

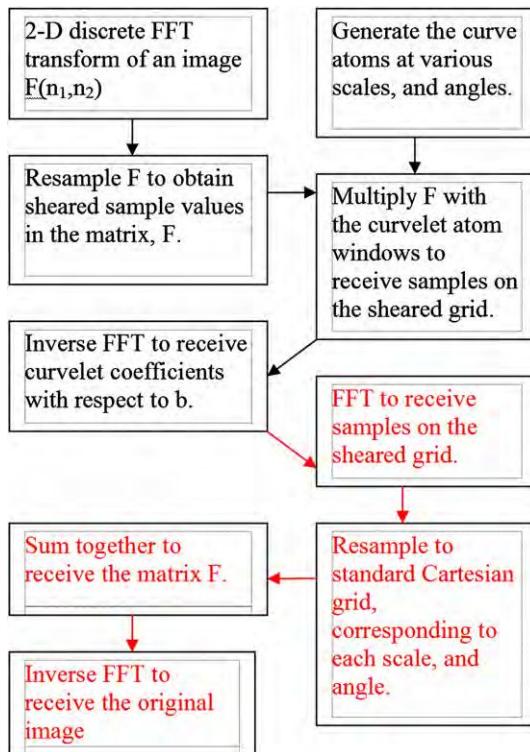

The inverse curvelet transform is simply computed by “reversing” all the operations of the direct transform, with some adjustments:

1. For each scale/angle pair  $(k, l)$ , perform a (properly normalized) 2-D FFT of each curvelet coefficient array  $C_f(k, l, s)$ , to obtain  $(Cf)_{k,l}(n_1, n_2)$  in  $\Psi_{k,l}$ .
2. The  $(Cf)_{k,l}(n_1, n_2)$  should be viewed as samples on the sheared grid. Resample them back to the standard Cartesian grid.
3. Integrate  $(Cf)_{k,l}(n_1, n_2)$  from all scales and angles together. This recovers  $F(n_1, n_2)$ .
4. Take a 2-D inverse FFT to obtain  $f(x, y)$ .

Figure 9.29 provides the diagram for implementing the USFFT curvelet transform and its inverse transform.

In Curveletlab, the following package in MATLAB is used to reconstruct the original image from the curvelet coefficients with syntax as:

```
Y = ifdct_usfft(C,is_real);
```

**FIGURE 9.29**

The USFFT curvelet transform diagram (in black color) and its inverse transform (in red color). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this book.)

The computational cost for the forward and inverse transform requires about  $O(n^2 \log n)$  operations, and  $O(n^2)$  memory storage.

### The wrapping method

The Wrapping is implemented by using the following formula to calculate the curvelet coefficients:

$$C_f(k, l, s) = \frac{1}{(2\pi)^2} \int_{\mathcal{R}^2} F(\Omega) \Psi_k(S_\theta^{-1}(\Omega)) \exp(j \langle \mathbf{b}, \Omega \rangle) d\Omega_x d\Omega_y.$$

Note that the  $S_\theta^{-1}\mathbf{b}$  in Eq. (9.75) is replaced by  $\mathbf{b}$  that takes its value on the rectangle grid. In this method, the curvelet atoms,  $\Psi_{k,l} = \Psi_k(S_{\theta_{k,l}}^{-1}(\Omega))$ , should be obtained by applying the shear operation  $S_{\theta_{k,l}}^{-1}$  to the rectangle  $R_k$  as in the USFFT method. The resulting window should be a trapezoidal shaped region.

The following is the procedure for implementing the Wrapping technique to calculate the discrete curvelet coefficients,

1. Calculate the 2-D FFT of an image  $f(x)$  to obtain the Fourier samples  $F(n_1, n_2)$ .

2. For  $(k, l)$ , decompose  $F(n_1, n_2)$  into each curvelet window by calculating  $F(n_1, n_2)\Psi_{k,l}(n_1, n_2)$ .
3. Perform wrapping in this stage, namely, wrap this product around the origin in the Fourier plane. This is done by relabeling the samples.
4. Apply the inverse 2-D FFT to the wrapped  $F(n_1, n_2)$  to calculate the discrete curvelet coefficients  $C_f(k, l, s)$ .

In Curveletlab, the following package is used to calculate the curvelet coefficients using the wrapping method with syntax as:

```
Curveletcoefwrp = fdct_wrapping(X, 0).
```

The inverse curvelet transform is computed as

1. For each  $(k, l)$ , perform a properly normalized 2-D FFT of each curvelet coefficient array  $C_f(k, l, s)$ , to obtain  $(Cf)_{k,l}(n_1, n_2)$  in  $\Psi_{k,l}$ .
2. For each  $(k, l)$ , multiply the array of the coefficients by the corresponding wrapped curvelet  $\Psi_{k,l}(n_1, n_2)$  which gives  $(|\Psi_{k,l}|^2 F)(n_1, n_2)$ .
3. Unwrap each array  $(|\Psi_{k,l}|^2 F)[n_1, n_2]$ . with  $\Psi_{k,l}(n_1, n_2)$  on the frequency grid and integrate them all to form  $F(n_1, n_2)$ .
4. Finally, take a 2-D inverse FFT of  $F(n_1, n_2)$  to obtain  $f(x, y)$ .

In Curveletlab, the following package is used to reconstruct the original image from the curvelet coefficients with syntax as:

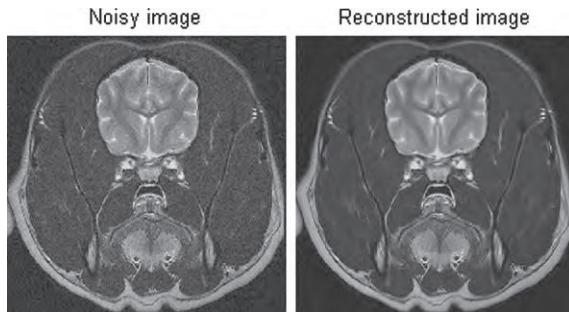

```
image = fdct_wrapping_dispcoef(Curveletcoefwrp).
```

In the wrapping approach, both the forward and inverse transforms are computed in  $O(n^2 \log n)$  operations, and require  $O(n^2)$  storage.

### 1.09.3.3 Applications

Researchers have applied the curvelet transform in solving PDEs and in numerous other applications including image processing, seismic exploration, fluid mechanics, and data compression [87, 89–100]. All applications take advantage of the flexibility of curvelets to selectively capture curve-based features. For illustration in this manuscript, we limit ourselves to the application of curvelets in image denoising.

The assumption about noisy signals in previous sections, can be similarly made for 2-D noisy images of interest herein. It is well known that a 2-D isotropic wavelet transform of an image exhibits a large number of significant coefficients at every fine scale, making wavelet denoising more complex as many more wavelet coefficients are needed for reconstructing edges while smoothing out the noise [68–70, 101]. The development of curvelet theory has shown that discrete curvelet coefficients provide near-optimal way to represent smooth objects with discontinuities along  $C^2$  continuous curves in an image. The curvelet-based denoising method is similar to that of the wavelet. It consists of determining which curvelet coefficients represent the transient features in an image. It is shown that the high amplitude curvelet coefficients usually indicate the position of edges, and the low amplitude curvelet coefficients usually capture noise present in the image. Therefore, the denoising is accomplished by applying a threshold to the curvelet coefficients.

**FIGURE 9.30**

Shown in the left is a noisy image, in the right is the image after applying the hard threshold denoising method.

A hard threshold estimator is defined as,

$$I_T(x) = \begin{cases} x & \text{if } |x| \geq T, \\ 0 & \text{if } |x| < T. \end{cases}$$

Applying the thresholds is equivalent to locally averaging the noise contribution present in the image around the local area the image is smooth over.

Here we assume the noise normal distribution,  $N(0, \sigma^2)$ , and denote by  $y(\mathbf{n})$  the discrete curvelet coefficients from a noisy image. The following hard-threshold is applied to estimate the curvelet coefficients,  $\tilde{y}(\mathbf{n})$ , of the denoised image as follows:

$$\tilde{y}(\mathbf{n}) = \begin{cases} y(\mathbf{n}) & \text{if } |y(\mathbf{n})|\sigma \geq T_a, \\ 0 & \text{if } |y(\mathbf{n})|\sigma < T_a. \end{cases}$$

The threshold  $T_a$  is chosen as scale depended, and can be estimated from the noisy image.

It is shown that the curvelet-based denoising displays higher sensitivity than the wavelet-based denoising, see Figure 9.30. In curvelet denoising, salient features in the noisy image can be clearly enhanced, while the noise can be selectively removed [102]. However, even though the pure discrete curvelet denoising has improved the image denoising method, it is interesting to see better denoising effects has been achieved by a hybrid approach [89] called total variational method (TV) that combines the discrete curvelet transform with the classical wavelet method. The TV method has shown a higher capability in exploiting curve-like features.

---

## 1.09.4 Contourlets and their applications

### 1.09.4.1 Contourlet transform

In this section, we introduce the contourlet transform, proposed by Do and Vetterli [9]. The contourlet transform is a discrete filter bank implementation that expands multi-dimensional signals into

multiresolution copies for analysis, approximation, and compression [9, 103]. Here we consider only two dimensional (2-D) signals-images. A filter bank technique uses multirate signal processing technique that has been successfully applied in many application areas [41, 104]. It is a natural and practical approach to efficiently compute a set of good basis functions for an image [105, 106]. The contourlet filter bank technique proceeds to decompose the frequency domain into angularly oriented directions from fine to coarse resolution. It implements similar features of the curvelet analysis so that certain frequency regions in coarse or detailed version can be focused on under a selected basis/frame. This advances the classical discrete filter bank technique that is used in the classical wavelet analysis. It allows the representation of a 2-D signal to be optimized using only a few significant coefficients corresponding to the geometrical features in an image, such as edges with continuous curves.

The multiresolution decomposition filter bank technique is represented by the Laplacian pyramid decomposition, originally developed by Burt and Adelson [107] for image coding. Its development has inspired the usage of discrete filter bank technique to decompose a 2-D image into images of multiresolution in discrete-time wavelet bases. This has further inspired the research for building the connection between the filter banks and classical wavelets led by Mallat [84] and Daubechies [20]. In turn, this has led to the development of the filter bank technique, which has played an active role in constructing various bases for classical wavelets. It has strengthened the connection between harmonic analysis and discrete signal processing. A filter bank with a directional oriented decomposition capacity was later proposed by Bamberger [108]. The recently proposed contourlet filter banks have integrated the Laplacian pyramid (LP) filter bank and the directional filter bank (DFB) for multiresolution anisotropic wavelet decomposition.

The contourlet transform is a tree-structured filter bank that cascades multiple LP and DFB filter banks iteratively. In general, the filter banks use maximally decimated filter banks similar to those in subband coding, and invoke the usage of multirate signal processing to reduce the computational complexity. Each filter bank in the structure can be divided into two stages: an analysis filter bank and a synthesis filter bank. An analysis filter bank decomposes a signal into different version sub-signals. Each subsignal is down-sampled to its frequency content concentrating in a segment in the Fourier plane. A synthesis filter bank up-samples and combines the output signals from the analysis filter bank into one signal. The basic structure of the contourlets is a two channel maximally decimated filter bank, referred to as a quadrature mirror filter (QMF) bank.

In synthesis, a perfect reconstruction is achieved when the output signal equals to the original signal, which is of interest for an optimal approximation of the original signal. This is useful in signal compression, as an individual image of reduced size is useful for transmission even though the total sampling size is increased. To avoid a redundant expansion of a signal, filters that implement orthonormal bases are sought. Filters that implement biorthogonal bases or tight frames are, however, necessary in some cases in order to relax some constraints.

A digital contourlet filter bank inevitably inherits the distortion problem in digital signal processing; to avoid this problem, a non downsampling version of the contourlets has been proposed [109], which is parallel to the non sub-sampled discrete wavelet transform (NSWT) with the à trous algorithm. Additionally, an M-band method that provided non-redundant DFB was proposed in [110].

In this section, we downplay the distortion problems with downsampling/upsampling to keep our focus on multiresolution analysis. As a polyphase decomposition is typically used to form a fast computing system for implementing filter banks [41, 106, 111], in the following, we start by introducing

some basic sampling operations in digital image processing. We then introduce the LP filter banks, and the DFB filter banks before we introduce the contourlets as the combination of the two type filter banks.

#### 1.09.4.1.1 The downsampling and upsampling operators

Downsampling is a decimation operator that reduces the original image size, while upsampling is the interpolation operator that increases the original image size. The two operations are the basic techniques that form the multirate digital system. In the 2-D digital image processing, downsampling is to generate multiple components of reduced size for the economy of analyzing an image, while upsampling is used to recover the parent image. In this section and the following,  $\mathbf{n} \in \mathcal{Z}^2$  is viewed as a column vector  $\mathbf{n} = (n_1, n_2)^T$  since matrix multiplication is involved. Here “ $T$ ” is referred to the transpose of a vector/matrix.

Both sampling operations involve a  $2 \times 2$  sampling matrix given by

$$\mathbf{M} = \begin{pmatrix} m_1 & 0 \\ 0 & m_2 \end{pmatrix}, \quad \text{where } m_1, m_2 \in \mathcal{Z}.$$

Given a 2-D image,  $x(\mathbf{n})$ ,  $\mathbf{n} = (n_1, n_2) \in \mathcal{Z}^2$ , with its  $z$ -transform  $X(z)$ , see appendix (A.1), an  $M$ -fold downsampling (decimator) takes  $x(\mathbf{n})$  as an input, and produces an output,  $x_d(\mathbf{n})$ , given by

$$x_d(\mathbf{n}) = x(\mathbf{M}\mathbf{n})$$

An  $M$ -fold upsampling (expander, or interpolator) takes  $x(\mathbf{n})$  as an input, and produces an output,  $x_u(\mathbf{n})$ , given by

$$x_u(\mathbf{n}) = \begin{cases} x(\mathbf{s}) & \text{if } \mathbf{n} = \mathbf{Ms}, \mathbf{s} \in \mathcal{Z}^2 \\ 0 & \text{otherwise.} \end{cases}$$

The  $z$ -transform of an  $M$ -fold downsampled signal,  $x_d(\mathbf{n})$ , is given as

$$X_d(z) = |\det(\mathbf{M})|^{-1} \sum_{\mathbf{k}=(k_1, k_2) \in \mathcal{S}} X\left(z_1^{1/m_1} e^{-j2\pi k_1/m_1}, z_2^{1/m_2} e^{-j2\pi k_2/m_2}\right).$$

The  $\mathcal{S}$  is the set of all integer points in  $\mathbf{Mt}$ ,  $t \in [0, 1) \times [0, 1)$ . The  $z$ -transform of an  $M$ -fold upsampled signal,  $x_u(\mathbf{n})$  is given as

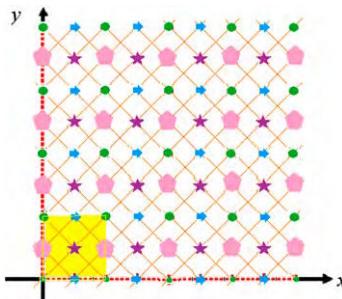

$$X_u(z) = X(z_1^{m_1}, z_2^{m_2}), \quad \text{with } z = (z_1, z_2).$$

The dyadic subsampling occurs in  $x$  or  $y$  direction when  $|\det(\mathbf{M})| = 2$ , where  $\det(\mathbf{M})$  is the determinant of a matrix  $\mathbf{M}$ . Dyadic subsampling in both  $x$  and  $y$  directions occurs when  $m_1 = 2$  and  $m_2 = 2$  in the diagonal matrix  $\mathbf{M}$ . The dyadic sampling is usually used in the digital filter bank design of a discrete wavelet transform or discrete anisotropic wavelet transform. Sampling operations that invoke non-diagonal matrix are to be introduced in the following section.

#### 1.09.4.1.2 The polyphase decomposition

The polyphase decomposition involves subsampling and upsampling operations which use a non-diagonal matrix,  $\mathbf{M}$ , of non-singular integer-value, given as

$$\mathbf{M} = \begin{pmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{pmatrix}.$$

**FIGURE 9.31**

The resampling lattice generated by a dyadic sampling matrix.

This corresponds to a shearing (resampling) operation. The collection of all the subsampling vectors,  $\mathbf{M}\mathbf{n}$ , is called a lattice given by

$$LAT(\mathbf{M}) = \{\mathbf{m} : \mathbf{m} = \mathbf{M}\mathbf{n}, \mathbf{n} \in \mathbb{Z}^2\}.$$

The  $LAT(\mathbf{M})$  is indeed a vector space spanned by the linear combination of basis column vectors from  $\mathbf{M}$ , written as  $n_1\mathbf{M}_1 + n_2\mathbf{M}_2$ , with  $\mathbf{M}_1 = (m_{11}, m_{21})^T$ ,  $\mathbf{M}_2 = (m_{12}, m_{22})^T$ . In our context, a non-singular subsampling matrix  $\mathbf{M}$  refers to the matrices defined in the section of DFB.

Let  $\mathcal{S}$  be the set of points of  $\mathbf{M}\mathbf{t}$ ,  $\mathbf{t} \in [0, 1] \times [0, 1]$ , called the fundamental parallelepiped of matrix  $\mathbf{M}$ . It consists of all real-valued vectors in an area of the parallelogram controlled by  $\mathbf{M}_1$  and  $\mathbf{M}_2$ . An example of  $\mathcal{S}$  is shown in the shadowed square area in Figure 9.31. However, we are only interested in the integer valued points in  $\mathcal{S}$ . According to the division theorem in number theory [41], any integer vector can be written as  $\mathbf{M}\mathbf{n} + s$  with  $s = (s_1, s_2) \in \mathcal{S}$ , so there are  $D = |\det(\mathbf{M})|$  integer points in  $\mathcal{S}$ . We can label each integer vector  $s \in \mathcal{S}$  using index  $k = 0, 1, \dots, D - 1$ . Note that  $k$  cannot be a natural ordering like 1-D case. The sampling lattice of  $\mathbf{M}\mathbf{n} + s$  results from shifting  $LAT(\mathbf{M})$  to the location  $s \in \mathcal{S}$ , yielding the  $k$ th coset of  $LAT(\mathbf{M})$  generated by an integer valued points inside  $\mathcal{S}$ . Therefore, the original lattice of integer numbers in the coordinate system is the union of all the cosets.

For a 2-D image, the polyphase decomposition is the subsampling over the cosets defined above. The  $k$ th component sub image takes a value at the location vector in the  $k$ th coset associated with  $s$ , and is defined as

$$x^{(k,s)}(\mathbf{n}) = x(\mathbf{M}\mathbf{n} + s).$$

Denote by  $x_u^{(k,s)}(\mathbf{n})$  the upsampled version of the  $k$ th polyphase component,  $x^{(k,s)}(\mathbf{n})$ , with a shifting by  $s \in \mathcal{S}$ , defined as

$$x_u^{(k,s)}(\mathbf{n}) = \begin{cases} x^{(k,s)}(\mathbf{m}) & \text{if } \mathbf{n} = \mathbf{M}\mathbf{m} + s, \mathbf{s} \in \mathcal{S}, \\ 0 & \text{otherwise.} \end{cases}$$

The parent image can then be reconstructed as the sum of  $x_u^{(k,s)}(\mathbf{n})$ , namely,

$$x(\mathbf{n}) = \sum_{k=0}^{D-1} x_u^{(k,s)}(\mathbf{n}).$$

Its  $z$ -transform can be written as

$$X(\mathbf{z}) = \sum_s z_1^{-s_1} z_2^{-s_2} X^{(k,s)}(\mathbf{z}^M), \quad \text{with } \mathbf{z} = (z_1, z_2), s = (s_1, s_2) \in \mathcal{S}.$$

Here, for a non-diagonal matrix  $M$ ,  $\mathbf{z}^M$  stands for  $(z_1^{m_{11}} z_2^{m_{21}}, z_1^{m_{12}} z_2^{m_{22}})$ , and  $X^{(k,s)}(\mathbf{z})$  is the  $\mathbf{z}$ -transform of  $x^{(k,s)}(\mathbf{n})$ , see [39].

**Definition 10.** To be consistent with the subsampling concepts, the polyphase representation of the  $z$ -transform,  $X(z)$ , of an image  $x(\mathbf{n})$  is defined as a vector,  $\mathbf{x}(z)$ , written as

$$\mathbf{x}(z) = (X_0(z), X_1(z), \dots, X_{D-1}(z)),$$

with  $X_k(z) = X^{(k,s)}(z)$ , for  $k = 0, 1, \dots, D - 1$ .

For example, a dyadic subsampling matrix  $M$  will have its cosets generated by points  $(i, j)$ ,  $i, j = 0, 1$  in  $S$ , and the  $z$ -transform of  $x(\mathbf{n})$  can be written as

$$X(z) = X_0(z_1^2, z_2^2) + z_1^{-1} X_1(z_1^2, z_2^2) + z_2^{-1} X_2(z_1^2, z_2^2) + z_1^{-1} z_2^{-1} X_3(z_1^2, z_2^2),$$

where  $X_k(z_1, z_2) = \sum_{n_1} \sum_{n_2} z_1^{-n_1} z_2^{-n_2} x(2n_1 + i, 2n_2 + j)$ ,  $k = 2 * j + i$ ,  $i, j = 0, 1$ . The polyphase representation can then be written as

$$\mathbf{x}(z) = (X_0(z_1, z_2), X_1(z_1, z_2), X_2(z_1, z_2), X_3(z_1, z_2)).$$

The use of a polyphase decomposition in the design of a finite input response (FIR) filter bank reduces the computational complexity in the realization of a filter bank, in which the polyphase representation is frequently used. Note that  $X(z)$  is a vector, the  $z$ -transfer function takes a scalar value, while the polyphase representation  $\mathbf{x}(z)$  takes vector value. We assume the signal is periodically expanded if it is of finite length.

A filter bank with a solo implementation of the polyphase decomposition is also termed as a lazy filter bank because of its simple reconstruction structure that involves only the basic operations, such as addition, delay, downsampling and upsampling. A iterated lazy filter bank leads to the so called lazy wavelet.

### 1.09.4.2 The Laplacian pyramid frames

Introduced by Burt and Adelson [8,107], the LP was initially aimed at representing data in a multiresolution setting from fine to coarse levels for data compression purpose. The analysis filter bank of LP iteratively decomposes an image into multiple sub images of coarse approximation, namely, the low resolution sub images with lowpass content, and detail images representing the difference between the lowpass filtered image and the input image. The synthesis filter bank integrates the outputs from the analysis filters into an estimate of the original image. The perfect reconstruction occurs when the estimate is a replica of the original image.

The analysis filter bank of the LP results in a sequence of bandpass images and a further upsampled low resolution image in the end level. The synthesis filters are used to recover the original image from this

sequence of sub-images. The double layered filter bank analyzes an image in various components of size-reduced images with their frequency contents limited to sub-bands. The pyramid design has inspired the connection of filter banks with the wavelet implementation and calculating linear expansions of multiresolution signals.

#### 1.09.4.2.1 The analysis filter banks and synthesis filter banks of the Laplacian pyramid

The analysis filter bank is shown in Figure 9.32. It computes the approximation and the detail image at one single level. Take  $x_0(\mathbf{n})$  as the input image, the analysis LP filter bank decomposes the image using a lowpass filter  $H$  with the impulse response  $\tilde{h}(\mathbf{n}) = h(-\mathbf{n})$ . The output from the lowpass filter  $H$  is down-sampled, resulting in  $x_1(\mathbf{n})$  that can be written as

$$x_1(\mathbf{n}) = \sum_{s \in \mathbb{Z}^2} x_0(s)h(\mathbf{M}\mathbf{n} - s) = \langle x, \tilde{h}(\cdot - \mathbf{M}\mathbf{n}) \rangle,$$

where  $\mathbf{M}$  is a sampling matrix which defines the downsampling. The  $z$ -transform of  $x_1(\mathbf{n})$  can be written in a polyphase representation as

$$X_1(z) = \mathbf{h}(z)x_0^T(z) \quad (9.76)$$

with

$$\mathbf{x}_0(z) = (X_{00}(z), X_{01}(z), \dots, X_{0(D-1)}(z)),$$

and

$$\mathbf{h}(z) = (H_0(z), H_1(z), \dots, H_{D-1}(z))$$

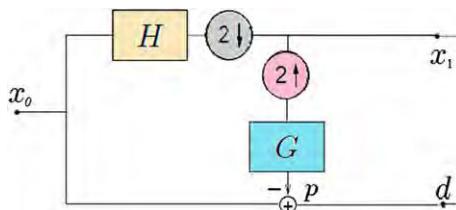

both are  $1 \times D$  polyphase representation vectors.

The detail image is the difference between the approximation image,  $x_1(\mathbf{n})$ , and the original image,  $x_0(\mathbf{n})$ . It is calculated as the difference between a different version of the approximation image,  $p(\mathbf{n})$ , and the original image,  $x_0(\mathbf{n})$ , written as

$$d(\mathbf{n}) = x_0(\mathbf{n}) - p(\mathbf{n}).$$

The lowpass image  $p(\mathbf{n})$  of the original size is obtained as the following,

$$p(\mathbf{n}) = \sum_{s \in \mathbb{Z}^2} x_1(s)g(\mathbf{n} - \mathbf{Ms}).$$

**FIGURE 9.32**

The LP filter bank in a single level.

To calculate  $p(\mathbf{n})$ , the already down-sampled image  $x_1(\mathbf{n})$  is upsampled, and filtered by another lowpass filter  $G$  with impulse response  $g(\mathbf{n})$ . The polyphase representation  $\mathbf{p}(z)$  can then be written as

$$\mathbf{p}^T(z) = (P_0(z), P_1(z), \dots, P_{D-1}(z))^T = \mathbf{g}^T(z)X_1(z), \quad (9.77)$$

where  $\mathbf{g}(z) = (G_0(z), G_1(z), \dots, G_{D-1}(z))$  is a  $1 \times D$  vector, and  $X_1(z)$  is a scalar function. Thus the polyphase representation of  $d(\mathbf{n})$ , can be calculated using Eqs. (9.76) and (9.77), and can be written as

$$\mathbf{d}^T(z) = (I - \mathbf{g}^T(z)\mathbf{h}(z))\mathbf{x}_0^T(z). \quad (9.78)$$

If we cascade Eqs. (9.78) and (9.76), we will have a vector equation

$$\begin{pmatrix} X_1(z) \\ \mathbf{d}^T(z) \end{pmatrix} = \begin{pmatrix} \mathbf{h}(z) \\ I - \mathbf{g}^T(z)\mathbf{h}(z) \end{pmatrix} \mathbf{x}_0^T(z) = \Phi(z) \mathbf{x}_0^T(z), \quad (9.79)$$

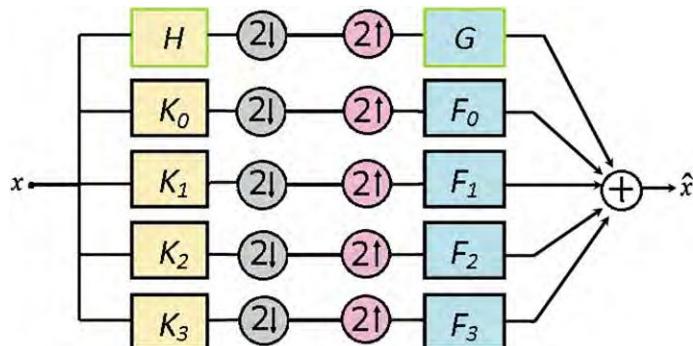

where  $\Phi(z)$  is a matrix of size  $(D + 1) \times D$ .

In the synthesis filter bank, a simple reconstruction of the original image can be computed by directly inverting the steps in the analysis filter. A more efficient reconstruction method is to search for the inverse operator under an orthogonal frame system to calculate the orthogonal projections that is defined as the pseudo inverse of matrix  $\Phi(z)$ . This approach provides the best approximation [112].

The LP filter bank can be realized through a polyphase filter bank structure, in which the lowpass filter  $H$  is determined by its transfer function  $H(z)$ , and the highpass filter  $K_i$ ,  $i = 0, 1, 2, \dots, D - 1$ , is determined by a transfer function whose polyphase representation is given as the  $i$ th row vector of the matrix  $\Phi(z) = (I - \mathbf{g}^T(z))\mathbf{h}(z)$ . Therefore the highpass filters are derived from the lowpass filter  $H$  and  $G$  in the filter bank described in Figure 9.32. Figure 9.33 shows the polyphase structure filter bank for dyadic subsampling which is to be used in the contourlet filter bank.

Based on the structure of a single level analysis filter bank shown in Figure 9.32, the procedure of multiresolution decomposition using the Laplacian pyramid (LP) filter bank is listed as follows:

- Input an image  $x_0(\mathbf{n})$  into the one level LP filter bank. The outputs are the low resolution upsampled image  $x_1(\mathbf{n})$  and a detailed difference image  $d_1(\mathbf{n})$ .

**FIGURE 9.33**

The LP filter implemented using the polyphase decomposition with dyadic subsampling.

- Input the  $x_1(\mathbf{n})$  into the analysis filters again. The outputs are a low resolution image  $x_2(\mathbf{n})$  that is further upsampled, and a detailed image  $d_2(\mathbf{n})$  that is the difference between  $x_1(\mathbf{n})$  and  $x_2(\mathbf{n})$ .
- Iterate the procedure  $K$  times.

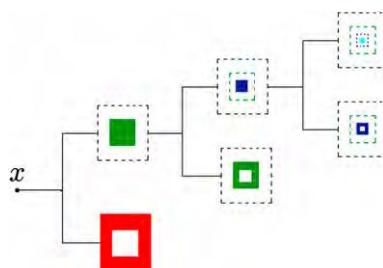

The output sequence  $\{x_k\}_{k=1,2,\dots,K}$  is called a Gaussian pyramid because the Gaussian lowpass filters are typically used. The filtering structure for generating the band pass sequence  $\{d_k\}_{k=1,2,\dots,K}$  is called the Laplacian pyramid. As the  $x_k$  is further decomposed, the final outputs are the sequence of detail images  $d_k$ , with only one low resolution image at the end level, thus yielding a filter bank is generally referred to as the Laplacian pyramid. It is a cascade of a sequence of filter banks for a multiresolution approximation of an original image.

#### 1.09.4.2.2 The wavelet frame associated with the Laplacian pyramid

A wavelet transform can be implemented by computing the fine to coarse multiresolution decomposition as shown in Figure 9.34. The wavelet frame [8] defined in Eq. (9.13) for the decomposition can be specified by using the filters  $H$  and  $G$  of the LP filter bank to determine the mother/father wavelets.

In the LP filter bank, a frame operator  $\widehat{K}_i$  can be defined as  $\widehat{K}_i(x, \phi_i) = \langle x, \phi_i \rangle$ , where each  $\phi_i$  is the  $(i+1)$ th row of the matrix  $\Phi(z)$  in Eq. (9.79). It characterizes the filter  $K_i$  in the polyphase filter bank. This shows that the Laplacian pyramid, with bounded output for any bounded input, provides a frame expansion in  $L^2(\mathcal{Z}^2)$  [9]. If the frame vector  $\{\phi_i\}$  is normalized with  $\|\phi_i\| = 1$  and we have  $A = B = 1$ , then  $\{\phi_i\}$  is an orthonormal basis in Eq. (9.13).

A non-orthonormal frame induces a redundant representation of an image, for which the reconstruction has to use a redundant frame operator that involves a dual frame of  $\widehat{K}_i$ , which performs the inverse/pseudo inverse of the matrix  $\Phi$ . It generates instability that affects the quality of reconstructing the original image. A perfect reconstruction occurs when the original image is replicated. In numerical analysis, the research interests have been focused on searching for orthonormal bases for optimal approximations. With an orthogonal basis, when a signal  $x(\mathbf{n})$  is projected onto a subspace  $V$ , given as  $P_V(x)$ , it generates the minimum approximation error. In some case, due to the requirement of the basis functions, we have to relax the requirement for an orthonormal basis and replace it with an orthogonal basis, a biorthogonal basis, or even a tight frame for multiresolution analysis. This is used to inject some flexibilities, such as, to minimize the redundancy of the expansion.

**FIGURE 9.34**

An LP filter bank that decomposes the frequency content of an image into three levels is shown.

The Laplacian pyramid uses a pair of biorthogonal filters with a sampling matrix  $\mathbf{M}$ , and satisfies

$$\langle \bar{h}(\cdot - \mathbf{M}\mathbf{v}), g(\cdot - \mathbf{M}\mathbf{l}) \rangle = \delta(\mathbf{v} - \mathbf{l}).$$

The filters become orthogonal when they satisfy

$$h(\mathbf{n}) = g(-\mathbf{n}) \quad \text{and} \quad \langle g(\cdot), g(\cdot - \mathbf{M}\mathbf{n}) \rangle = \delta(\mathbf{n}).$$

The orthogonal requirement on the filters  $H$  and  $G$  is equivalent to

$$H^*(z) = G(z) \quad \text{and} \quad G^*(z)G(z) = 1.$$

A perfect reconstruction can then be achieved, thus providing a simple structure that connects the LP filter bank with the classical wavelets [84] for multiresolution analysis. A similar implementation involving a directional decomposition that further connects the anisotropic curvelets with the discrete filter banks is discussed next.

### 1.09.4.3 The directional filter banks

Introduced by Bamberger and Smith [108] in 1992, a directional filter bank (DFB) is a maximally decimated QMF bank that partitions the 2-D Fourier plane with  $2^r$  directional oriented wedge-shaped sub-bands at each level  $r$ . A perfect reconstruction of the original image may be obtained. The implementation introduced here is using a polyphase like tree structured FIR filter bank [9, 113]. This DFB has a simplified structure and uses fan filters and resampling operators with a dyadic downsampling in each level.

#### 1.09.4.3.1 The resampling operators

The design of a directional filter bank requires resampling operators controlled by sampling matrices, such as shearing operators. Here we first introduce the resampling matrices.

**Definition 11.** A quincunx sampling matrix is defined as one of the following two matrices

$$\mathbf{Q}_0 = \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}, \quad \mathbf{Q}_1 = \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}.$$

**Definition 12.** An integer matrix  $\mathbf{M}$  is said to be a unimodular matrix if  $|det(\mathbf{M})| = 1$ . Here, we refer to the following four matrices  $\mathbf{R}_i$ ,  $i = 0, 1, 2, 3$ ,

$$\mathbf{R}_0 = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \quad \mathbf{R}_1 = \begin{pmatrix} 1 & -1 \\ 0 & 1 \end{pmatrix}, \quad \mathbf{R}_2 = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}, \quad \mathbf{R}_3 = \begin{pmatrix} 1 & 0 \\ -1 & 1 \end{pmatrix}.$$

The two quincunx matrices can be further decomposed as

$$\mathbf{Q}_0 = \mathbf{R}_1 \mathbf{D}_0 \mathbf{R}_2 = \mathbf{R}_2 \mathbf{D}_1 \mathbf{R}_1 \quad \text{and} \quad \mathbf{Q}_1 = \mathbf{R}_0 \mathbf{D}_0 \mathbf{R}_3 = \mathbf{R}_3 \mathbf{D}_1 \mathbf{R}_0,$$

where the two diagonal matrices  $\mathbf{D}_0$  and  $\mathbf{D}_1$  are the dyadic subsampling matrix along  $x$ , or  $y$  directions, and are given as

$$\mathbf{D}_0 = \begin{pmatrix} 2 & 0 \\ 0 & 1 \end{pmatrix}, \quad \mathbf{D}_1 = \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}.$$

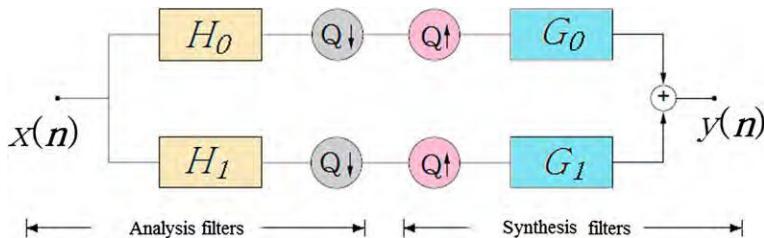

A filter that uses  $Q_0$  or  $Q_1$  carries out a downsampling operation that sheers an image along the orientation at  $45^\circ$  or  $-45^\circ$ . In the DFB,  $Q_0$  and  $Q_1$  are typically cascaded together to result in dyadic down-sampling in both  $x$  and  $y$  directions. This is because  $Q_0 Q_1 = Q_1 Q_0 = 2I$ , where  $I$  is the unit matrix.

#### 1.09.4.3.2 The design of the quincunx filter banks

A quincunx filter bank (QFB) [113, 114] is a two-channel QMF as shown in Figure 9.35. It incorporates the analysis and synthesis filters with the decimators and expanders being the quincunx resampling matrices. A QFB with fan filters used in the analysis part is a typical example. The fan filters are non-separable filters. In Figure 9.36 is shown the support of one fan filter which can be designed starting from a 1-D filter [41].

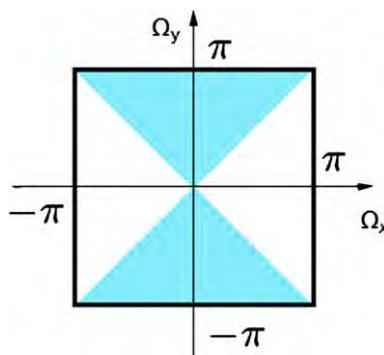

The single level structure analysis filter bank of QFB decomposes the frequency plane of a 2-D image into two wedge shaped cones. The horizontal cone uses  $H_0$ , a horizontal pass fan filter. The vertical cone uses  $H_1$ , a vertical pass fan filter. The synthesis filters, denoted by  $G_0$  and  $G_1$ , perfectly reconstruct the original image when the two dual filter frames satisfy the following conditions,

$$H_0(\omega)G_0(\omega) + H_1(\omega)G_1(\omega) = 2,$$

**FIGURE 9.35**

The quincunx filter bank with resampling matrix  $Q$ .

**FIGURE 9.36**

The support of a fan filter in the Fourier plane. The shaded area is the bandpass area.

$$H_0(\omega + \pi)G_0(\omega) + H_1(\omega + \pi)G_1(\omega) = 0.$$

If the synthesis filters are the reversed versions of the analysis filters then the frame generated by the QFB is an orthogonal frame. This simplifies the design of the synthesis filters. When the analysis and synthesis filters are restricted to be finite impulse response (FIR), the perfect reconstruction conditions imply that the synthesis filters are specified by the analysis filters (up to a shift and scale factor  $i$ ) as the following,

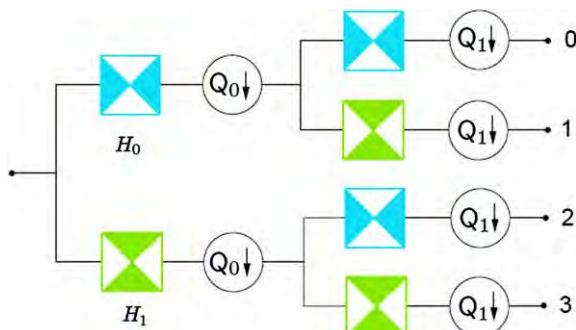

$$G_0(z) = z^i H_1(-z), \quad G_1(z) = -z^i H_0(z).$$

#### 1.09.4.3.3 The design of the directional filter banks

A QFB is the essential QMF bank in a tree structured DFB filter bank. An iterative DFB decomposes the frequency space of a 2-D image into  $2^r$  small angularly oriented wedges at the  $r$ th level. The DFB is a cascade of multiple QFBs, together with selective resampling matrices to determine the shearing angle of the segmented wedge in Fourier plane. The iterative DFB can be viewed as proceeding in multiple stages. According to the Nobel identity shown in Figure 9.38a, the overall output in two adjacent stages can be viewed as applying a decimation  $M = Q_0 Q_1$  using the overall analysis filter  $H_1(z)H_2(z^{M^T})$ . Figure 9.38b shows the overall effect of a DFB in two stages.

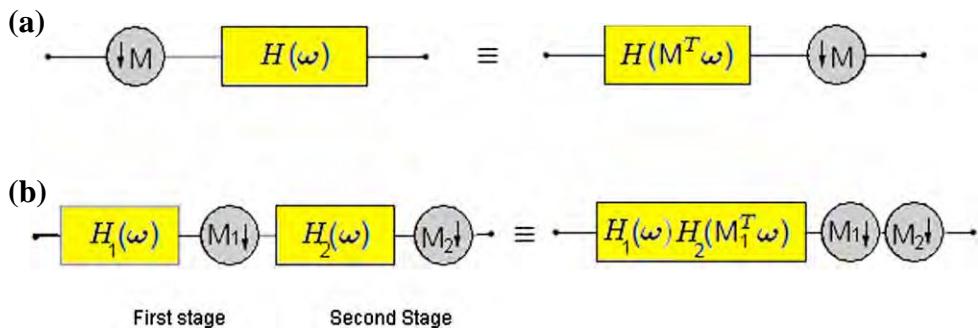

The DFB decompositions in multiple levels are carried out in the following procedures:

- At the first level decomposition, the DFB uses a pair of fan filters with supports complementing each other. The output is resampled using  $Q_1$ . The two fan filters split the Fourier plane into two cone shaped regions: one along the vertical direction, and another one along the horizontal direction. The output is downsampled by two in the  $x$  direction.
- At the second level, the same pair of fan filters are used, however, the output image is re-sampled using  $Q_1$ , so that the four sub images correspond to the four directional sub-bands shown in Figure 9.39. The filter structure for generating these four images is shown in Figure 9.37. The outputs at this level are down-sampled by 2 in both  $x$  and  $y$  directions.
- At the level  $r \geq 3$ , the DFB partitions the Fourier plane into  $2^r$  wedges. Figure 9.40 shows the partition at the level  $r = 3$ . This is realized by attaching to the QFB at the previous level with one of

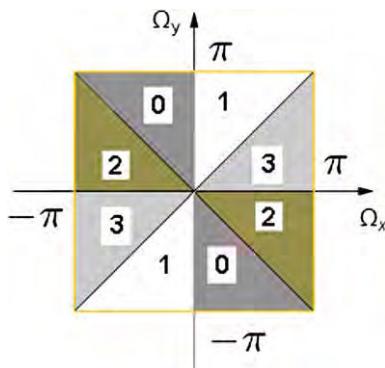

**FIGURE 9.37**

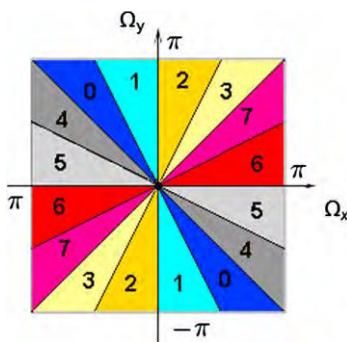

The partition of the Fourier plane using DFB at the first two levels.

**FIGURE 9.38**

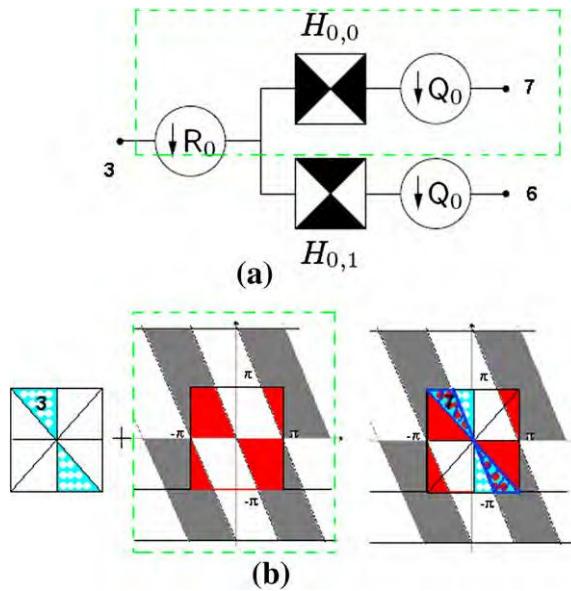

The effect of Noble identity.

**FIGURE 9.39**

The four directional bands output from the first two level partitions.

**FIGURE 9.40**

The eight directional bands output from a DFB at the level  $r = 3$ .

**FIGURE 9.41**

(a) A resampling operator is attaching to a QFB to implement the DFB, (b) Its effects on partitioning the Fourier plane: the 3rd region in the four partitions is used as the input, the output is the wedge indicated in the last picture.

the four uni-modular resampling operations,  $R_i$ ,  $i = 0, 1, 2, 3$ , before and after the analysis filters. Figure 9.41 shows the filter bank structure for generating the 0th wedge in Fourier frequency plane at the 3rd level.

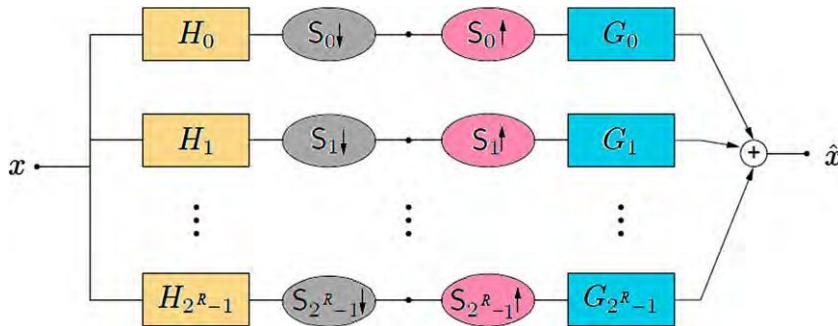

To ensure that each channel of the filters uses a diagonal sampling matrix, a back-sampling operation [115] is applied so that, at each level  $r$ , the  $v$ th channel sub-band can be equivalently viewed as being filtered by an analysis filter  $H_v$ , for  $v = 0, 1, \dots, 2^r - 1$ . The diagonal sampling operator is represented by the sampling matrix

$$S_v^{(r)} = \begin{cases} \text{diag}(2^{r-1}, 2) & 0 \leq v < 2^{r-1}, \\ \text{diag}(2, 2^{r-1}) & 2^{v-1} \leq v < 2^r. \end{cases}$$

The DFB is a perfect reconstruction filter bank if and only if the QFB used at each level implements perfect reconstruction.

#### 1.09.4.3.4 Constructing the basis for the directional filter bank

As shown in Figure 9.42, in the DFB at the  $r$ th level, every analysis filter  $H_v$  with impulse response  $h_v$ , is followed by a diagonal sampling  $S_v^{(r)}$ ,  $v = 0, 1, \dots, 2^r - 1$ . The outputs are  $2^r$  wedges in the Fourier plane. Each wedge is an angularly oriented segment of the original image's Fourier content. Correspondingly, the original image can be reconstructed from applying the diagonal sampling matrix

**FIGURE 9.42**

The analysis and synthesis filters in a DFB that partitions the Fourier plane into  $2^R$  wedges.

$S_v^{(r)}$  to the outputs at the  $r$ th level, followed by applying the synthesis filters  $\{G_v\}_{v=0,1,\dots,2^r-1}$ , with impulse response  $\{g_v(\mathbf{n})\}_{v=0,1,\dots,2^r-1}$ . We also write  $g_v(\mathbf{n}), h_v(\mathbf{n})$  as  $g_v^{(r)}(\mathbf{n}), h_v^{(r)}(\mathbf{n})$  for the  $r$ th level.

Each filter pair, with  $H_v$  and  $G_v$  in the filter bank as the analysis and synthesis filters, is related to the angular wedge region  $U_v$ ,  $v = 0, 1, \dots, 2^r - 1$ . The filters generate a pair of dual frames of  $l^2(\mathbb{Z}^2)$ . Therefore, a basis of  $l^2(\mathbb{Z}^2)$  can be obtained by translating the impulse responses of synthesis filters,  $g_v(\mathbf{n})$ , as  $\left\{ g_{v,\mathbf{m}}^{(r)}(\mathbf{n}) = g_v^{(r)}(\mathbf{n} - S_v^{(r)}\mathbf{m}) : 0 \leq v < 2^r, \mathbf{m} \in \mathbb{Z}^2 \right\}$ . Under this basis, an image  $x(\mathbf{n}) \in l^2(\mathbb{Z}^2)$  can be uniquely reconstructed as

$$x(\mathbf{n}) = \sum_{v=0}^{2^r-1} \sum_{\mathbf{m} \in \mathbb{Z}^2} c_v(\mathbf{m}) g_v^{(r)}(\mathbf{n} - S_v^{(r)}\mathbf{m}),$$

where  $c_v(\mathbf{m}) = \langle x(\cdot), h_v^{(r)}(S_v^{(r)}\mathbf{m} - \cdot) \rangle$ ,  $v = 0, 1, \dots, 2^r - 1$  are the coefficients with respect to a basis  $h_v(S_v^{(r)}\mathbf{m} - \cdot)$  of  $l^2(\mathbb{Z}^2)$  at the  $r$ th DFB decomposition level. The two dual bases  $l^2(\mathbb{Z}^2)$  satisfy the following conditions when they are biorthogonal frames:

$$\langle g_{v'}^{(r)}(\cdot - S_{v'}^{(r)}\mathbf{m}'), h_v^{(r)}(S_v^{(r)}\mathbf{m} - \cdot) \rangle = \delta(v - v')\delta(\mathbf{m} - \mathbf{m}'),$$

with the Dirac function given as

$$\delta(a - a') = \begin{cases} 0, & \text{when } a \neq a', \\ 1, & \text{when } a = a'. \end{cases}$$

An orthogonal basis of  $l^2(\mathbb{Z}^2)$  is obtained when  $h_v^{(r)}(\mathbf{n}) = g_v^{(r)}(-\mathbf{n})$ , that is, when the synthesis filters of the DFB are time-reverses of the analysis filters.

The following are two extreme cases of DFBs. In the first case, the filter system generates a basis of the  $l^2(\mathbb{Z}^2)$  whose elements have compact supports that do not overlap each other in the spatial domain. The second case shows a filter system that generates a basis of  $l^2(\mathbb{Z}^2)$  whose elements have compact supports that do not overlap each other in the Fourier domain.

*Case 1:* In this case, the analysis DFB implements a polyphase decomposition with the  $v$ th polyphase component  $x_v(\mathbf{n}) = x(p_v^T + S_v^{(r)}\mathbf{n})$ , where

$$\mathbf{p}_v = \begin{cases} (v, v) & \text{if } 0 \leq v < 2^{r-1}, \\ (v+1-2^{r-1}, v-2^{r-1}) & \text{if } 2^{r-1} \leq v < 2^r. \end{cases}$$

The polyphase decomposition is realized when each filter  $G_v$  takes the  $z$ -transform as  $G_v(z) = z^{-\mathbf{p}_v}$ , where the basis  $g_v^{(r)}(\mathbf{n} - S_v^{(r)}\mathbf{m}) = \delta(\mathbf{n} - p_v^T - S_v^{(r)}\mathbf{m})$  extends a standard orthonormal basis of  $L^2(\mathcal{Z}^2)$ .

*Case 2:* Another orthonormal basis of  $L^2(\mathcal{Z}^2)$  is obtained using a DFB with ideal fan filters at each level, resulting in the synthesis filters  $G_v$  with Fourier transform given by

$$G_v(\boldsymbol{\omega}) = 2^{v/2} \delta_{R_v}(\boldsymbol{\omega}) \exp \left\{ j \left\langle \boldsymbol{\omega}, \mathbf{p}_v^T \right\rangle \right\}.$$

These two cases, however, will have non-compact support in their dual spaces. Namely, in the first case, the Fourier content of each element in the basis is supported in the whole Fourier plane, while in the second case, each element in the basis is a sinc function with support in the whole spatial domain.

In application, a DFB realization that generates a basis of compact support in the Fourier plane and fast decay in the spatial plane works better to separate a signal into sub-signals that are localized in various frequency regions. In the contourlets [9], a biorthogonal filter pair “9–7” is usually used.

#### 1.09.4.4 The contourlet filter bank

Now we are ready to address the contourlet filter bank, which is a tree structured double layered filter bank that combines the LP and DFB to decompose an original image iteratively. Figure 9.43 shows the multiscale decomposition result generated by the contourlet filter bank. The implementation uses a combination of LP and DFB filter banks.

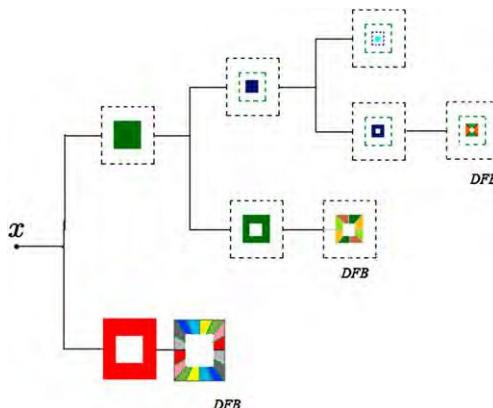

##### 1.09.4.4.1 The wavelet frames of Laplacian filter banks

The LP filters in the contourlet filter bank are octave-band filters: The image is decomposed into a lowpass frequency content, and a bandpass content. The lowpass filtered image is an approximation of the high resolution image with a dyadic downsampling applied in both directions. The bandpass filtered image is the detail difference between the original image and the approximation image. This decomposition proceeds iteratively. At level  $k$ , the original input image is decomposed into several subimages that are focused on sub-bands with a corona support as shown in Figure 9.34, where the Fourier plane of an image is decomposed into three levels.

The LP filter provides a frame expansion in  $L^2(\mathcal{R}^2)$ . Under the multiresolution analysis (MRA), the LP filter bank is associated with a wavelet frame represented by nested subspaces  $\{V_k\}_{k \in \mathcal{Z}}$  (refer to Section 1.09.2) that satisfies

$$V_k \subset V_{k-1}, \quad \text{for } \forall k \in \mathcal{Z},$$

$$\text{Closure} \left( \bigcup_{k=-\infty}^{\infty} V_k \right) = L^2(\mathcal{R}^2).$$

**FIGURE 9.43**

The contourlet filter bank partitions the Fourier plane into wedges for three levels.

The lowpass filter  $G$  in Figure 9.32 defines a wavelet frame of  $L^2(\mathcal{R}^2)$ . The filter structure uniquely defines the function  $\phi(t)$  that satisfies the following equation (called an orthogonal scaling function),

$$\phi(t) = D^{\frac{1}{2}} \sum_{\mathbf{n} \in \mathbb{Z}^2} g(\mathbf{n}) \phi(\mathbf{M}t - \mathbf{n}).$$

Recall that, in general,  $D = |\det(\mathbf{M})|$ , where  $\mathbf{M}$  is a diagonal matrix that corresponds to subsampling. In our LP filter bank introduced here, the subsampling is constrained to a dyadic subsampling only; therefore we have  $D = 4$ , and

$$\mathbf{M} = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix}.$$

The sub-space  $V_k$  is spanned by an orthogonal basis  $\{\phi_{k,\mathbf{n}}\}_{\mathbf{n} \in \mathbb{Z}^2}$  that is defined as

$$\phi_{k,\mathbf{n}}(t) = D^{-\frac{k}{2}} \phi(\mathbf{M}^{-k}t - \mathbf{n}).$$

Writing the orthogonal complement of  $V_k$  in  $V_{k-1}$  as  $W_k$  (see Section 1.09.2), we have

$$V_{k-1} = V_k \bigoplus W_k.$$

Now let  $\{f_i\}_{i=0,1,2,3}$  represent the impulse responses of the highpass synthesis filters  $\{F_i\}_{i=0,1,2,3}$  in the reconstruction part of the LP polyphase structured filter bank, see Figure 9.77. It generates the mother wavelet function  $\psi_i$  for each  $i = 0, 1, 2, 3$  as the following equation:

$$\psi_i(t) = D^{\frac{1}{2}} \sum_{s \in \mathbb{Z}^2} f_i(s) \phi(\mathbf{M}t - s), \quad t \in \mathcal{R}^2, \quad i = 0, 1, 2, 3.$$

A tight frame of the detail space  $W_k$  can be obtained as a family of dilated and translated functions,  $\psi_{k,i,n}(t)$ , given as

$$\psi_{k,i,n}(t) = D^{-\frac{k}{2}} \psi_i(\mathbf{M}^{-k} t - \mathbf{n}), \quad \text{for } k \in \mathcal{Z}, \mathbf{n} \in \mathcal{Z}^2, \quad t \in \mathcal{R}^2, \quad i = 0, 1, 2, 3. \quad (9.80)$$

Here,  $\psi_{k,i,n}(t)$  corresponds to the  $i$ th polyphase component of LP filter bank at level  $k$ . Under this set of tight frames, given an input image  $x(\mathbf{n})$ , the outputs of the LP filter bank at the  $k$ th level are the approximation wavelet coefficients  $c_k(\mathbf{n})$ , and the detail wavelet coefficients  $d_{k,i}(\mathbf{n})$ , they can be obtained from the following formulas based on the approximation coefficients at the previous level,

$$\begin{aligned} c_k(\mathbf{n}) &= \langle x, \phi_{k,n} \rangle = \sum_{s \in \mathcal{Z}^2} c_{k-1}(s) g(s - \mathbf{M}\mathbf{n}), \\ d_{k,i}(\mathbf{n}) &= \langle x, \psi_{k,i,n} \rangle = \sum_{s \in \mathcal{Z}^2} c_{k-1}(s) f_i(s - \mathbf{M}\mathbf{n}). \end{aligned}$$

**Theorem 5.** [112] It can be shown that  $L^2(\mathcal{R}^2)$  can be decomposed into detail spaces  $\{W_k, k \in \mathcal{Z}\}$  that are mutually orthogonal, and can be written as

$$L^2(\mathcal{R}^2) = \bigoplus_{k \in \mathcal{Z}} W_k.$$

At a scale level  $k$ , the family of functions  $\{\psi_{k,i,n}(t) : 0 \leq i < D, \mathbf{n} \in \mathcal{Z}^2\}$  is a tight frame of  $W_k$ . In addition, the entire family  $\{\psi_{k,i,n}(t) : 0 \leq i < D, k \in \mathcal{Z}, \mathbf{n} \in \mathcal{Z}^2\}$  forms a tight frame of  $L^2(\mathcal{R}^2)$ .

#### 1.09.4.4.2 The wavelet frames of directional filter banks

In a contourlet filter bank, the highpass content output from the LP filter bank is the input for the DFB filter bank. The DFB generates  $2^r$  directional oriented wedges that partition the Fourier plane. Typically, only the high frequency content is decomposed since it corresponds to salient features in an image. The directional oriented filter bank provides an anisotropic basis for an efficient decomposition.

As provided in Section 1.09.4.3.4, under the DFB, at level  $r$ , the family  $\{g_{v,n}^{(r)}(\mathbf{m}) = g_v^{(r)}(\mathbf{m} - \mathbf{S}_v^{(r)}\mathbf{n}) : 0 \leq v < 2^r, \mathbf{n} \in \mathcal{Z}^2\}$  is generated and is called a directional orthonormal basis of  $l^2(\mathcal{Z}^2)$ . Each  $g_{v,n}^{(r)}(\mathbf{m})$  is the impulse response of a directional filter. When  $v = 0, \dots, 2^{r-1} - 1$ , it corresponds to an angle in  $[-45^\circ, 45^\circ]$ , and when  $v = 2^{r-1}, \dots, 2^r - 1$ , it corresponds to an angle in  $[45^\circ, 135^\circ]$ .

This directional orthonormal basis  $\{g_{v,n}^{(r)}(\mathbf{m}) : 0 \leq v < 2^r, \mathbf{n} \in \mathcal{Z}^2\}$  is used to construct the frames of the further decomposed detail space. Since the detail subspaces  $W_k$  from the LP correspond to four components of the polyphase decomposition, the following function is introduced using Eq. (9.80),

$$\mu_{k,2n+s_i}(t) = \psi_{k,i,s}(t),$$

where  $s_0 = (0, 0)$ ,  $s_1 = (1, 0)$ ,  $s_2 = (0, 1)$ ,  $s_3 = (1, 1)$ . With a lattice of dyadic subsampling in both directions, the points  $s_i$ ,  $i = 0, 1, 2, 3$ , represent all the cosets with the dyadic subsampling, therefore, any integer vector  $s$  can be written as  $\mathbf{n} + s_i$ , and we have the family  $\mu_{k,s}(t)$  constituting a tight frame of  $W_k$  at level  $k$  in the LP decomposition.

Now define

$$\psi_{k,v,\mathbf{n}}^{(r)}(t) = \sum_{s \in \mathcal{Z}^2} g_v^{(r)}(s - S_v^{(r)}\mathbf{n}) \mu_{k,s}(t).$$

The set of functions,  $\{\psi_{k,v,\mathbf{n}}^{(r)}\}_{\mathbf{n} \in \mathcal{Z}^2}$ , constitutes a tight frame of the finer partition subspace of the detail space  $W_k$ , written as  $W_{k,v}^{(r)}$ , with  $v$  referring to the  $v$ th angular direction. The frame bounds are equal to 1 for each  $k = 1, \dots, K$ , and  $v = 0, \dots, 2^r - 1$ . Also note that the indexing  $v$  is referred to an angular direction in DFB, which is different from the indexing  $i$ , which refers to a polyphase component in the LP filter.

A directional subspace  $W_{k,v}^{(r)}$  is defined on a wedge contained in a rectangular grid that has support in a spatial domain as an oval area, similar to what is shown in Figure 9.26. These subspaces are orthogonal with

$$W_{k,v}^{(r)} = W_{k-1,2v}^{(r+1)} \bigoplus W_{k-1,2v+1}^{(r+1)},$$

and

$$W_k = \bigoplus_{v=0}^{2^r-1} W_{k,v}^{(r)}.$$

Further, combining  $\psi_{k,v,\mathbf{n}}^{(r)}(t)$  together with  $\phi_{k_0,\mathbf{n}}$  for  $k \leq k_0$ ,  $0 \leq v < 2^r$ ,  $\mathbf{n} \in \mathcal{Z}^2$ , we obtain a tight frame of  $l^2(\mathcal{R}^2)$ , as in the following Theorem [114],

**Theorem 6.** *The  $l^2(\mathcal{R}^2)$  can be decomposed into mutually orthogonal subspaces as*

$$l^2(\mathcal{R}^2) = V_{k_0} \bigoplus \left( \bigoplus_{k \leq k_0} W_k \right).$$

*For a sequence of finite positive integers  $k \leq k_0$ , the family*

$$\{\phi_{k_0,\mathbf{n}}(t), \psi_{k,v,\mathbf{n}}^{(r)}(t) : k \leq k_0, 0 \leq v < 2^r, \mathbf{n} \in \mathcal{Z}^2\}$$

*is a tight frame of  $L^2(\mathcal{R}^2)$ .*

**Theorem 7.**  *$l^2(\mathcal{R}^2)$  can be decomposed into mutually orthogonal subspaces as*

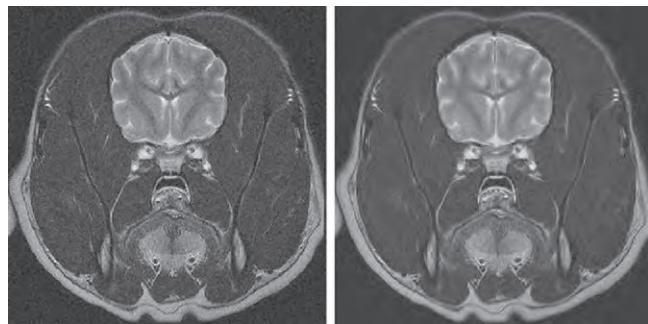

$$l^2(\mathcal{R}^2) = \bigoplus_{k \in \mathcal{Z}} W_k.$$

*The family*

$$\left\{ \psi_{k,v,\mathbf{n}}^{(r)}(t) : k \in \mathcal{Z}, 0 \leq v \leq 2^r - 1, \mathbf{n} \in \mathcal{Z}^2 \right\}$$

*is a directional wavelet tight frame of  $L^2(\mathcal{R}^2)$ . In each case, the frame bounds are equal to 1.*

This combination of frames from both the LP and DFB filter banks yields frequency partitions similar to those achieved by curvelets. The support of the LP is reduced to one fourth of its original size while

**FIGURE 9.44**

Shown in the left is a noisy image, in the right is the image after applying the hard threshold denoising method using the contourlets.

the number of directions of the DFB is doubled. Hence, it connects the directional anisotropic wavelets with the digital filter bank system.

In Contourlet MATLAB program [116], the syntax that is used for decomposition is:

```
coeffs = pdfbdec(double(im), pfilter, dfilter, nlevels);
```

The syntax that is used for reconstruction the original image from the contourlet coefficients is:

```
imrec = pdfbrec(coeffs, pfilter, dfilter);
```

Since the contourlets can be viewed as a filter bank implementation of the curvelets, here we only show in Figure 9.44 an image that demonstrates the denoising outcome using the contourlets.

## 1.09.5 Shearlets and their applications

The shearlet transform is an alternative anisotropic multiresolution system proposed by Guo, Labate and their colleagues [11–13, 117–124]. It was inspired by the composite wavelet theory, which takes advantage of geometric affine transforms, such as translation and dilation (or resampling) in a multi-dimensional Cartesian coordinate system (our focus is on 2-D). In the spatial plane, the affine transforms generate a frame of functional elements (also called building blocks) that are oscillatory waveforms across various scales, locations, and orientations.

Similar to the curvelet transform, a shearlet transform provides a Parseval (normalized tight) frame equipped with well localized functions at various scales, locations and directions. When a 2-D function is projected into this system, sparse significant coefficients, which correspond to discontinuities occur along  $C^2$  piecewise smooth curves, can be used to optimally approximate 2-D functions. It overcomes the problem with the classical 2-D wavelet transform, in which a larger amount of coefficients are needed in order to optimally represent a 2-D function with discontinuities.

Meanwhile, the shearlet transform has its advantages over the curvelet transform. One advantage with the continuous shearlet transform is that, it can be defined directly in a rectangular coordinate system using an affine transform. It avoids the usage of polar coordinates (as curvelets) and hence avoid the computationally complex numerical conversion from polar coordinates to rectangular coordinates. The second advantage with the shearlet transform is that, it exhibits a better capability at distinguishing different types of corner (junction) points. This can be used to separate corner (junction) points from the regular edge points. In addition, shearlet transform can be mathematically related to group theoretic methods, and can hence be interpreted as a natural building blocks in measuring the smoothness of a 2-D function. It can also be related to the so-called co-orbit space theory [125].

In this subsection, we first describe the composite wavelets [10, 126] before we introduce the shearlets, since the shearlets be viewed as a special class of the composite wavelets. Applications of the shearlet transform in image processing enjoys some interesting properties in applications in edge detection, feature extraction, and denoising. We will also discuss more recent applications at the end of this section.

### 1.09.5.1 The composite wavelets

The composite wavelet system provides a general framework with angularly oriented oscillatory spatial waveforms that can be used for representing geometrical features of curves. Since it heavily relies on the affine transform, we proceed by first introducing the affine transform system,  $\mathcal{H}$ , given as the following:

**Definition 13.** Given a function  $\psi(\mathbf{x}) \in L^2(\mathbb{R}^2)$ , a continuous affine system,  $\mathcal{H}$ , generated by  $\psi(\mathbf{x})$  is defined as

$$\mathcal{H} = \left\{ \psi_{\mathbf{G}, \mathbf{b}}(\mathbf{x}) = |\det \mathbf{G}|^{1/2} \psi(\mathbf{G}(\mathbf{x} - \mathbf{b})) : \mathbf{b}, \mathbf{x} \in \mathbb{R}^2, \mathbf{G} \in \mathcal{G} \right\}, \quad (9.81)$$

where  $\mathcal{G}$  is a set of invertible  $2 \times 2$  matrices.

All elements in this affine system,  $\mathcal{H}$ , are called composite wavelets when this affine system forms a tight (Parseval) frame of  $L^2(\mathbb{R}^2)$ , namely, for any  $f \in L^2(\mathbb{R}^2)$ , the following equation holds:

$$\sum_{\mathbf{b}, \mathbf{G}} |\langle f, \psi_{\mathbf{G}, \mathbf{b}} \rangle|^2 = \|f\|^2, \quad (9.82)$$

where  $\mathbf{G}$  is an invertible  $2 \times 2$  matrix in the set  $\mathcal{G}$ .

Under this general framwork of composite wavelets, various wavelet systems can be introduced as special cases for decomposing an image. The 2-D isotropic continuous (the classical) wavelet transform is a special example. It can be obtained when  $\mathcal{G}$ , the set of matrices in Eq. (9.81), takes the form  $\mathcal{G} = \{c\mathbf{I} : c > 0\}$ , here  $\mathbf{I}$  is the unit matrix. Furthermore, the separable classical wavelets can also be obtained when we further use a 2-D separable function  $\psi(\mathbf{x})$ , given as  $\psi(x, y) = \psi_1(x)\psi_2(y)$ . The most exciting case of composite wavelets is the shearlet transform system obtained from using the shearing and translating operations. A shearlet transform system defines a new class of wavelets that produces a set of efficient anisotropic components that can flexibly be adapted to represent the geometrical shapes.

### 1.09.5.2 The shearlet atoms in the spatial plane

The shearlet atoms are defined by selecting the matrix set  $\mathcal{G}$  in Eq. (9.81), in the affine system,  $\mathcal{H}$ , as  $\mathcal{G} = \{\mathbf{M}_{as} : a > 0, s \in \mathcal{R}\}$ , with  $\mathbf{M}_{as}$  given as

$$\mathbf{M}_{as} = \begin{pmatrix} a & -\sqrt{as} \\ 0 & \sqrt{a} \end{pmatrix}. \quad (9.83)$$

It is useful to write the matrix  $\mathbf{M}_{as} = \mathbf{B}_s \mathbf{A}_a$ , where

$$\mathbf{A}_a = \begin{pmatrix} a & 0 \\ 0 & \sqrt{a} \end{pmatrix} \quad \text{and} \quad \mathbf{B}_s = \begin{pmatrix} 1 & -s \\ 0 & 1 \end{pmatrix}.$$

Note that the inverse matrix  $\mathbf{M}_{as}^{-1}$  can be written as  $\mathbf{A}_a^{-1} \mathbf{B}_s^{-1}$ , and is given as

$$\mathbf{M}_{as}^{-1} = \begin{pmatrix} a^{-1} & sa^{-1} \\ 0 & a^{-1/2} \end{pmatrix}. \quad (9.84)$$

Indeed, the matrix  $\mathbf{M}_{as}$  is the composition of two affine operations in a plane: a parabolic scaling,  $\mathbf{A}_a$ , followed by a shearing,  $\mathbf{B}_s$ . The shearlets are defined on the basis of the operator,  $D_{\mathbf{M}_{as}}$ , defined by the Matrix  $\mathbf{M}_{as}$ , as

$$D_{\mathbf{M}_{as}} \psi(\mathbf{x}) = |\det(\mathbf{M}_{as})|^{-\frac{1}{2}} \psi(\mathbf{M}_{as}^{-1} \mathbf{x}),$$

and the translation operator  $T_b$ , defined as

$$T_b \psi(\mathbf{x}) = (\mathbf{x} - \mathbf{b}),$$

yielding the shearlet atoms defined as

$$\psi_{a,s,b}(\mathbf{x}) = T_b D_{\mathbf{M}_{as}} \psi(\mathbf{x}). \quad (9.85)$$

**Definition 14.** The family of shearlet atoms in the spatial plane is defined as the collection of all atoms in the affine system generated by  $\psi(\mathbf{x}) \in L^2(\mathcal{R}^2)$ , given by

$$\psi_{a,s,b}(\mathbf{x}) = |\det(\mathbf{M}_{as})|^{-\frac{1}{2}} \psi(\mathbf{M}_{as}^{-1}(\mathbf{x} - \mathbf{b})), \quad a > 0, \quad s \in \mathcal{R}, \quad \mathbf{x}, \mathbf{b} \in \mathcal{R}^2. \quad (9.86)$$

The function  $\psi(\mathbf{x}) \in L^2(\mathcal{R}^2)$  is called the mother shearlet window.

Note that, because  $\det(\mathbf{M}_{as}) = a^{3/2}$ , Eq. (9.86) can also be written as

$$\psi_{a,s,b}(\mathbf{x}) = a^{-\frac{3}{4}} \psi(\mathbf{M}_{as}^{-1}(\mathbf{x} - \mathbf{b})). \quad (9.87)$$

In the literature about shearlets, the matrix  $\mathbf{M}_{as}$  can also be chosen as

$$\mathbf{M}_{as} = \begin{pmatrix} a & \sqrt{as} \\ 0 & \sqrt{a} \end{pmatrix}, \quad \text{with} \quad \mathbf{M}_{as}^{-1} = \begin{pmatrix} a^{-1} & -sa^{-1} \\ 0 & a^{-1/2} \end{pmatrix}.$$

In this paper, we stick with the matrix  $\mathbf{M}_{as}$ , given by (9.83), for Eq. (9.86) to achieve the shearing effects. Hence, the inverse matrix,  $\mathbf{M}_{as}^{-1}$ , is used in its Fourier domain definition; however, one can alternatively use  $\mathbf{M}_{as}^{-1}$  in the spatial domain, and use  $\mathbf{M}_{as}$  in the Fourier plane [119].

### 1.09.5.3 The shearlet atoms in the frequency domain

The mother shearlet window defines the properties of the shearlet atoms. Every shearlet atom is a result of an affine transform of the mother shearlet window. Hence, we first discuss the choice of the mother shearlet window in order to quickly address the geometrical features of an image using a shearlet transform.

#### 1.09.5.3.1 The mother shearlet window

The rule of thumb for selecting a mother shearlet window in a shearlet transform, is to generate shearlet atoms that are able to focus on localized frequency content to represent geometrical features. Under this shearlet system, the energy of a function  $f(\mathbf{x})$  will be mostly focused on a sparse number of coefficients, when the function is decomposed. In general, the mother shearlet window is chosen as a  $C^\infty$  function with a compact support in the Fourier plane, so that it decays rapidly in the spatial domain. The mother shearlet window function,  $\psi(x, y)$ , is defined by its Fourier transform,  $\Psi(\Omega)$ ,  $\Omega = (\Omega_x, \Omega_y)$ , as

$$\Psi(\Omega) = \Psi_1(\Omega_x)\Psi_2\left(\frac{\Omega_y}{\Omega_x}\right),$$

where  $\Psi_1(\Omega_x)$  and  $\Psi_2(\Omega_y)$  satisfy the following two conditions:

- $\Psi_1(\Omega_x)$  is a 1-D highpass odd function that satisfies the regular 1-D admissibility condition,

$$\int_0^\infty |\Psi_1(a\Omega_x)|^2 \frac{da}{a} = 1. \quad (9.88)$$

- $\Psi_2(\Omega_y)$  is a 1-D positive lowpass even function that satisfies,

$$\int_{\mathcal{R}} |\Psi_2^2(\Omega_y)| d\Omega_y = 1. \quad (9.89)$$

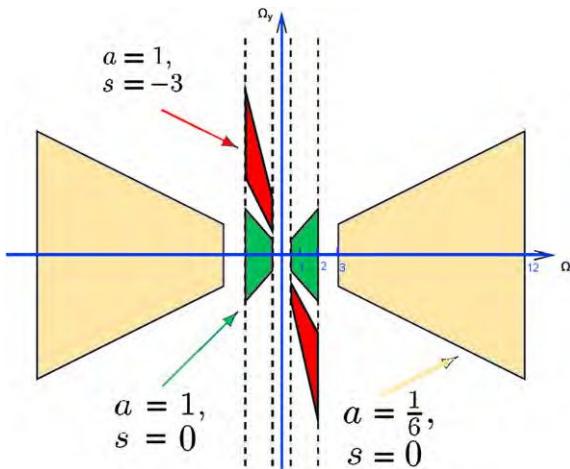

A good choice for the two 1-D windows are the Meyer's wavelet windows defined in Section 1.09.3.

#### 1.09.5.3.2 The Fourier content of shearlet atoms

Given the mother shearlet window defined above, the Fourier transform of the shearlet atoms defined in Eq. (9.86) can be written as

$$\begin{aligned} \Psi_{a,s,\mathbf{b}}(\Omega) &= a^{\frac{3}{4}} e^{-j2\pi\langle\Omega, \mathbf{b}\rangle} \Psi\left(\mathbf{M}_{as}^T \Omega\right) \\ &= a^{\frac{3}{4}} e^{-j2\pi\langle\Omega, \mathbf{b}\rangle} \Psi_1(a\Omega_x) \Psi_2\left(\frac{\sqrt{a}(\Omega_y - s\Omega_x)}{a\Omega_x}\right) \\ &= a^{\frac{3}{4}} e^{-j2\pi\langle\Omega, \mathbf{b}\rangle} \Psi_1(a\Omega_x) \Psi_2\left(a^{-\frac{1}{2}}\left(\frac{\Omega_y}{\Omega_x} - s\right)\right), \quad a > 0, \quad s \in \mathcal{R}, \quad \mathbf{b} \in \mathcal{R}^2. \end{aligned} \quad (9.90)$$

In addition to requiring that the functions  $\Psi_1$  and  $\Psi_2$  satisfy the conditions in Eqs. (9.88) and (9.89), we also assume  $\text{supp}\{\Psi_1\} \subset [-2, -\frac{1}{2}] \cup [\frac{1}{2}, 2]$  and  $\text{supp}\{\Psi_2\} \subset [-1, 1]$ . The frequency content of each shearlet atom, which is yielded from the mother shearlet window, is supported on a pair of trapezoids that are symmetric with respect to the origin point. They are centered between the two lines,  $\Omega_y = m\Omega_x$ , with slopes  $m = s \pm \sqrt{a}$ . We refer to  $s$  as the orientation of this pair of trapezoids. Figure 9.45 shows

**FIGURE 9.45**

The frequency supports of some shearlet atoms in the Fourier plane,  $a$  is the scale,  $s$  is the orientation of a pair of trapezoids.

some examples of the trapezoid pairs. Each supporting region may be written as

$$\left\{ (\Omega_x, \Omega_y) \in \mathcal{R}^2 : \Omega_x \in \left[ -\frac{2}{a}, -\frac{1}{2a} \right] \cup \left[ \frac{1}{2a}, \frac{2}{a} \right], -\sqrt{a} + s \leq \frac{\Omega_y}{\Omega_x} \leq \sqrt{a} + s \right\}.$$

So far, the mother shearlet window generates real-valued spatial shearlet atoms; however, the complex valued spatial shearlet atoms can also be obtained if the support of  $\Psi_1$  is confined to  $\left[ \frac{1}{2}, 2 \right]$ . In both cases, the mother shearlet reproduces the shearlet atoms that are angularly oriented waveforms in the spatial domain, with its shape controlled by the shearing parameter  $s$  and scaling parameter  $a$ , see Figure 9.46.

#### 1.09.5.4 The continuous shearlet transform

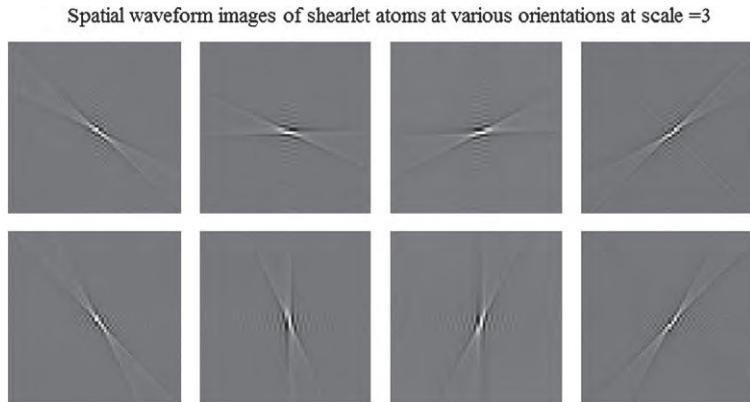

**Definition 15.** Let  $f(\mathbf{x}) \in L^2(\mathcal{R}^2)$ , and let  $\{\psi_{a,s,b}(\mathbf{x}) : a > 0, s \in \mathcal{R}, \mathbf{b} \in \mathcal{R}^2\}$  be the family of shearlet atoms defined in Eq. (9.86), the continuous shearlet transform is defined as

$$\gamma_f(a, s, \mathbf{b}) = \langle f, \psi_{a,s,b} \rangle = \int_{\mathcal{R}^2} f(\mathbf{x}) \psi_{a,s,b}^*(\mathbf{x}) d\mathbf{x}, \quad (9.91)$$

where  $\{\gamma_f(a, s, \mathbf{b})\}_{a>0, s \in \mathcal{R}, \mathbf{b} \in \mathcal{R}^2}$  are called the shearlet coefficients of the function  $f(\mathbf{x})$ .

Note that the shearlet coefficients of the function  $f(\mathbf{x})$  can also be obtained in the Fourier domain as

$$\begin{aligned} \gamma_f(a, s, \mathbf{b}) &= \langle F, \Psi_{a,s,b} \rangle \\ &= \int_{\mathcal{R}^2} F(\boldsymbol{\Omega}) \Psi_{a,s,b}^*(\boldsymbol{\Omega}) d\boldsymbol{\Omega} \end{aligned}$$

**FIGURE 9.46**

The eight spatial waveform images of shearlet atoms correspond to different orientations at scale = 3 are shown here. Note that the images are zoomed to show only the center portions of the images.

$$= a^{3/4} \int_{\mathcal{R}^2} F(\Omega) \Psi_1(a\Omega_x) \Psi_2 \left( a^{-\frac{1}{2}} \left( \frac{\Omega_y}{\Omega_x} - s \right) \right) e^{j2\pi \langle \Omega, b \rangle} d\Omega. \quad (9.92)$$

It can be proved that the mother shearlet window function given in the previous section satisfies the following admissibility condition,

$$\int_{\mathcal{R}} \int_0^\infty |\Psi(M_{as}^T \Omega)|^2 a^{-3/2} da ds = 1 \quad \text{for a.e. } \Omega \in \mathcal{R}^2.$$

This admissibility condition shows that the family of shearlets generates a reproducing system, which yields the following theorem,

**Theorem 8.** *For a function  $f \in L^2(\mathcal{R}^2)$ , the exact reproduction can be obtained by the following generalized Calderón reproducing formula:*

$$f(\mathbf{x}) = \int_{\mathcal{R}^2} \int_{-\infty}^\infty \int_0^\infty \gamma_f(a, s, \mathbf{b}) \psi_{a,s,\mathbf{b}}(\mathbf{x}) \frac{da}{a^3} ds d\mathbf{b}. \quad (9.93)$$

In addition, we have

$$\|f(\mathbf{x})\|^2 = \int_{\mathcal{R}^2} \int_{-\infty}^\infty \int_0^\infty |\gamma_f(a, s, \mathbf{b})|^2 \frac{da}{a^3} ds d\mathbf{b}. \quad (9.94)$$

#### 1.09.5.4.1 Properties of the shearlet transform

A 2-D function  $f$  that is smooth away from discontinuities along a curve  $\Gamma$  can be modeled as an image in  $[0, 1]^2$  showing an object and a boundary, written as,  $O \cup \Gamma = \cup_{n=1}^L (O_n \cup C_n)$ , namely,  $L$  small

objects  $O_n, n = 1, 2, \dots, L$  form a connected open set  $O$  in the image with a boundary,  $\Gamma$ , connected by piecewise smooth curves of finite length, with finite number of corner (junction) points.

As  $a \rightarrow 0$ , a shearlet atom has a slim support in the spatial domain, see Figure 9.46. If this slim support is centered at a point on a edge curve and is aligned along the normal direction of the curve, it results in slow decay or large value shearlet coefficients.

The following conclusions demonstrate that the location and orientation of singularities can be well characterized by the decay rate of continuous shearlet coefficients, which can be used to further classify the geometrical features at singularity points [121, 122, 127].

- If  $\mathbf{b} \notin \Gamma$ , then

$$\lim_{a \rightarrow 0+} a^{-N} \gamma_f(a, s, \mathbf{b}) = 0, \quad \text{for } \forall s \in \mathcal{R}, \forall N \in \mathcal{N},$$

namely, the continuous shearlet coefficients satisfy

$$|\gamma_f(a, s, \mathbf{b})| \leq \text{Const.} a^N, \quad \forall N \in \mathcal{N}, \quad \text{when } a \rightarrow 0+.$$

- If  $\mathbf{b} \in \Gamma$  is a regular edge point, namely, the curve is at least  $C^2$  smooth near  $\mathbf{b}$ , but  $s$  is not at the normal direction of the curve at  $\mathbf{b}$  then we have

$$\lim_{a \rightarrow 0+} a^{-N} \gamma_f(a, s, \mathbf{b}) = 0,$$

namely,  $\gamma_f(a, s, \mathbf{b})$  decays rapidly to 0 as  $a \rightarrow 0$ .

- If  $\mathbf{b} \in \Gamma$  is a regular edge point, namely, the curve is at least  $C^2$  smooth near  $\mathbf{b}$ , and  $s$  is at the normal direction of the curve at  $\mathbf{b}$ ; that is,  $s$  is at the orientation that is perpendicular to  $\Gamma$  at  $\mathbf{b}$ , we have

$$\lim_{a \rightarrow 0+} a^{-3/4} \gamma_f(a, s, \mathbf{b}) = \text{Const.} f_b,$$

where  $f_b$  is the jump of a function  $f$  at  $\mathbf{b}$  along the normal direction.

In regard to the case that  $\mathbf{b} \in \Gamma$  is a corner (junction) point, the following results follow:

- If  $\mathbf{b} \in \Gamma$  is a corner (junction) point, that is, more than two curves merged together at  $\mathbf{b}$ , and the curves are not smooth at  $\mathbf{b}$ , and if  $s$  corresponds to one of the normal directions of the curves, we have

$$0 < \lim_{a \rightarrow 0+} a^{-3/4} \gamma_f(a, s, \mathbf{b}) < +\infty.$$

Namely,  $\gamma_f(a, s, \mathbf{b})$  decays as  $a^{3/4}$ , as  $a \rightarrow 0$ .

- If  $\mathbf{b} \in \Gamma$  is a corner (junction) point, but  $s$  does not correspond to any of the normal directions of the curves, the shearlet transform decays as  $a^{9/4}$  except in some special case. Note that, in the corner points, as  $a \rightarrow 0+$ , we will have  $\gamma_f(a, s, \mathbf{b})$  decays as  $a^{3/4}$  in two or more different normal directions at  $\mathbf{b}$  when two or more curves are merged together at  $\mathbf{b}$ .
- A spike-type singularity point has a different behavior for the decay of the shearlet coefficients. For example, for a Dirac delta function centered at  $\mathbf{b}_0$ , we have  $|\gamma_f(a, s, \mathbf{b})| \asymp a^{-3/4}$ , as  $a \rightarrow 0$  for all  $s$  when  $\mathbf{b} = \mathbf{b}_0$ . Therefore, the shearlet coefficients actually grow at fine scales for  $\mathbf{b} = \mathbf{b}_0$ . This is in contrast to the case that  $|\gamma_f(a, s, \mathbf{b})|$  rapidly decays to zero if  $\mathbf{b}$  is a regular edge point.

The Lipschitz regularity is commonly used to describe the local regularity of a function. In shearlet theory, it is shown [121] that the decay rate of the shearlet coefficients of a function  $f$  depends on the local regularity of  $f$ . This further says that amplitudes of the shearlet coefficients are useful to describe the regularity points of a curve when the curve can be measured by Lipschitz regularity. If inequality (9.3) holds for all  $\mathbf{b} \in O$  with constant  $K > 0$  that is independent of  $\mathbf{b}_0$ , then the function  $f$  is uniformly Lipschitz  $\alpha$  over an open set  $O$ .

The following result [121] provides us with a further insight of the shearlet coefficients. It takes advantage of the fact that the mother shearlet has an infinite number of vanishing moments, namely

$$\int x^k \psi(x, y) dx = 0, \quad \text{for } k = 0, 1, \dots$$

**Theorem 9.** *If function  $f(\mathbf{x}) \in L^2(\mathcal{R}^2)$  is Lipschitz- $\alpha$ ,  $\alpha > 0$  near a point  $\mathbf{b}_0$ , we will have*

$$|\gamma_f(a, s, \mathbf{b})| \leq \text{Const.} a^{\frac{1}{2}(\alpha + \frac{3}{2})} \left( 1 + |a^{-1/2}(\mathbf{b} - \mathbf{b}_0)| \right), \quad \text{for } a < 1.$$

#### 1.09.5.4.2 Shearlets in the horizontal and vertical directions

In this section, we explain that the family of shearlet atoms can be split into two families, one in the horizontal direction, another one in the vertical direction. The separation will ease the numerical implementation of the shearlet transform because the non-uniform angular covering of the frequency plane becomes a problem when the slope of a trapezoid is too steep, namely, when  $|s|$  takes a large value, see Figure 9.45.

The following proposition ensures that reproducing a function  $f \in L^2(\mathcal{R}^2)$  using shearlets can be separated into reconstruction under three systems: two (horizontal and vertical) shearlet systems, plus a coarse scale isotropic system. First, we introduce the horizontal shearlet family, which can be defined by restricting the value of  $a$  and  $s$  to  $0 < a < 1$ ,  $-2 \leq s \leq 2$ . The shearlets are focused on the horizontal direction zone  $C^{(h)}$  defined as

$$C^{(h)} = \left\{ (\Omega_x, \Omega_y) \in \mathcal{R}^2 : |\Omega_x| \geq 2 \text{ and } \left| \frac{\Omega_y}{\Omega_x} \right| \leq 1 \right\}.$$

**Proposition 7.** *Any function  $f(\mathbf{x}) \in L^2(\mathcal{R}^2)$  that has its support in the horizontal zone  $C^{(h)}$  can be exactly reconstructed by the following reproducing formula:*

$$f(\mathbf{x}) = \int_{\mathcal{R}^2} \int_{-2}^2 \int_0^1 \gamma_f(a, s, \mathbf{b}) \psi_{a,s,\mathbf{b}}(\mathbf{x}) \frac{da}{a^3} ds d\mathbf{b}, \quad (9.95)$$

assume the mother shearlet  $\psi(\mathbf{x})$  satisfies the conditions given in Section 1.09.5.3.1, and the shearlet atoms,  $\psi_{a,s,\mathbf{b}}(\mathbf{x})$ , are defined as in Eq. (9.86).

The proof of this proposition can be found in [120]. The overall requirement for  $s$  is to indeed satisfy  $-\sqrt{a} - 1 < s < \sqrt{a} + 1$ . This proposition can be extended to show that any function  $f(\mathbf{x}) \in L^2(\mathcal{R}^2)$  with support in the vertical zone defined as,

$$C^{(v)} = \left\{ (\Omega_x, \Omega_y) \in \mathcal{R}^2 : |\Omega_x| \geq 2 \text{ and } \left| \frac{\Omega_y}{\Omega_x} \right| > 1 \right\},$$

can be exactly reproduced using the shearlet system defined by Eq. (9.86); however, the matrix  $\mathbf{M}_{as}$  should be replaced by  $\mathbf{M}_{as}^T$ , and the mother shearlet window be replaced by  $\psi^{(v)}$  with its Fourier transform,  $\Psi^{(v)}(\Omega)$ , being defined as

$$\Psi^{(v)}(\Omega) = \Psi_1(\Omega_y)\Psi_2\left(\frac{\Omega_x}{\Omega_y}\right).$$

To distinguish the mother shearlet functions for the vertical/horizontal zones, we write the one used in generating the horizontal shearlets as  $\psi^{(h)}(\mathbf{x})$  ( $\psi^{(v)}(\mathbf{x})$  respectively). In addition, we can also define an isotropic function  $\phi(\mathbf{x})$  as a  $C^\infty$  window function in the spatial plane  $\mathcal{R}^2$ , its Fourier transform is defined as  $\Phi(\Omega) = 1$  for  $\Omega \in [-1/2, 1/2]^2$ ,  $\Phi(\Omega) = 0$  for  $\Omega \notin [-2, 2]^2$ . This function,  $\Phi$ , can be called the scaling function, or the father shearlet function.

Now, any function  $f(\mathbf{x}) \in L^2(\mathcal{R}^2)$  can be reconstructed using these three systems introduced above as

$$\begin{aligned} f(\mathbf{x}) &= \int_{\mathcal{R}^2} \langle f(\cdot), \phi(\cdot - \mathbf{b}) \rangle \phi(\mathbf{x} - \mathbf{b}) d\mathbf{b} \\ &\quad + \int_{\mathcal{R}^2} \int_{-2}^2 \int_0^1 \gamma_f^{(h)}(a, s, \mathbf{b}) \psi_{a,s,\mathbf{b}}^{(h)}(\mathbf{x}) \frac{da}{a^3} d\mathbf{b} ds \\ &\quad + \int_{\mathcal{R}^2} \int_{-2}^2 \int_0^1 \gamma_f^{(v)}(a, s, \mathbf{b}) \psi_{a,s,\mathbf{b}}^{(v)}(\mathbf{x}) \frac{da}{a^3} d\mathbf{b} ds. \end{aligned} \quad (9.96)$$

Typically, in finding the salient features of an image, only the high frequency content of a function in  $L^2(\mathcal{R}^2)$  matters, and it corresponds to the curvelet atoms in the horizontal and vertical cones, written as  $\gamma_f^{(h)}(a, s, \mathbf{b})$  and  $\gamma_f^{(v)}(a, s, \mathbf{b})$ . In general, we refer to the following two horizontal/vertical cones after we separate the lowpass content from the bandpass content.

1. The horizontal cone,

$$\mathcal{D}^{(h)} = \left\{ (\Omega_x, \Omega_y) : \left| \frac{\Omega_y}{\Omega_x} \right| \leq 1 \right\}.$$

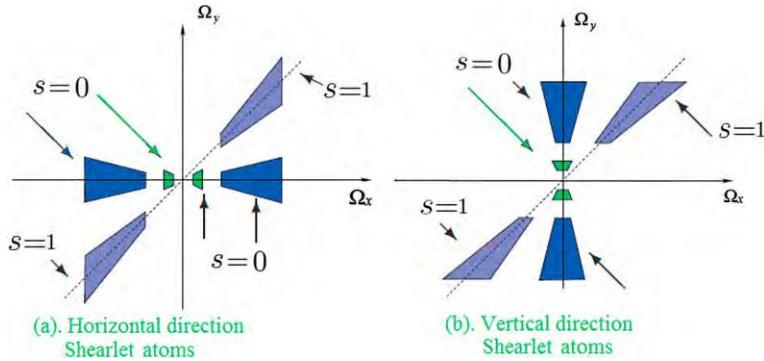

2. The vertical cone,

$$\mathcal{D}^{(v)} = \left\{ (\Omega_x, \Omega_y) : \left| \frac{\Omega_x}{\Omega_y} \right| \geq 1 \right\}.$$

Separating shearlet atoms into two families that cover the horizontal or vertical directions has made it easier for numerical implementation of the shearlet transform. Indeed, each “vertical” direction shearlet atom can be obtained by rotating the corresponding “horizontal” shearlet atom by  $\frac{\pi}{2}$ . Figure 9.47 shows some examples of horizontal and vertical shearlet atoms for  $s = 0, s = 1$  and some  $a$ . In the following, we focus on the numerical implementation of shearlets in these two directions.

### 1.09.5.5 The discrete shearlet atoms

Several discretization methods may be chosen to generate the discrete shearlet atoms along the horizontal cone and the vertical cone directions. We discretize the continuous shearlet transform by sampling the

**FIGURE 9.47**

The frequency support of some horizontal and vertical shearlet atoms in the Fourier plane at two different scales.

scale, shear and translation parameters as follows [117]: the scale parameter is sampled at  $a = 2^{-2k}$ ,  $k \geq 0$ ; the shearing parameter is sampled as  $s_{k,l} = l2^{-k}$ ,  $-2^k \leq l < 2^k$ ; and the translation parameter is sampled at  $\mathbf{b} = A_2^k B_l \mathbf{m}$ , with  $\mathbf{m} \in \mathcal{Z}^2$ , and

$$A_2^k = \begin{pmatrix} 2^{-2k} & 0 \\ 0 & 2^{-k} \end{pmatrix} \quad \text{and} \quad \mathbf{B}_l = \begin{pmatrix} 1 & -l \\ 0 & 1 \end{pmatrix}.$$

After sampling, Eq. (9.87) is rewritten as

$$\psi_{k,l,\mathbf{m}}(\mathbf{x}) = 2^{3k/2} \psi \left( B_l^{-1} A_2^{-k} (\mathbf{x} - A_2^k B_l \mathbf{m}) \right). \quad (9.97)$$

The following equation leads to the discretization method that we introduce in this section,

$$\left\{ T_{A_2^k B_l \mathbf{b}} \right\} D_{A_2^k B_l} \psi(\mathbf{x}) = D_{A_2^k B_l} T_{\mathbf{b}} \psi(\mathbf{x}), \quad \mathbf{x} \in \mathcal{R}^2.$$

The discrete shearlet atoms in the horizontal direction are therefore given as the following set,

$$\left\{ \psi_{k,l,\mathbf{m}}^{(h)}(\mathbf{x}) = D_{A_2^k B_l} T_{\mathbf{b}} \psi^{(h)}(\mathbf{x}) : k \geq 0, -2^k \leq l < 2^k, \mathbf{m} \in \mathcal{Z}^2 \right\}.$$

The discrete shearlet atoms can be further written as,

$$\psi_{k,l,\mathbf{m}}^{(h)}(\mathbf{x}) = 2^{3k/2} \psi^{(h)} \left( \mathbf{B}_l^{-1} A_2^{-k} \mathbf{x} - \mathbf{m} \right), \quad (9.98)$$

where

$$\mathbf{B}_l^{-1} A_2^{-k} = \begin{pmatrix} 2^{2k} & l2^k \\ 0 & 2^k \end{pmatrix} \quad \text{and} \quad A_2^k \mathbf{B}_l = \begin{pmatrix} 2^{-2k} & -l2^{-2k} \\ 0 & 2^{-k} \end{pmatrix}.$$

The Fourier transform of  $\psi_{k,l,m}^{(h)}(\mathbf{x})$  can be written as

$$\begin{aligned}\Psi_{k,l,m}^{(h)}(\Omega) &= 2^{-3k/2} \Psi^{(h)} \left( \left( A_2^k \mathbf{B}_l \right)^T \Omega \right) e^{-j2\pi \langle A_2^k \mathbf{B}_l m, \Omega \rangle} \\ &= 2^{-3k/2} \Psi_1 \left( 2^{-2k} \Omega_x \right) \Psi_2 \left( 2^k \frac{\Omega_y}{\Omega_x} - l \right) e^{-j2\pi \langle A_2^k \mathbf{B}_l m, \Omega \rangle}.\end{aligned}\quad (9.99)$$

The mother shearlet function can be similarly chosen as in the continuous case. Recall that the function  $\Psi_1(\Omega_x)$ ,  $\Psi_2(\Omega_y)$  are  $C^\infty(\mathcal{R})$ , and they are well localized in the Fourier plane. The window  $\Psi_1(\Omega_x)$  is supported on  $[-2, -1/2] \cup [1/2, 2]$  in the Fourier plane, and it satisfies

$$\sum_{k=0}^{\infty} \left| \Psi_1 \left( 2^{-2k} \Omega_x \right) \right|^2 = 1, \text{ for } |\Omega_x| > \frac{1}{2}. \quad (9.100)$$

The window  $\Psi_2(\Omega_y)$  is supported on  $[-1, 1]$  in the Fourier plane, and it satisfies

$$|\Psi_2(\Omega_y - 1)|^2 + |\Psi_2(\Omega_y)|^2 + |\Psi_2(\Omega_y + 1)|^2 = 1, \text{ for } |\Omega_y| \leq 1, \quad (9.101)$$

which leads to the following equation,

$$\sum_{l=-2^k}^{2^k-1} \left| \Psi_2 \left( 2^k \Omega_y + l \right) \right|^2 = 1, \text{ for } |\Omega_y| \leq 1, \ k \geq 0. \quad (9.102)$$

The Fourier content of a discrete shearlet atom,  $\Psi_{k,l,m}^{(h)}$ , is supported on a pair of trapezoids oriented along a line with slope  $l2^{-k}$ , of size about  $2^{2k} \times 2^k$ , written as

$$W_{k,l} = \left\{ \Omega = (\Omega_x, \Omega_y) : \Omega_x \in [-2^{2k+1}, -2^{2k-1}] \cup [2^{2k-1}, 2^{2k+1}], \left| \frac{\Omega_y}{\Omega_x} - l2^{-k} \right| \leq 2^{-k} \right\}.$$

This system of discrete shearlet atoms defines a Parseval frame on the horizontal cone  $\mathcal{D}^{(h)}$ . An exact reproducing theorem can then be obtained and stated as,

**Theorem 10.** *Let the horizontal shearlet atoms be defined as in Eq. (9.98), using the shearlet window that satisfies Eqs. (9.100) and (9.102). This shearlet system is a Parseval frame for  $L^2(\mathcal{D}^{(h)}, 2)$ .*

The discrete shearlets on the vertical zone can be similarly defined as above. In addition, the lowpass isotropic scaling shearlets can be generated by the translations of a scaling function.

### 1.09.5.6 Numerical implementation of shearlet transform

A numerically efficient implementation of a shearlet transform was previously introduced in [119, 128] based on combining a Laplacian pyramid with appropriate shearing filters. The problem with the implementation is the large side lobe effects around significant edges. Recently, an improved implementation based on separately calculating the vertical and horizontal shearlets was proposed by Yi et al. [13, 123, 124] and will be introduced here.

For convenience, the new implementation reformulates the shearlet transform by introducing the following functions in the horizontal and vertical zones separately,

$$W_{kl}^{(h)}(\Omega) = 2^{k/2} \Psi_2 \left( 2^k \frac{\Omega_y}{\Omega_x} - l \right) \chi_{\mathcal{D}^{(h)}}(\Omega), \quad (9.103)$$

$$W_{kl}^{(v)}(\Omega) = 2^{k/2} \Psi_2 \left( 2^k \frac{\Omega_x}{\Omega_y} - l \right) \chi_{\mathcal{D}^{(v)}}(\Omega). \quad (9.104)$$

The function  $W_{kl}^{(d)}(\Omega)$  where  $d = v, h$  is a window function supported on a pair of trapezoids in the Fourier plane. It corresponds to a spatial function  $w_{kl}^{(d)}(n_1, n_2)$ . Now the Fourier content of the shearlets in Eq. (9.98) can be written as

$$\Psi_{k,l,m}^{(d)}(\Omega) = 2^{-2k} V^{(d)}(2^{-2k}\Omega) W_{kl}^{(d)}(\Omega) e^{-j2\pi\langle m, \Omega \rangle}, \quad d = v, h,$$

where  $V^{(d)}(\Omega_x, \Omega_y)$ ,  $d = v, h$  is defined as

$$V^{(h)}(\Omega_x, \Omega_y) = \Psi_1(\Omega_x) \quad \text{and} \quad V^{(v)}(\Omega_x, \Omega_y) = \Psi_1(\Omega_y).$$

The discrete shearlet transform of a discrete sampled function  $f(n_1, n_2)$  can be computed as

$$\begin{aligned} \gamma_f^{(d)}(k, l, m) &= \int_{\mathcal{R}^2} F(\Omega) \Psi_{k,l,m}^{(d*)}(\Omega) d\Omega \\ &= \int_{\mathcal{R}^2} 2^{-2k} F(\Omega) V^{(d*)}(2^{-2k}\Omega) W_{kl}^{(d*)}(\Omega) e^{j2\pi\langle m, \Omega \rangle} d\Omega \\ &= \int_{\mathcal{R}^2} V_k^{(d*)} f(\Omega) W_{kl}^{(d*)}(\Omega) e^{j2\pi\langle m, \Omega \rangle} d\Omega \quad \text{for } d = v, h. \end{aligned} \quad (9.105)$$

Note that here “\*” as a sup-script indicates complex conjugate, with

$$V_k^{(d)} f(\Omega) = a F(\Omega) V^{(d)}(a\Omega), \quad a = 2^{-2k}.$$

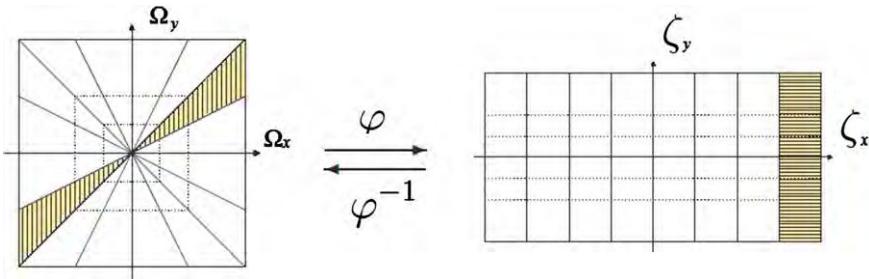

The  $V_k^{(d)} f(\Omega)$  is the output from the highpass filter in the horizontal/vertical zone. Equation (9.105) can be viewed as the inverse Fourier transform, which is equivalent to a convolution in the spatial plane, and can be written as

$$\gamma_f^{(d)}(k, l, m) = \left( v_k^{(d)} f * w_{kl}^{(d)} \right)(m).$$

Here  $v_k^{(d)} f$  is the inverse Fourier transform of the function  $V_k^{(d*)} f(\Omega)$ , and can be written as

$$v_k^{(d)} f(\mathbf{b}) = \int_{\mathcal{R}^2} V_k^{(d*)} f(\Omega) e^{j2\pi\langle \mathbf{b}, \Omega \rangle} d\Omega.$$

The value of  $v_k^{(d)} f(\mathbf{b})$  is obtained through an iterative calculation as in the algorithm introduced later. The value of  $w_{kl}^{(d)}(\mathbf{b})$  is the inverse Fourier transform of  $W_{kl}^{(d*)}(\Omega)$ , obtained through a mapping of

**FIGURE 9.48**

The mapping from a wedge in the Fourier plane to a rectangle in the Pseudo-polar coordinates according to Eq. (5.6).

the Fourier plane from the Cartesian grid to the pseudo-polar grid, which is defined using the following pseudo-polar coordinates  $(\zeta_x, \zeta_y) \in \mathbb{R}^2$ :

$$\begin{aligned} (\zeta_x, \zeta_y) &= \left( \Omega_x, \frac{\Omega_y}{\Omega_x} \right) \quad \text{if } (\Omega_x, \Omega_y) \in \mathcal{D}^{(v)}; \\ (\zeta_x, \zeta_y) &= \left( \Omega_y, \frac{\Omega_x}{\Omega_y} \right) \quad \text{if } (\Omega_x, \Omega_y) \in \mathcal{D}^{(h)}. \end{aligned}$$

Figure 9.48 shows the mapping from the Fourier plane to the pseudo-polar coordinates. Under this mapping, the following result is obtained,

$$\begin{aligned} V_a^{(d)} f(\zeta_x, \zeta_y) &= V_a^{(d)} f(\Omega_x, \Omega_y), \\ W^{(d)}(2^k(\zeta_y - l)) &= W_{kl}^{(d)}(\Omega_x, \Omega_y). \end{aligned}$$

Note that each directional window  $W_{kl}^{(d)}$  in the Fourier plane can be obtained by translating the window  $W^{(d)}$  in the pseudo-polar grid using the function  $\Psi_2$  in Eqs. (9.103) and (9.104), resulting in the directional localization supported in a wedge in the Fourier plane, as shown in Figure 9.49. This results in the spatial waveform  $w_{kl}^{(d)}(\mathbf{m})$  to be used in the following algorithm.

The digital implementation of the discrete shearlet transform in Eq. (9.105) can be realized through a filter bank as follows. Let  $H_k$  ( $G_k$ ) be the lowpass (highpass) filter of a wavelet transform with  $2k - 1$  zeros inserted between consecutive coefficients of a given 1-D filter  $H$  ( $G$  respectively). Define  $u * (H, G)$  to be the separable convolution of the rows and the columns of  $u$  with  $H$  and  $G$ , respectively.

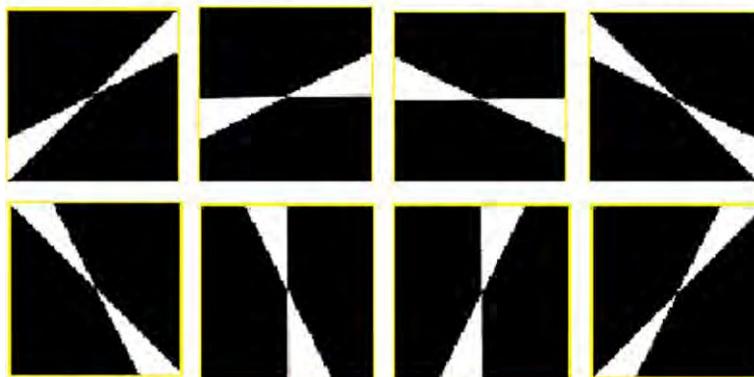

Notice that  $G$  is the wavelet filter corresponding to a highpass odd function  $\psi_1$ ,  $H$  is the filter corresponding to the coarse scale. The window  $W^{(d)}$  is related to an even lowpass function  $\psi_2$ . The  $\psi_1$  and  $\psi_2$  can be selected through the 1-D Meyer's wavelets.

The following is a cascade algorithm for implementing the discrete shearlet transform.

Let  $f \in l_2(\mathbb{Z}^2)$  be a 2-D image, define

$$\begin{aligned} S_0 f &= f(\mathbf{x}) \\ S_k f &= (S_{k-1} f) * (H_k, H_k), \quad k \geq 1. \end{aligned}$$

Images of the windows that partition the Fourier plane at various orientations

**FIGURE 9.49**

The  $2^3$  partition windows of the Fourier plane.

For  $d = v, h$ , the discrete shearlet transform can be calculated by the following

$$\gamma_f^{(d)}(k, l, \mathbf{m}) = \left( v_k^{(d)} f * w_{kl}^{(d)} \right) (\mathbf{m}), \quad \text{for } k \geq 0, -2^k \leq l \leq 2^k - 1, \mathbf{m} \in \mathcal{Z}^2, \quad (9.106)$$

where

$$v_k^{(h)} f = (S_k f) * (G_k, \delta), \quad v_k^{(v)} f = (S_k f) * (\delta, G_k).$$

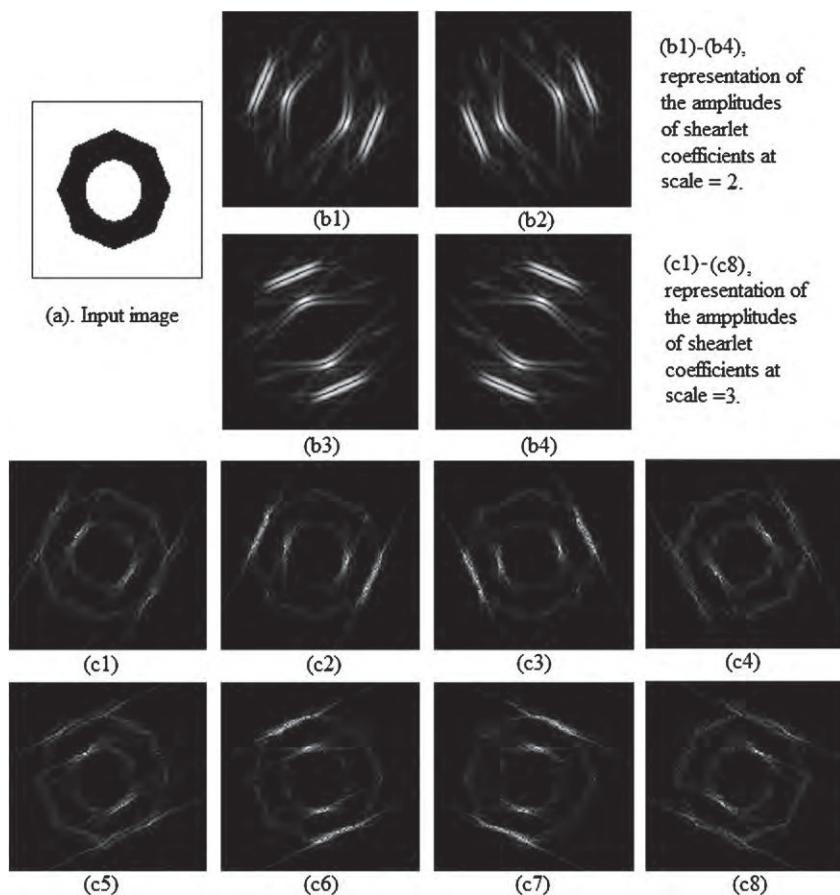

Figure 9.50 shows a representation of the discrete shearlet coefficients for different orientations at decomposition levels 2 and 3. For convenience, the vertical and horizontal shearlet coefficients are re-labeled according to the parameter  $l$  that represents the orientation,

$$\gamma_f(k, l, \mathbf{m}) = \begin{cases} \gamma_f^{(h)}(k, l - 1 - 2^k, \mathbf{m}) & 1 \leq l \leq 2^{k+1}, \\ \gamma_f^{(v)}(k, 3 * 2^k - 1 - l, \mathbf{m}) & 2^{k+1} < l \leq 2^{k+2}. \end{cases} \quad (9.107)$$

### 1.09.5.7 Applications

In the following, we are to separately introduce the applications of shearlet transform in processing edge related information, for example, estimation of edge orientation, edge detection, feature classification, and image denoising.

Edge related tasks, such as edge detection can be very difficult when noise, mixed with multiple edges, is presented in an image. The asymptotic decay property of the shearlet coefficients  $\gamma_f$  suggests that a shearlet transform can be a very efficient tool to determine the edges and their orientations inside an image  $f$ . A shearlet transform not only captures the singularities in a 2-D function, but also identifies the geometrical feature of curves where the singularities are located. This leads to the feature classification, namely, to determine whether a singularity point is a regular edge point or a irregular edge point, such as a corner and junction point.

**FIGURE 9.50**

(a) The image of a disk is shown. (b1-b4) The representations of shearlet coefficients of the disk image at multiple scales are shown for several values of the orientation index  $l$  for scale = 2. (c1-c8) The representations for scale = 3 are shown.

Another difficult task in image processing is denoising. Noise is the most prevalent as spike singularities are classified as isolated points that have significantly higher gradients than their neighbors. The fact that the shearlet transform coefficients on spike points actually grow at fine scales shows that a shearlet transform can be used to distinguish noise points from true edge points, and can therefore be an efficient tool for denoising.

#### 1.09.5.7.1 Estimation of edge orientation

Detecting edge orientation using a shearlet transform takes advantage of geometrical information contributions at various scales, directions, and locations. Multiple orientations may be found when there

are more than two curves merged at a location. Recently, Yi et al. [13, 123, 124] proposed to estimate the edge orientation using the following formula:

$$l(k, \mathbf{m}) = \arg \max_l |\gamma_f(k, l, \mathbf{m})|, \quad (9.108)$$

where  $\mathbf{m}$  is an edge point,  $k$  is a fine scale. The orientation angle,  $l(k, \mathbf{m})$ , can then be directly calculated. Note that this angle is a discrete value associated with  $l = 1, 2, 3, \dots, 2^k$  possible orientations. To reduce the quantization error, the values of the orientations will be interpolated using a parabolic function of  $l$  to model the continuous shearlet transform  $\gamma_f(k, l, \mathbf{m})$ , and the orientation angle of the edge is associated with the maximum value in the parabolic function. The following procedure describes the algorithm that uses shearlet transform to detect the orientation of an edge.

#### Shearlet Orientation Detection Algorithm:

- Compute  $l_1 = l(k, \mathbf{m})$  using Eq. (9.108); let  $l_0 = (l_1 - 1)(\text{mod } N)$ ,  $l_2 = (l_1 + 1)(\text{mod } N)$ , where  $N$  is the size of the set of indices  $l$ .
- $l_i$ ,  $i = 0, 1, 2$  are the slopes of three adjacent discretized directions. Let  $\theta_i$ ,  $i = 0, 1, 2$ , be the angles of orientations calculated from the  $l_i$ .
- Let  $S(\theta) = c_1\theta^2 + c_2\theta + c_3$ . When  $\theta = \theta_i$ ,  $S(\theta_i)$  is identified with  $\gamma_f(k, l_i, \mathbf{b})$ ,  $i = 0, 1, 2$ . Then  $c_1, c_2, c_3$  is obtained by fitting the system  $S(\theta_i) = c_1\theta_i^2 + c_2\theta_i + c_3$ . The detected angle,  $\theta_{\max} = -\frac{c_2}{2c_1}$ ,  $c_1 < 0$  is the value where the parabolic function  $S(\theta)$  achieves its maximum.

Figure 9.51 provides an error analysis of applying this algorithm to an image with a circle object.

#### 1.09.5.7.2 Feature classification

We present in this section a computationally efficient shearlet approach for classifying several different feature points in an image. This method has advantages over wavelet-based method, on account of the fact that the shearlet transform catches the directional features of an image.

In a typical image, there usually exist four classes of points, namely, junction and corner points; points near edges; points on smooth edges; points inside a smooth region. The different types of points may be classified by examining the behavior of the discrete shearlet transform coefficients according to the shearlet properties at these points.

First, at a fixed scale  $k_0$ , we define the energy function at each spatial point  $\mathbf{m}$  as

$$E_{k_0}(\mathbf{m}) = \sum_l |\gamma_f(k_0, l, \mathbf{m})|. \quad (9.109)$$

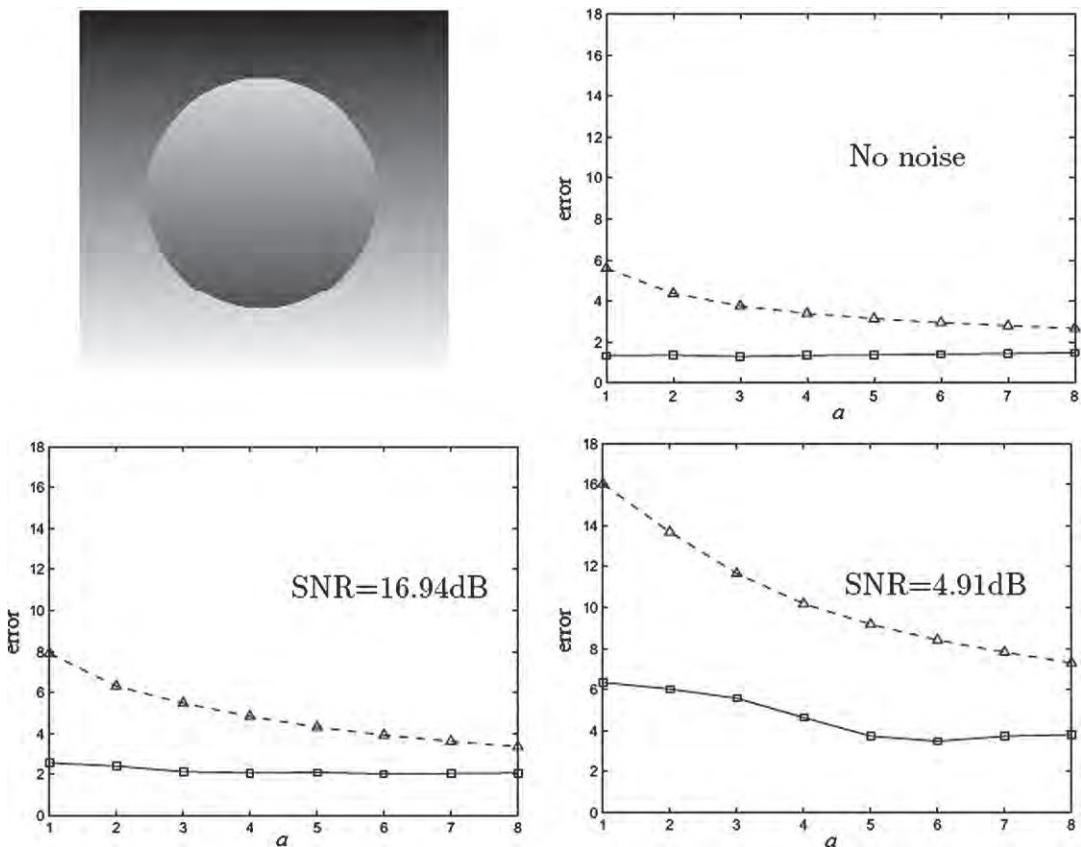

The points with large energy values  $E(\mathbf{m})$  are classified as boundary points.

Second, define the following function:

$$s_{\mathbf{m}_0}(l) = |\gamma_f(k_0, l, \mathbf{m}_0)|.$$

The function is tested on the boundary points, and the corners and junction points will be separated from the regular edge points by applying the following criteria:

- The point  $\mathbf{m}_0$  is a corner/junction point if more than one peak is presented in the function  $s_{\mathbf{m}_0}(l)$  at  $\mathbf{m}_0$ .
- The point  $\mathbf{m}_0$  is a regular edge point if the function  $s_{\mathbf{m}_0}(l)$  has only a single peak at  $\mathbf{m}_0$ .

**FIGURE 9.51**

Courtesy image [124]. Comparison of the average error in the estimation of edge orientation (expression (3.4.9)), for the disk image shown on the left, using the wavelet method (dashed line) versus the shearlet method (solid line), as a function of the scale  $a$ , for various SNRs (additive white Gaussian noise).

In order to implement this algorithm, for each boundary point  $\mathbf{m}$  at scale  $k_0$ , let  $L_{\mathbf{m}}$  be the set that collects all the orientations at which the local maxima of the amplitudes of the discrete shearlet coefficients occur along parameter  $l$ , namely,

$$L_{\mathbf{m}} = \{l : |\gamma_f(k_0, l, \mathbf{m})| > |\gamma_f(k_0, l + 1, \mathbf{m})| \text{ and } |\gamma_f(k_0, l, \mathbf{m})| > |\gamma_f(k_0, l - 1, \mathbf{m})|\}.$$

To verify the significance of the peaks in  $L_{\mathbf{m}}$  for each boundary point  $\mathbf{m}$ , in the following algorithm, we use normalized shearlet coefficients at the point  $\mathbf{m}$  defined as the following in order to find the local maximum points,

$$p_{\mathbf{m}}(l) = \begin{cases} \frac{|\gamma_f(k_0, l, \mathbf{m})|}{\sum_{l \in L_k} |\gamma_f(k_0, l, \mathbf{m})|}, & l \in L_k, \\ 0, & l \notin L_k. \end{cases} \quad (9.110)$$

Feature Classification Algorithm:

- Use the energy function  $E_{k_0}(\mathbf{m})$  defined in Eq. (9.109) to cluster the image points into three mutually exclusive sets  $I_1, I_2, I_3$ , the K-Mean clustering algorithm with Euclidean metric is used in the clustering algorithm.
- Reorder the index of sets  $I_i$ , namely, let

$$i_{\max} = \operatorname{argmax}_i \frac{1}{|I_i|} \sum_{\mathbf{m} \in I_i} E_{k_0}(\mathbf{m}), \text{ and } i_{\min} = \operatorname{argmin}_i \frac{1}{|I_i|} \sum_{\mathbf{m} \in I_i} E_{k_0}(\mathbf{m}).$$

The set  $I_{i_{\max}}$  is the set of boundary points, because the significant coefficients only occur at the boundary points. The set  $I_{i_{\min}}$  contains regular points inside a region because the coefficients rapidly decay to zero at these points. The set  $I_i$  between sets  $I_{i_{\min}}$  and  $I_{i_{\max}}$  contains the near edge points.

- For a point  $\mathbf{m} \in I_{i_{\max}}$ , sort the entries of the normalized coefficients  $p_{\mathbf{m}}(l)$  from the greatest to the smallest, and denote it as  $[\tilde{p}_{\mathbf{m}}(1), \dots, \tilde{p}_{\mathbf{m}}(N)]$ . Using again the K-Mean clustering algorithm on  $I_{i_{\max}}$ , this set can be further classified into one group of smooth edge points, and another group of corner and junction points according to the number of peaks at each boundary point.

Note that corner points can be further separated from junction points, and junction points can be separated into different classes corresponding to different geometric features. Figure 9.52 illustrates the result of applying the feature classification algorithm.

#### 1.09.5.7.3 Edge detection

Edge detection is a difficult task when noise is presented, and when several edges intersect each other and they are close together. The asymptotic decay rate of the continuous shearlet transform provides a better solution to precisely capture the geometry of edges, and it can be used to obtain both locations and orientations of edges in an image  $f$ . Here, we describe an effective edge detection scheme to precisely detect the shape of an edge using the shearlet transform that can be attributed to the anisotropic analytic and geometric properties of shearlets.

In this algorithm, the first step is to identify the edge candidates in an image  $f$ . They are selected by the shearlet transform modulus maxima at the  $k$ th scale level, that is, those points,  $\mathbf{m}$ , that are the local maxima of the function

$$M_k f(\mathbf{m})^2 = \sum_l |\gamma_f(k, l, \mathbf{m})|^2.$$

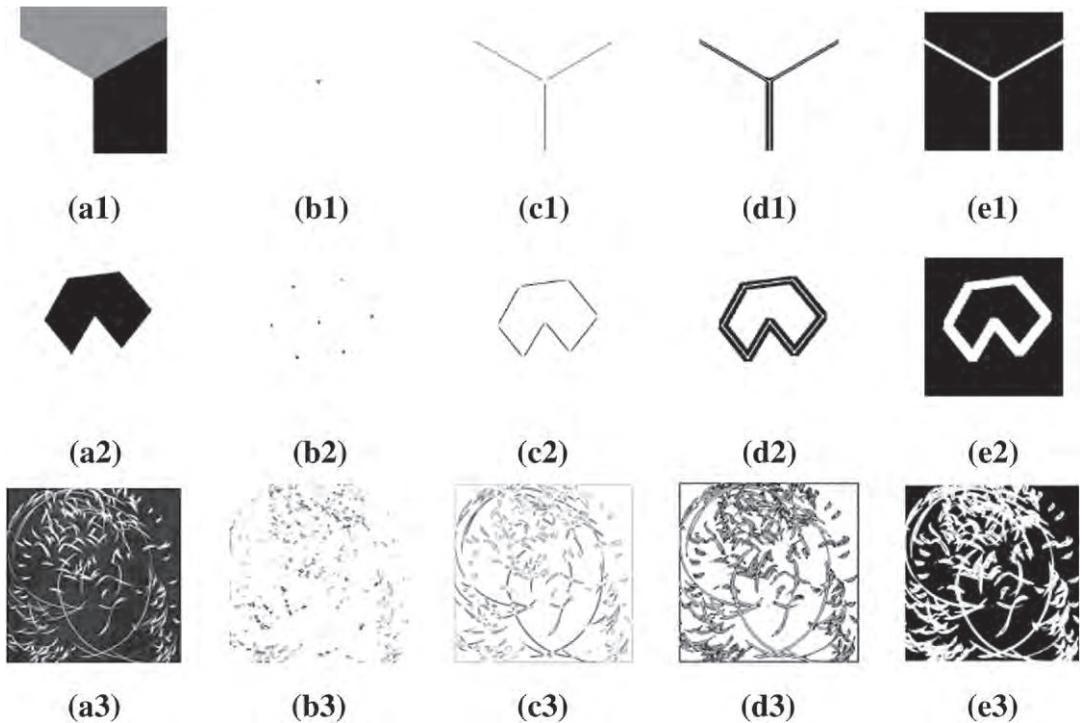

The second step is to confirm edge points by excluding the noise points. According to the property of shearlet transform, if  $\mathbf{m}$  is an edge point, the shearlet transform of  $f$  has the property that

$$|\gamma_f(k, l, \mathbf{m})| \sim C 2^{-\beta k}, \quad \beta > 0.$$

Note that points with  $\beta < 0$  will be classified as noise; therefore, the edge points can be identified as those points that have  $\beta > 0$ , and the task of edge detection is transferred to the task of determining the sign of  $\beta$ .

Theoretically, this can be estimated by computing the best linear fit to data

$$\{\log |\gamma_f(k, l, \mathbf{m})|\}_{k=1,2,\dots,L}.$$

**FIGURE 9.52**

Courtesy image [124]. (a1–a3) Test images. (b1–b3) Identification of corners and junctions. (c1–c3) Identification of smooth edge points. (d1–d3) Identification of points near the edges. (e1–e3) Identification of regular points (smooth regions).

The magnitude of the shearlet coefficients at each point is compared with the values of its neighbor's along the gradient direction (this is obtained from the orientation map of the shearlet decomposition). If the magnitude is smaller, the point is discarded; if it is the largest, it is kept. This yields a set of possible edge points. This is the so called non-maximal suppression routine. Further, this edge candidate set will be filtered by a window filter, and a smooth edge set can be selected by threshold. In practice, the following shearlet edge detection algorithm is implemented to simplify the computation complexity.

#### Shearlet Edge Detection Algorithm:

- Let  $f \in l_2(\mathbb{Z}^2)$  be a 2-D image, calculate  $\gamma_f^{(d)}(k, l, \mathbf{m})$  given as follows:

$$\gamma_f^{(d)}(k, l, \mathbf{m}) = \left( v_k^{(d)} f * w_{kl}^{(d)} \right) (\mathbf{m}), \quad \text{for } k \geq 0, -2^k \leq l \leq 2^k - 1, \mathbf{m} \in \mathbb{Z}^2, \quad (9.111)$$

where

$$S_0 f = f(\mathbf{x}),$$

$$\begin{aligned} S_k f &= (S_{k-1} f) * (H_k, H_k), \quad k \geq 1, \\ v_k^{(h)} f &= (S_k f) * (G_k, \delta), \\ v_k^{(v)} f &= (S_k f) * (\delta, G_k). \end{aligned}$$

- Define

$$\chi_l^{(d)}(\mathbf{m}) = \begin{cases} 1 & \text{if } \gamma_f^{(d)}(k, l, \mathbf{m}) > \gamma_f^{(d)}(k-1, l, \mathbf{m}) \\ 0 & \text{otherwise} \end{cases}, \quad d = v, h. \quad (9.112)$$

This defines a function to indicate the points that has negative Lipschitz regularity.

- Based on this indicator function, define

$$R_k^{(d)} f(\mathbf{m}) = \sum_l \gamma_f^{(d)}(k, l, \mathbf{m}) \chi_l^{(d)}(\mathbf{m}), \quad d = v, h.$$

- Modify  $v_k^{(d)} f$ ,  $d = v, h$ , according to the following formula:

$$v_k^{(d)} f = \begin{cases} v_k^{(d)} f + R_k^{(d)} f & \text{if } |v_k^{(d)} f| \leq |R_k^{(d)} f| \\ R_k^{(d)} f & \text{otherwise} \end{cases}, \quad d = v, h. \quad (9.113)$$

This formula modifies  $v_k^{(d)} f$  so that the value of  $v_k^{(d)} f$  is kept small (unchanged) for locations with positive Lipschitz regularity and the value of  $v_k^{(d)} f$  is increased over the scales for locations with negative Lipschitz regularity.

- After the discrete shearlet  $\gamma_f^{(d)}(k, l, \mathbf{m})$  is calculated using the updated  $v_k^{(d)} f$ . The edge at level  $k$  will be decided by checking the local maxima of the following function:

$$E_k(\mathbf{m}) = \left( \sum_l \gamma_f^{(v)}(k, l, \mathbf{m}) \right)^2 + \left( \sum_l \gamma_f^{(h)}(k, l, \mathbf{m}) \right)^2.$$

Figure 9.53 shows the results of edge detection, in which the Pratt's figure of merit (FOM) is used to measure the performance of an edge detector [129].

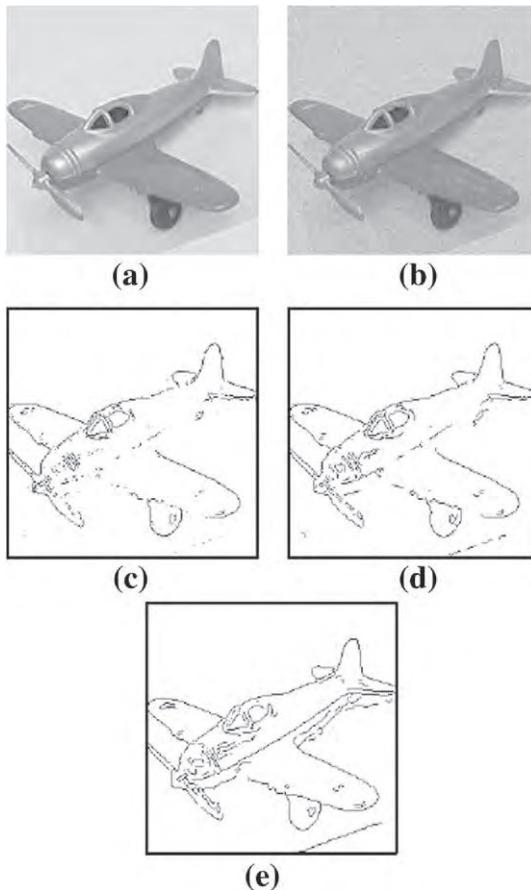

#### 1.09.5.7.4 Image denoising

The properties of shearlet coefficients at fine scales show that a 2-D function  $f$  can be reproduced using the following shearlet representation, see [130],

$$f(\mathbf{b}) = \sum_{k,l,\mathbf{m} \in M_1} \langle f, \psi_{k,l,\mathbf{m}} \rangle \psi_{k,l,\mathbf{m}}(\mathbf{b}) + \sum_{k,l,\mathbf{m} \in M_2} \langle f, \psi_{k,l,\mathbf{m}} \rangle \psi_{k,l,\mathbf{m}}(\mathbf{b}), \quad (9.114)$$

where  $M_1$  is the set of coefficients associated with the smooth regions of  $f$ , and  $M_2$  is the set of coefficients associated with the edges of  $f$ .

A simple approach to achieve image denoising is carried out by using a shrinkage approach to remove shearlet coefficients below a threshold,  $\tau$ . A denoised image using the discrete shearlet transform can

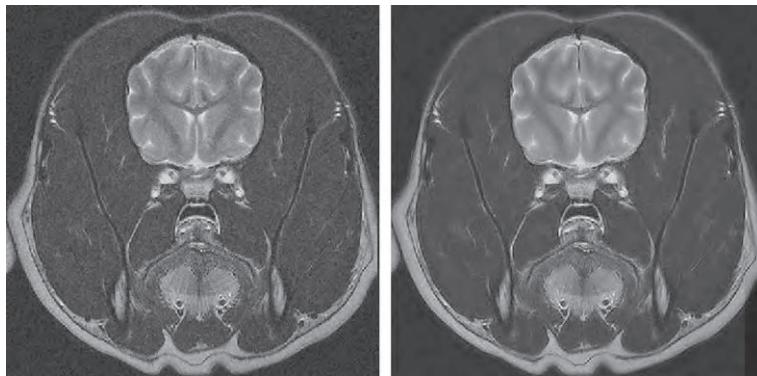

**FIGURE 9.53**

Courtesy image [124]. Results of edge detection methods. From (a) to (e): (a) original image, (b) noisy image (PSNR = 24.58 dB), (c) Sobel result (FOM = 0.54), (d) wavelet result (FOM = 0.84), and (e) shearlet result (FOM = 0.94).

be expressed as

$$\tilde{f}(\mathbf{b}) \approx \sum_{k,l,\mathbf{m} \in M_1} \langle f, \psi_{k,l,\mathbf{m}} \rangle \psi_{k,l,\mathbf{m}}(\mathbf{b}) + \sum_{k,l,\mathbf{m} \in M_2^c} \langle f, \psi_{k,l,\mathbf{m}} \rangle \psi_{k,l,\mathbf{m}}(\mathbf{b}), \quad (9.115)$$

where  $M_2^c$  is the set of shearlet coefficients whose values are greater than  $\tau$ . This approach is able to optimally capture directional features, and reach the desired denoising effect. Figure 9.54 shows a denoising result using the shrinkage method.

**FIGURE 9.54**

In this picture, the noisy brain image is shown to the left, and the filtered image using the shearlet denoising method, is shown to the right.

## A Appendix

### A.1 The $z$ -transform

Much like in the continuous time domain, we can cover the whole complex plane by using a Laplace Transform in contrast to the harmonic Fourier Transform along the imaginary axis, we may cover the whole interior of the unit circle in the discrete domain by invoking the so-called  $z$ -Transform. For purposes of direct relevance to the derivations of the various multi-scale transforms in this chapter, we define the  $z$ -transform in the 2-D plane. Given a 2-D discretized signal,  $x(\mathbf{n})$ ,  $\mathbf{n} \in \mathbb{Z}^2$ , its  $z$ -transform,  $X(z)$ ,  $z \in \mathbb{Z}^2$  is defined as

$$X(z) = \sum_{n \in \mathbb{Z}^2} x(\mathbf{n})z^{-\mathbf{n}} = \sum_{n \in \mathbb{Z}^2} x(\mathbf{n})z_1^{-n_1}z_2^{-n_2}, \text{ with } \mathbf{n} = (n_1, n_2), z = (z_1, z_2).$$

Note that the  $z$ -transform of an image  $x(\mathbf{n})$  is reduced to its discrete time Fourier series when we evaluate its  $z$ -transform function at  $z = e^{j\omega}$ .

Given a discrete 2-D image  $x(\mathbf{n})$  as an input to a 2-D linear discrete invariant system with an impulse response of  $h(\mathbf{n})$ , the resulting output is the following convolution sum:

$$y(\mathbf{n}) = x(\mathbf{n}) * h(\mathbf{n}) = \sum_{s \in \mathbb{Z}^2} x(s_1, s_2)h(n_1 - s_1, n_2 - s_2).$$

The  $z$ -transform of the output,  $y(\mathbf{n})$  of the system is similarly (to the continuous analog)  $Y(z) = H(z)X(z)$ , where  $z$ -transform of the impulse response  $h(\mathbf{n})$ , is written as  $H(z)$ , and called the transfer function of the filter system. The  $z$ -transform is a very widely used tool in the analysis and design of discrete filter systems.

## 1.10.1 Introduction

Frames were introduced by Duffin and Schaeffer [1] in 1952 for the study of non-harmonic Fourier series [2,3]. The central idea was to represent a signal by its projections on a sequence of elements  $\{e^{j\lambda_n t}\}_n$ ,  $n \in \mathbb{Z}$ , not restricting the  $\lambda_n$  to be multiples  $n\Omega$  of a fundamental frequency  $\Omega$  as in harmonic (traditional) Fourier series. One can readily see that the set  $\{e^{j\lambda_n t}\}_n$  is highly overcomplete, in the sense that, for example, in a space  $L^2(-T, T)$ , it may consist of a sequence of elements or functions that are greater in number than a basis for  $L^2(-T, T)$ , being the last given for example by harmonic Fourier series, among others.

As a side effect, overcompleteness may make it hard to find a representation of a function  $f(t) \in L^2(-T, T)$  using the set  $\{e^{j\lambda_n t}\}_n$ , in the form

$$f(t) = \sum_n c_n e^{j\lambda_n t}. \quad (10.1)$$

This is because, due to overcompleteness, the weights or coefficients  $c_n$  in Eq. (10.1) can not be computed by the simple approach of projecting  $f(t)$  into each element of  $\{e^{j\lambda_n t}\}_n$ . This would be equivalent to using  $c_n = \langle f(t), e^{j\lambda_n t} \rangle$ , where  $\langle f(t), g(t) \rangle$  represents the inner product  $\int f(t)g^*(t)dt$  and  $g^*(t)$  denotes the complex conjugate of  $g(t)$ . One should note that, when using an orthonormal Basis for representing a signal (as is the sequence of elements defining harmonic Fourier series), computing the inner product is the standard approach for finding the  $c_n$ .

Despite that difficulty, overcompleteness may bring some advantages as one may obtain more compact, robust or stable signal representations than using Bases [4–7]. This is why frames are being widely researched and employed in the last two decades in mathematics, statistics, computer science and engineering [4].

The basic idea leading to the definition of frames is the representation of signals from a given space using more “points” or coefficients than the minimum necessary—this is the whole concept behind overcompleteness. This idea is behind modern analog-to-digital converters (ADC) that sample signals at rates that are higher than the Nyquist rate with low resolution [8]. Since, the signal is sampled at

high rate, the requirement on the sample precision can be relaxed [6]. This is a different perspective as compared to sampling based on the Nyquist criterion, when in general one assumes that a good quantization precision is employed so that quantization errors can be neglected.

In addition to the above, there is the motivation of achieving nonuniform and/or irregular sampling (since sampling clock jitter is equivalent to irregular sampling). This has led to a large set of results and some applications of the “frame theory” [9]. These ideas were further extrapolated leading to the definition of “Rate of Innovation” of signals [10]. In this case one considers the number of degrees of freedom per unit of time of a class of signals; this is employed in [10] for sampling purposes. In some way, these concepts have lead to the so-called “Compressed Sensing” (CS) perspective [11].

Although frames provide the mathematical justification for several signal processing methods and are at the heart of the flow of ideas and achievements shortly and briefly described above, it took a long time until frames came definitely into play. The first book concerning the topic was written by Young in 1980 [2]. In [12] Daubechies, Grossman and Meyer realized that frames can somehow be understood in a way very similar to expansions using bases. This established the link among frames and wavelets [5, 13, 14], and new breath was given to the research on frames. Applications of the “frame theory” have broadly appeared. Frames have been an active area of research, allowing the production of a plethora of theoretical results and applications. Good material on frames can be found in [4, 5, 13], and a book dedicated to this topic is [6]. We try to show a few of the relevant results regarding frames in this chapter.

### 1.10.1.1 Notation

In the following we use  $\mathbf{x}$ , to denote a signal in a discrete space, for a finite dimensional discrete space the same notation is employed. The value of the  $n$ th coordinate or sample of  $\mathbf{x}$  is referred to by  $x[n]$ . A bold capital is used for matrices, as  $\mathbf{G}$ . Continuous functions or signals are explicitly denoted with reference to the independent variable, as in  $x(t)$ . When just a letter like  $x$  is employed it is because the definition or result applies in both cases—discrete or continuous spaces.  $\|x\|$  refers to  $\langle x, x \rangle$ . The inner product  $\langle f, g \rangle$  is to be understood as  $\langle f(t), g(t) \rangle = \int f(t)g^*(t)dt$  in continuous spaces, and  $\langle \mathbf{f}, \mathbf{g} \rangle = \sum_n f[n]g^*[n]$  in discrete spaces.

---

## 1.10.2 Basic concepts

Let us try to briefly introduce what are frames. A frame of a space  $\mathbb{H}$  is a set of elements that spans  $\mathbb{H}$ . Therefore, a frame  $\mathcal{G} = \{g_k\}_{k \in \mathcal{K}}$  (a set of elements  $g_k$  which are indexed by  $k \in \mathcal{K}$ ), can be used to express any  $x \in \mathbb{H}$  by means of

$$\mathbf{x} = \sum_{k \in \mathcal{K}} c_k \mathbf{g}_k, \quad (10.2)$$

where the  $c_k$  are called the frame coefficients.

The only restriction that we have imposed on  $\mathcal{G} = \{g_k\}_{k \in \mathcal{K}}$  for it being a frame is that it should span  $\mathbb{H}$ . Therefore,  $\mathcal{G}$  is in general overcomplete, meaning that the set of frame coefficients  $\{c_k\}_{k \in \mathcal{K}}$  that can express  $x$  by means of Eq. (10.2) is not unique, as the overcompleteness of  $\mathcal{G}$  means that its elements are not linearly independent.

From above one sees that there may exist different ways to compute the frame coefficients  $c_k$  used in Eq. (10.2) to synthesize  $x$ . We employ interchangeably both terms “expansion” as well as representation

since all the frame elements (generally in larger number than the space dimension) may a priori be employed to express the signal. Due to overcompleteness one usually employs more elements than the support or dimension of the signal space  $\mathbb{H}$  to represent the signal. This is equivalent to saying that the frame coefficients for a given signal may be in larger number than the coefficients employed in the canonical signal representation.

**Example 10.1.** Consider the set of elements  $\mathcal{G}$  in  $\mathbb{R}^2$ ,  $\mathcal{G} = \{[0 \ 1/2], [1/4 \ -1/4], [-1/2 \ 0]\}$ . Any vector  $\mathbf{x} = [x[0], x[1]]$  projected into these elements gives a set of coefficients:

$$\tilde{\mathbf{c}} = \begin{bmatrix} \tilde{c}_0 \\ \tilde{c}_1 \\ \tilde{c}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1/2 \\ 1/4 & -1/4 \\ -1/2 & 0 \end{bmatrix} \begin{bmatrix} x[0] \\ x[1] \end{bmatrix} = \begin{bmatrix} x[1]/2 \\ (x[0] - x[1])/4 \\ -x[0]/2 \end{bmatrix}. \quad (10.3)$$

The original vector can be obtained from  $\tilde{\mathbf{c}}$  using, for example

$$\begin{bmatrix} x[0] \\ x[1] \end{bmatrix} = \tilde{\mathbf{G}}^T \tilde{\mathbf{c}} = \begin{bmatrix} 0 & 0 & -2 \\ 2 & 0 & 0 \end{bmatrix} \begin{bmatrix} \tilde{c}_0 \\ \tilde{c}_1 \\ \tilde{c}_2 \end{bmatrix} \text{ or } \begin{bmatrix} x[0] \\ x[1] \end{bmatrix} = \tilde{\mathbf{G}}^T \tilde{\mathbf{c}} = \begin{bmatrix} 0 & 0 & -2 \\ 0 & -4 & -2 \end{bmatrix} \begin{bmatrix} \tilde{c}_0 \\ \tilde{c}_1 \\ \tilde{c}_2 \end{bmatrix}, \quad (10.4)$$

among several other possibilities for  $\tilde{\mathbf{G}}^T$ . That is, the  $\tilde{\mathbf{G}}^T$  that reconstructs  $\mathbf{x}$  from its projection on a set  $\mathcal{G}$  is not unique.

Consider that  $\mathbf{G}$  is the matrix constructed from the frame elements by stacking them as rows.  $\mathbf{G}$  is used to compute the coefficients vector  $\tilde{\mathbf{c}}$  using

$$\tilde{\mathbf{c}} = \mathbf{G}\mathbf{x}. \quad (10.5)$$

Note that in the current example  $\dim(\mathbf{x}) = 2 \times 1$ ,  $\dim(\mathbf{G}) = 3 \times 2$ ,  $\dim(\tilde{\mathbf{c}}) = 3 \times 1$  and  $\dim(\tilde{\mathbf{G}}^T) = 2 \times 3$ . If a frame for  $\mathbb{R}^N$  has  $K > N$  elements, one has that  $\dim(\mathbf{x}) = N \times 1$ ,  $\dim(\mathbf{G}) = K \times N$ ,  $\dim(\tilde{\mathbf{c}}) = K \times 1$  and  $\dim(\tilde{\mathbf{G}}^T) = N \times K$ . That is, one has that the matrix  $\tilde{\mathbf{G}}^T$  used to obtain  $\mathbf{x} = \tilde{\mathbf{G}}^T \tilde{\mathbf{c}}$  must be such that  $\tilde{\mathbf{G}}^T \mathbf{G} = \mathbf{I}_N$  ( $\mathbf{I}_N$  is the identity matrix of dimension equating the dimension of the vectors in  $\mathcal{G}$ , which is 2 in the present example).

Obviously, the roles of the matrices  $\mathbf{G}$  and  $\tilde{\mathbf{G}}$  above can be interchanged. Since  $\tilde{\mathbf{G}}^T \mathbf{G} = \mathbf{I}_N$  one has that  $\mathbf{G}^T \tilde{\mathbf{G}} = \mathbf{I}_N$ , and thus one can employ  $\tilde{\mathbf{G}}$  as a projection operator on  $\mathbf{x}$  for finding a set of coefficients  $\mathbf{c}$ , and reconstruct  $\mathbf{x}$  using

$$\mathbf{x} = \mathbf{G}\mathbf{c}. \quad (10.6)$$

Note that in this case one can make

$$\tilde{\mathbf{G}}^T = \begin{bmatrix} 1 & 2 & -1 \\ 1 & -2 & -1 \end{bmatrix}, \quad (10.7)$$

or define  $\tilde{\mathbf{G}}$  as in (10.4). □

As we have seen in the example above, one should note that the set  $\mathbf{c}$  is redundant in the sense that the vectors employed to compute the  $\{c_k\}_{k \in \mathcal{K}}$  (onto which  $\mathbf{x}$  is projected) may be linearly dependent. One advantage of this is that the wrong computation of some coefficients of the expansion or even their losses may still allow the recovery of the original signal from the remaining coefficients within

an acceptable error, as one has different possible signal reconstruction operators provided by the frame concept. These ideas have led to applications of frame expansions for signal sampling with low quantization requirements [4], and also to the development of transmission systems that are robust to erasures (when data is lost or erased) over a network, which corresponds to the deletion of the correspondent frame elements [15–17].

### 1.10.2.1 The dual frame

The above example links to the strategy for computing frame coefficients using the inverse or dual frame [4–7], that provides the dual reconstruction formulas

$$\mathbf{x} = \sum_{k \in \mathcal{K}} \langle \mathbf{x}, \mathbf{g}_k \rangle \tilde{\mathbf{g}}_k = \sum_{k \in \mathcal{K}} \langle \mathbf{x}, \tilde{\mathbf{g}}_k \rangle \mathbf{g}_k. \quad (10.8)$$

From Eq. (10.8) one may define  $\tilde{\mathcal{G}} = \{\tilde{\mathbf{g}}_k\}_{k \in \mathcal{K}}$  as the inverse or dual frame to the frame  $\mathcal{G} = \{\mathbf{g}_k\}_{k \in \mathcal{K}}$ . For a given signal  $\mathbf{x}$ , since  $\mathcal{G}$  is overcomplete,  $\tilde{\mathcal{G}}$  is, in general, not unique [6], as shown in Example 10.1.

Considering a frame expansion of a signal—the set of coefficients  $c_k$ , the frame expansion can be viewed as a measure of “how much” the signal “has” of each frame element  $\{\mathbf{g}_k\}_{k \in \mathcal{K}}$ . As it can be readily seen, this property can be used to infer or analyze signal characteristics. Since in an overcomplete frame its elements are linearly dependent, at least two of its elements are not orthogonal. This implies that characteristics that are different, but similar to one another, can be effectively observed by projecting the signal into different frame elements that are similar to these characteristics. If an orthogonal basis was used instead, such characteristics would not be as evident from the projections, since each projection would have at most a small amount of each characteristic. This way, the similar characteristic would be mixed among different projections, and would therefore not be as evident as in the case of a redundant frame.

The reasoning in the above paragraph has been largely employed to justify the use of the so-called Gabor frames, that are discussed in Section 1.10.5.4. Gabor frames are constructed by modulation and translation of a prototype function, providing thus a time-frequency analysis capability [4, 18–22]. Gabor frames employ sets of time and frequency translated versions of a predefined function to analyze or synthesize a signal. These frames are named after Gabor due to their origins in [23]. The main idea is to explore functions that have some desired energy concentration in time and frequency domain to analyze the content or information that is represented in a signal. Several tools have been developed for achieving this, using the decomposition of a signal into a Gabor frame [24–26]. As the example regarding the Gaborgram in Section 1.10.6.2 ahead shows, the inverse frame elements may not resemble the frame elements and some care must be taken when using frame expansions to capture specific signal features.

Although the elements of a frame that are used to express a signal are in general selected *a priori*, frame expansions allow for the use of elements with special properties. The Balian-Low theorem [13] shows that it is not possible to construct a basis with elements that are well localized in both time and frequency domains simultaneously. Frames do not impose uniqueness to the signal representation, therefore the definition of the frame elements is less restrictive than it is for basis elements. Hence, we can achieve, for a frame, a better localization of its elements simultaneously in time and frequency domain than for a basis, better dealing with the limitations imposed by the uncertainty principle [4, 19, 21].

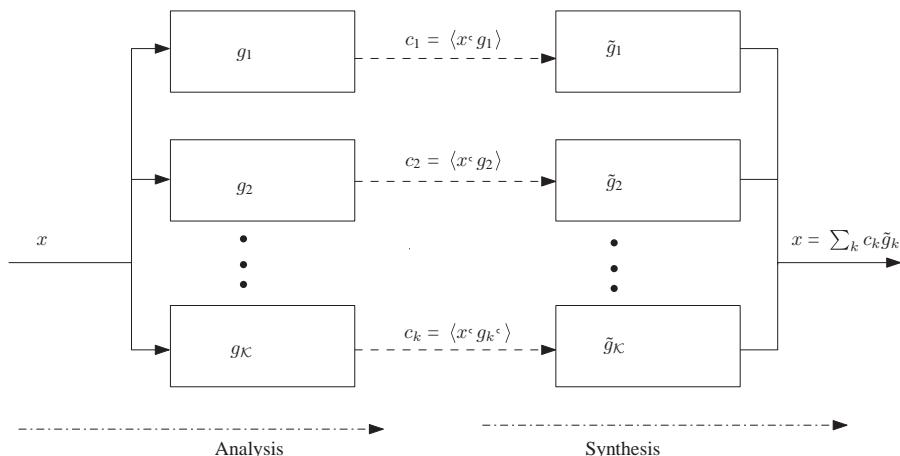

The property of frames discussed above has been largely employed by the so-called Windowed Fourier Analysis schemes [4,27]. In addition, since the frame coefficients may not be unique for a given signal, the set of frame coefficients can be altered or improved—considering the linear dependencies among frame elements—in order to highlight desired signal features. Moreover, frames can be designed for specific applications depending on the features that one desires to extract or analyze in the signal. Examples of such specific designs are ones using wavelets [4,5,7] and other time-frequency [4,28] or structurally/ geometrically oriented analysis techniques [29,30].

In general, the computational burden of obtaining signal representations into frames surpasses the computational demands of traditional expansions into basis, as, for example, the ones of the Fast Fourier Transform (FFT) [31]. However, as mentioned above, with frame expansions we can obtain a separation of signal structures that is much higher than the one that is possible using traditional approaches. Mallat [4] explores this in his proposed super-resolution techniques.

Due to the characteristics above, frame applications range from signal coding [4], signal sampling [1,4,6], signal analysis [4,5] and transient detection [24,25], to communication systems design [6,32]. Frames have also been related to the analysis and design of Filter Banks [33,34].

### 1.10.2.2 Signal analysis and synthesis using frames

A frame or its dual can be employed to analyze a signal and obtain the signal expansion, i.e., the frame coefficients, and to synthesize it from the coefficients obtained in the analysis process. This is shown in Figure 10.1. As it can be noticed, from Eq. (10.22), the roles of  $\{g_k\}_{k \in \mathcal{K}}$  and  $\{\tilde{g}_k\}_{k \in \mathcal{K}}$  can be interchanged in Figure 10.1, providing different perspectives for signal analysis.

**FIGURE 10.1**

Analysis and synthesis of a signal using a frame and its inverse—as noted in the text, the roles can be interchanged.

One notes that the “system model” of Figure 10.1 is very similar to the one employed in several signal processing tasks—for example in filter banks. This resemblance between frames and several signal processing tasks provides a large range of potential applications for frames. To highlight an important feature, the frame elements may be designed to highlight or analyze desired signal features that may be “overlapping” or linearly dependent.

In the scenario of filter banks, a relevant and special case is the one of a “perfect reconstruction filter bank” [31]. In this case the analysis and reconstruction filter banks correspond to a pair of dual frames. A more detailed analysis of the input-output mapping in this case is provided in Section 1.10.4.1 where we discuss frames of discrete spaces.

Some examples of common frame constructions for signal analysis purposes are Gabor and Wavelet frames. These provide expansion systems or representations that have different supports on the time-frequency plane. We will discuss them in Sections 1.10.5.4 and 1.10.5.5 respectively.

### 1.10.3 Relevant definitions

Now, that we have discussed some basic properties of frames, we are ready to present a more formal definition.

**Definition 10.1.** A sequence of elements  $\mathcal{G} = \{g_k\}_{k \in \mathcal{K}}$  in a space  $\mathbb{H}$  is a *frame* for  $\mathbb{H}$  if there exist constants  $A$  and  $B$ ,  $0 < A < B < \infty$ , such that [4–7]

$$A\|x\|^2 \leq \sum_{k \in \mathcal{K}} |\langle x, g_k \rangle|^2 \leq B\|x\|^2, \quad \forall x \in \mathbb{H}. \quad (10.9)$$

- i. The numbers  $A$  and  $B$  are called the lower and upper *frame bounds*, respectively, and are not unique. The optimal lower frame bound is the supremum on all  $A$  and the optimal upper frame bound is the infimum on all  $B$  [6].
- ii. It is said that the frame is normalized [5] if  $\|g_k\| = 1$ ,  $\forall k \in \mathcal{K}$ . □

A commonly addressed problem, related to frames, is how to determine if a given sequence of elements  $\{g_k\}_{k \in \mathcal{K}}$  in  $\mathbb{H}$  is a frame of  $\mathbb{H}$ . This is often referred to as the frame characterization problem [6]. This characterization is commonly accomplished by the frame bounds. From Eq. (10.9), one notes that if for any signal one obtains  $A = 0$  then the signal is orthogonal to all the elements  $\{g_k\}_{k \in \mathcal{K}}$  and the signal can not be represented using these elements. That is the reason for the requirement that  $A > 0$ . Also, if for a given signal there is no upper bound in Eq. (10.9) then this means that the elements are too “dense” for that signal and the frame does not provide a stable representation.

Given a set of elements in a space  $\mathbb{H}$ , in order to verify if it is or is not a frame one may compute the frame bounds. It is in general much easier to find the upper frame bound  $B$  than the lower frame bound  $A$ .

**Example 10.2.** For instance, note that in a space  $\mathbb{R}^N$  any quantity  $M > N$  of finite norm vectors will always provide a  $B < \infty$ . However, for the lower bound defines if the set spans or not  $\mathbb{H}$  and in this case a more careful analysis is required. □

#### 1.10.3.1 The frame operator

Let us now define the frame operator and state the frame decomposition result.

**Definition 10.2.** Define the *frame operator*  $S\{\cdot\}$  as

$$S : \mathbb{H} \rightarrow \mathbb{H}, S\{x\} = \sum_{k \in \mathcal{K}} \langle x, g_k \rangle g_k. \quad (10.10)$$

From this definition some properties hold [6]:

- i. The frame operator is bounded, invertible, self-adjoint and positive. Therefore, it assumes an inverse  $S^{-1}\{\cdot\}$ . This is referred to as the *inverse frame operator*.

$$x = S\{S^{-1}\{x\}\} = \sum_{k \in \mathcal{K}} \langle S^{-1}\{x\}, g_k \rangle g_k. \quad (10.11)$$

- ii. If the lower and upper frame bound of  $\{g_k\}_{k \in \mathcal{K}}$  are, respectively  $A$  and  $B$ , then  $\{S^{-1}\{g_k\}\}_{k \in \mathcal{K}}$  is a frame with bounds  $B^{-1}$  and  $A^{-1}$ , and the frame operator for  $\{S^{-1}\{g_k\}\}_{k \in \mathcal{K}}$  is  $S^{-1}$ .  $\square$

From the definition of the frame operator one has the *frame decomposition* result that provides the reconstruction formulas [6]

$$x = \sum_{k \in \mathcal{K}} \langle x, g_k \rangle S^{-1}\{g_k\} = \sum_{k \in \mathcal{K}} \langle x, S^{-1}\{g_k\} \rangle g_k \quad (10.12)$$

Note that this provides a way to compute the  $\tilde{g}_k = S^{-1}\{g_k\}$  which are the elements of the inverse frame or the so-called canonical dual.

**Example 10.3.** Suppose that a normalized frame  $\{g_k\}_{k \in \mathcal{K}}$  is used to express the information of a signal  $x$ , to transmit or store this information and to reconstruct  $x$ . In this scenario, assume that one transmits/stores the frame coefficients

$$c_k = \langle x, S^{-1}\{g_k\} \rangle, \quad (10.13)$$

where we employ the inverse frame operator. From the definitions one has that

$$x = \sum_k c_k g_k. \quad (10.14)$$

However, due to quantization coefficients are corrupted by noise. In this case one must reconstruct  $\hat{x}$

$$\hat{x} = \sum_{k \in \mathcal{K}} (c_k + w_k) g_k = \sum_{k \in \mathcal{K}} (\langle x, S^{-1}\{g_k\} \rangle + w_k) g_k. \quad (10.15)$$

Obviously, due to the frame reconstruction one has that

$$\hat{x} = x + \sum_{k \in \mathcal{K}} w_k g_k. \quad (10.16)$$

The reconstructed signal is corrupted by noise.

One should note that in this scenario, we know that the  $c_k$  (obtained by means of Eq. (10.13) are the expansion of a signal over a frame). However, this may not be the case for the set of coefficients

$$\left\{ \langle x, S^{-1} \{g_k\} \rangle + w_k \right\}_{k \in \mathcal{K}} \quad (10.17)$$

used to reconstruct  $\hat{x}$  in Eq. (10.15). Assuming that  $w_k \in \ell^2(\mathbb{N})$ —i.e., the noise is bounded, that fact may be compensated by projecting  $\{\langle x, S^{-1} \{g_k\} \rangle + w_k\}_{k \in \mathcal{K}}$  using the operator [4,6]:

$$Q \{c_k\} = \left\{ \left\langle \sum_k c_k S^{-1} \{g_k\}, g_j \right\rangle \right\}_{j \in \mathcal{K}}. \quad (10.18)$$

Using this operator in the projected-quantized frame coefficients scenario above one has that (apply  $Q\{\cdot\}$  to Eq. (10.17))

$$Q \left\{ \langle x, S^{-1} \{g_k\} \rangle + w_k \right\}_{k \in \mathcal{K}} = \{c_k\}_{k \in \mathcal{K}} + Q \{w_k\}_{k \in \mathcal{K}}. \quad (10.19)$$

Using this, the signal can be reconstructed by means of

$$\hat{x} = \sum_{k \in \mathcal{K}} (c_k + Q \{w_k\}) g_k = x + \sum_{k \in \mathcal{K}} Q \{w_k\} g_k. \quad (10.20)$$

Supposing that the frame  $\{g_k\}_{k \in \mathcal{K}}$  is normalized, considering the quantization noise in Eq. (10.15) to be white and zero-mean, using  $E[\cdot]$  to denote the expected value, then in [4] it is shown that

$$E \left[ |Q \{w\}|^2 \right] \leq \frac{1}{A} E \left[ |w|^2 \right]. \quad (10.21)$$

That is, the resulting noise when reconstructing the signal by means of the processed coefficients as in Eq. (10.19) is reduced if  $A$  (the lower frame bound) is greater than one.  $\square$

### 1.10.3.2 The inverse frame

**Definition 10.3.** The *inverse frame*  $\tilde{\mathcal{G}} = \{\tilde{g}_k\}_{k \in \mathcal{K}}$  to a frame  $\mathcal{G} = \{g_k\}_{k \in \mathcal{K}}$ , is the one that provides the reconstruction formulas

$$x = \sum_{k \in \mathcal{K}} \langle x, \tilde{g}_k \rangle g_k = \sum_{k \in \mathcal{K}} \langle x, g_k \rangle \tilde{g}_k. \quad (10.22)$$

$\square$

**Example 10.4.** Let us go back to Example 10.1, where we have seen two different possibilities for “inversion” of the frame given by the rows of the matrix

$$\mathbf{G} = \begin{bmatrix} 0 & 1/2 \\ 1/4 & -1/4 \\ -1/2 & 0 \end{bmatrix}. \quad (10.23)$$

However, one can now find its canonical dual, associated with the inverse frame operator. Using a pseudo-inversion algorithm [4] one finds the pseudo-inverse  $\mathbf{G}^+$  to  $\mathbf{G}(\mathbf{G}^+\mathbf{G} = \mathbf{I}_2)$ :

$$\mathbf{G}^+ = \begin{bmatrix} 1/3 & 2/3 & -5/3 \\ 5/3 & -2/3 & -1/3 \end{bmatrix}. \quad (10.24)$$

Note that, this is just another example of possible frame inversion, as it is shown in [4], since  $\mathbf{G}$  assumes an infinite number of left inverses.  $\square$

**Definition 10.4.** When  $A = B$  the frame is said to be *tight* [6] and

$$S^{-1}\{\cdot\} = S\{\cdot\}/A. \quad (10.25)$$

In addition:

- i. Frames for which  $A \approx B$  are said to be *snug* [34] and for these  $S^{-1}\{\cdot\} \approx S\{\cdot\}/A$ .  $\square$

**Definition 10.5.** A frame  $\mathcal{G} = \{g_k\}_{k \in \mathcal{K}}$  is said to be *normalized* when

$$\|g_k\| = c, \forall k \in \mathcal{K}, \quad c > 0 \text{ is a real constant.} \quad (10.26) \quad \square$$

### 1.10.3.3 Characterization of frames: basic property

Frame bounds provide limits for the energy scaling of signals when they are represented using the projections into the frame elements. Due to that, frames are often characterized in terms of their frame bounds. It is very common to define the *frame bounds ratio*  $A/B$  [13]. It is also possible to define the “tightness” of a frame from its frame bounds ratio: the closer that  $A$  and  $B$  are, then the tighter the frame is.

Daubechies [5] shows that the use of the frame operator (Eq. (10.10)) gives

$$S\{x\} = \frac{A+B}{2}(x - R\{x\}), \text{ i.e., } x = \frac{2}{A+B} \sum_{k \in \mathcal{K}} \langle x, g_k \rangle g_k + R\{x\}, \quad (10.27)$$

where  $R\{x\}$  can be understood as the error incurred in reconstructing  $x$  from the projections of  $x$  into the frame elements instead of into the inverse frame elements.

In addition, she also shows that

$$R\{x\} = I\{x\} - \frac{2}{A+B} S\{x\}, \quad (10.28)$$

where  $I\{x\}$  is the identity operator. Therefore one has that

$$-\frac{B-A}{B+A} I\{x\} \leq R\{x\} \leq \frac{B-A}{B+A} I\{x\} \quad \rightarrow \quad \|R\{x\}\| \leq \frac{B-A}{B+A} \|x\|. \quad (10.29)$$

Hence, one sees that if  $B/A$  is close to one, then the error incurred in the reconstruction by equating the inverse frame to the direct frame is small. This error gets smaller as  $A$  and  $B$  become closer.

Therefore, from an analysis-synthesis perspective if a frame is tight there is no need to find its inverse. Tight frames are self-dual [35], that is, the inverse frame to a tight frame is a scaled version of the frame itself.

For normalized frames, Daubechies calls  $\frac{A+B}{2}$  the frame redundancy. Several studies have been developed on normalized tight frames. For example [36] shows that these frames have some noise reduction property. That is, if a given reconstruction distortion is required one can use less bits to represent the frame coefficients in comparison to the precision required to represent basis coefficients. This is related to the acquisition-quantization problem we have discussed previously.

**Example 10.5.** Let  $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$  be an orthonormal basis of the three-dimensional space. Define the vectors:

$$\begin{aligned}\mathbf{g}_1 &= \frac{\sqrt{2}}{2} \mathbf{e}_1 + \frac{\sqrt{2}}{2} \mathbf{e}_2 & \mathbf{g}_2 &= \frac{\sqrt{2}}{2} \mathbf{e}_2 + \frac{\sqrt{2}}{2} \mathbf{e}_3 & \mathbf{g}_3 &= \frac{\sqrt{2}}{2} \mathbf{e}_1 + \frac{\sqrt{2}}{2} \mathbf{e}_3 \\ \mathbf{g}_4 &= \frac{1}{2} \mathbf{e}_1 + \frac{\sqrt{3}}{2} \mathbf{e}_2 & \mathbf{g}_5 &= \frac{1}{2} \mathbf{e}_2 + \frac{\sqrt{3}}{2} \mathbf{e}_3 & \mathbf{g}_6 &= \frac{\sqrt{3}}{2} \mathbf{e}_1 + \frac{1}{2} \mathbf{e}_3.\end{aligned}$$

For any  $\mathbf{x} \in \mathbb{R}^3$  we have that

$$\begin{aligned}\sum_k |\langle \mathbf{x}, \mathbf{g}_k \rangle|^2 &= \left| \left\langle \mathbf{x}, \frac{\sqrt{2}}{2} \mathbf{e}_1 \right\rangle + \left\langle \mathbf{x}, \frac{\sqrt{2}}{2} \mathbf{e}_2 \right\rangle \right|^2 + \left| \left\langle \mathbf{x}, \frac{\sqrt{2}}{2} \mathbf{e}_2 \right\rangle + \left\langle \mathbf{x}, \frac{\sqrt{2}}{2} \mathbf{e}_3 \right\rangle \right|^2 \\ &\quad + \left| \left\langle \mathbf{x}, \frac{\sqrt{2}}{2} \mathbf{e}_1 \right\rangle + \left\langle \mathbf{x}, \frac{\sqrt{2}}{2} \mathbf{e}_3 \right\rangle \right|^2 + \left| \left\langle \mathbf{x}, \frac{1}{2} \mathbf{e}_1 \right\rangle + \left\langle \mathbf{x}, \frac{\sqrt{3}}{2} \mathbf{e}_2 \right\rangle \right|^2 \\ &\quad + \left| \left\langle \mathbf{x}, \frac{1}{2} \mathbf{e}_2 \right\rangle + \left\langle \mathbf{x}, \frac{\sqrt{3}}{2} \mathbf{e}_3 \right\rangle \right|^2 + \left| \left\langle \mathbf{x}, \frac{\sqrt{3}}{2} \mathbf{e}_1 \right\rangle + \left\langle \mathbf{x}, \frac{1}{2} \mathbf{e}_3 \right\rangle \right|^2 \\ &= 2 |\langle \mathbf{x}, \mathbf{e}_1 \rangle + \langle \mathbf{x}, \mathbf{e}_2 \rangle + \langle \mathbf{x}, \mathbf{e}_3 \rangle|^2 \\ &= 2 \|\mathbf{x}\|.\end{aligned}$$

Therefore the six vectors define a tight frame with  $A = B = 2$ . This number can in some sense be understood as a measure of redundancy of the frame expansion [4].  $\square$

Tight frames turned out to be relevant, due to their operational simplicity and applications. For example tight frames were shown to be the most resistant to coefficients erasures [15]. Erasures means that when transiting information over a network one knows that the information is unreliable. If a frame is used to compute the information that is transmitted over the network then the reconstruction error under erasures is lower for a tight frame than for non tight ones. Tight frames can also provide sparse signal decompositions [37]. Due to these and other interesting properties a lot of attention has been given to the construction of tight frames [16, 37–40].

## 1.10.4 Some computational remarks

In general signal processing algorithms are implemented in digital processors. In this case, the signal is discrete and some simplifications take place.

### 1.10.4.1 Frames in discrete spaces

Consider the case of discrete spaces as the  $\ell^2(\mathbb{Z})$  (the space of squareable summable sequences). In general, in such spaces, signal analysis is accomplished by using sliding-windows. This is actually the case for Filter-Banks [31], using the structure depicted in Figure 10.1, the synthesis equation becomes [33,34]

$$\mathbf{x}[n] = \sum_{k=0}^{K-1} \sum_{m=-\infty}^{\infty} c_{k,m} \mathbf{g}_{k,m}[n]. \quad (10.30)$$

In the above equation each signal's sample  $\mathbf{x}[n], n \in \mathbb{Z}$ , is synthesized as a sum of the samples  $\mathbf{g}_{k,m}[n] = \mathbf{g}_k[n - mN], N \leq K$ ,  $K$  is the cardinality of the frame, the  $\mathbf{g}_{k,m}$  are translated versions of the  $\mathbf{g}_k$ , referring to the  $m$ th  $N$ -length signal block.

Similar concepts can be brought to frames in  $\ell^2(\mathbb{Z})$ , bearing in mind the correct usage of a frame and its dual. In this case, one should note that Eq. (10.30) must be understood as

$$\mathbf{x}[n] = \sum_{k=0}^{K-1} \sum_{m=-\infty}^{\infty} \langle \mathbf{x}, \tilde{\mathbf{g}}_{k,m} \rangle \mathbf{g}_{k,m}[n]. \quad (10.31)$$

That is, as discussed in Section 1.10.2.2, the frame and its dual should be employed in the two distinct tasks of analysis/decomposition and synthesis/recomposition of  $\mathbf{x}$ .

The previous definitions on frames considered any space  $\mathbb{H}$ . When considering  $\ell^2(\mathbb{Z})$ , the space in which digital signal processing applications exist (as well as in finite vector spaces—which are discussed in the next subsection) using finite support vectors may be handy, as in FIR Filters.

A signal  $\mathbf{x} \in \ell^2(\mathbb{Z})$  can be expressed using Eq. (10.30) if the family of functions [33]

$$\mathcal{G} = \{ \mathbf{g}_{k,m} : \mathbf{g}_{k,m}[n] = \mathbf{g}_k[n - mN], k = 0, 1, \dots, K-1, m \in \mathbb{Z} \} \quad (10.32)$$

is a frame for  $\ell^2(\mathbb{Z})$ . This result provides an important feature of frames for  $\ell^2(\mathbb{Z})$ .

**Definition 10.6.** A set of vectors  $\mathcal{G}$  as defined in Eq. (10.32) (block translated) is a *frame* of  $\ell^2(\mathbb{Z})$ , if there exist constants  $0 < A < B < \infty$  such that for any  $\mathbf{x} \in \ell^2(\mathbb{Z})$  one has

$$A \|\mathbf{x}\|^2 \leq \sum_{k=0}^{K-1} \sum_{m=-\infty}^{\infty} |\langle \mathbf{x}, \mathbf{g}_{k,m} \rangle|^2 \leq B \|\mathbf{x}\|^2. \quad (10.33)$$

□

One should note that if Eq. (10.33) holds for  $\mathcal{G}$  as in Eq. (10.32), then there exists another frame

$$\tilde{\mathcal{G}} = \{ \tilde{\mathbf{g}}_{k,m} : \tilde{\mathbf{g}}_{k,m}[n] = \tilde{\mathbf{g}}_k[n - mN], k = 0, 1, \dots, K-1, m \in \mathbb{Z} \} \quad (10.34)$$

that can be employed for obtaining the coefficients  $c_{k,m}$  in Eq. (10.31), Obviously, the roles of  $\mathcal{G}$  and  $\tilde{\mathcal{G}}$  can be interchanged, providing

$$\mathbf{x}[n] = \sum_{k=0}^{K-1} \sum_{m=-\infty}^{\infty} \langle \mathbf{x}, \mathbf{g}_{k,m} \rangle \tilde{\mathbf{g}}_{k,m}[n]. \quad (10.35)$$

As it can be noted, given  $\mathcal{G}$  as in Eq. (10.32), the  $\tilde{\mathcal{G}}$  as (10.34) satisfying Eqs. (10.31) and (10.35) is not unique.

#### 1.10.4.2 Finite vector spaces

In a finite vector space  $\mathbb{H}^N$  one in general restricts the frame to have  $K$  elements; and thus Eq. (10.9) becomes

$$A\|\mathbf{x}\|^2 \leq \sum_{k=1}^K |\langle \mathbf{x}, \mathbf{g}_k \rangle|^2 \leq B\|\mathbf{x}\|^2, \quad \mathbf{x} \in \mathbb{H}^N. \quad (10.36)$$

In this case, as motivated in previous examples some computational simplifications take place.

**Definition 10.7.** *Analysis and Synthesis operators:*

- i. Let the *synthesis operator* be

$$T\{\cdot\} : \mathbb{C}^K \rightarrow \mathbb{H}^N, \quad T\{c_k\}_{k=1}^K = \sum_{k=1}^K c_k \mathbf{g}_k, \quad (10.37)$$

where  $\mathbb{C}^K$  is a  $K$ -dimensional complex vector space.

- ii. Let the *analysis operator*  $T^*\{\cdot\}$  (adjunct operator of  $T\{\cdot\}$ ) be given by

$$T^*\{\cdot\} : \mathbb{H}^N \rightarrow \mathbb{C}^K, \quad T^*\{\mathbf{x}\} = \{\langle \mathbf{x}, \mathbf{g}_k \rangle\}_{k=1}^K. \quad (10.38)$$

- iii. The operator  $T\{\cdot\}$  synthesizes  $\mathbf{x}$  from the frame coefficients  $c_k$  that are obtained by the analysis operator of a dual frame given by

$$\tilde{T}^*\{\cdot\} : \mathbb{H}^N \rightarrow \mathbb{C}^K, \quad \tilde{T}^*\{\mathbf{x}\} = \{\langle \mathbf{x}, \tilde{\mathbf{g}}_k \rangle\}_{k=1}^K. \quad (10.39)$$

- iv. Using the analysis and synthesis operators the frame operator is then given by

$$S : \mathbb{H}^N \rightarrow \mathbb{H}^N, \quad S\{\mathbf{x}\} = T\{T^*\{\mathbf{x}\}\} = \sum_{k=1}^K \langle \mathbf{x}, \mathbf{g}_k \rangle \mathbf{g}_k. \quad (10.40)$$

□

In vector spaces the operators  $T\{\cdot\}$  and  $T^*\{\cdot\}$  can be interpreted as matrices [6], as in the examples provided before.

Assuming that  $\mathbf{x}$  is a column vector that is  $\dim(\mathbf{x}) = N \times 1$  and the coefficients are organized in a column vector  $\mathbf{c} (\dim(\mathbf{c}) = K \times 1)$  as well. One has that

$$\begin{aligned}\mathbf{x} & \quad \dim(\mathbf{x}) = N \times 1 \\ \mathbf{c} & \quad \dim(\mathbf{c}) = K \times 1 \\ \mathbf{g}_k & \quad \dim(\mathbf{g}_k) = N \times 1 \\ \mathbf{T} &= \begin{bmatrix} \mathbf{g}_1^T \\ \vdots \\ \mathbf{g}_K^T \end{bmatrix} \quad \dim(\mathbf{T}) = K \times N\end{aligned}\tag{10.41}$$

$$T\{\mathbf{c}\} = \mathbf{T}^T \mathbf{c} \quad \dim(\mathbf{T}^T) = N \times K\tag{10.42}$$

$$T^*\{\mathbf{x}\} = \mathbf{T} \mathbf{x} \quad \dim(\mathbf{T}^*) = K \times N\tag{10.43}$$

$$S\{\mathbf{x}\} = T\{\mathbf{T}\{\mathbf{x}\}\} = \mathbf{T}^T \mathbf{T} \mathbf{x} = \mathbf{S} \mathbf{x} \quad \dim(\mathbf{S}) = N \times N\tag{10.44}$$

$$S^{-1}\{\mathbf{x}\} = (\mathbf{T}^T \mathbf{T})^{-1} \mathbf{x} = \mathbf{S}^{-1} \mathbf{x} \quad \dim(\mathbf{S}^{-1}) = N \times N.\tag{10.45}$$

The dual frame elements can be computed by means of

$$\tilde{\mathbf{g}}_k = S^{-1}\{\mathbf{g}_k\} = (\mathbf{T}^T \mathbf{T})^{-1} \mathbf{g}_k,\tag{10.46}$$

and we have that

$$\tilde{T}\{\mathbf{c}\} = \tilde{\mathbf{T}}^T \mathbf{c} = \mathbf{T} (\mathbf{T}^T \mathbf{T})^{-1} \mathbf{c} \quad \dim(\tilde{\mathbf{T}}^T) = N \times K\tag{10.47}$$

$$\tilde{T}^*\{\mathbf{x}\} = \tilde{\mathbf{T}}^* \mathbf{x} = (\mathbf{T}^T \mathbf{T})^{-1} \mathbf{T} \mathbf{x} \quad \dim(\tilde{\mathbf{T}}^*) = K \times N.\tag{10.48}$$

**Example 10.6.** As we have seen above  $\mathbf{S} = \mathbf{T}^T \mathbf{T}$ . Let  $\rho_i$  be the eigenvalues of  $\mathbf{S}$ , then the frame bounds are given by  $A = \min_i \rho_i$ , and  $B = \max_i \rho_i$  [6]. Thus, if  $\mathbf{T}^T \mathbf{T} = A \mathbf{I}_N$  ( $\mathbf{I}_N$  is the identity matrix of size  $N$ ) then the frame is tight ( $A = B$ ). Hence, for a tight frame  $\mathbf{S}^{-1} \mathbf{S} = \mathbf{I}_N$ .  $\square$

**Example 10.7.** The Gram matrix or Gramian of a sequence of vectors  $\{\mathbf{g}_k\}_{k \in \mathcal{K}}$  is the matrix  $G$ , whose elements are defined by  $g_{i,j} = \langle \mathbf{g}_i, \mathbf{g}_j \rangle_{i,j \in \mathcal{K}}$ . It has been employed to analyze different frames characteristics. For example, in [41], it is employed to investigate the symmetry properties of tight frames, providing tight frames design procedures. In [37] the Gramian is also employed for analyzing and designing frames with desired features.

We have seen the analysis, synthesis, and frame operators, and its inverse frames counterparts. As one may notice, a lot of the frame characteristics can be extracted from them. Now, define the Gram matrix  $G = \mathbf{T} \mathbf{T}^T$ . One readily notes that  $\dim(G) = K \times K$  and that each of its entries  $g_{i,j} = \langle \mathbf{g}_i, \mathbf{g}_j \rangle_{i,j \in \mathcal{K}}$ . This Gram matrix provides how similar are the frame elements one to another, therefore, it can be understood as an indicative of the connections among the different  $c_k$ .  $\square$

**Example 10.8.** In a vector space if the lower frame bound  $A$  were zero for a signal  $\mathbf{x}$  then the frame elements would all be orthogonal to  $\mathbf{x}$ , and the frame would not be capable of representing  $\mathbf{x}$ . In addition, note that if the frame has a finite set of elements, then, necessarily, due to the Cauchy-Schwartz inequality, the upper frame bound condition will be always satisfied.  $\square$

## 1.10.5 Construction of frames from a prototype signal

It is common to process signals in order to search for specific patterns in time, frequency or even scale. In this case, one often a priori specifies a set of desired behaviors or patterns to be searched in signals to be analyzed. These are specified as a set of pre-defined waveforms. If synthesis is not required the restrictions on the set are milder than in the case when synthesis is required. In the later case, one should guarantee the set of pre-defined functions or waveforms to be a frame. This is what we discuss now. We suppose a signal processing scenario where a given signal has to be analyzed and synthesized using a set of pre-defined waveforms that are derived from operations such as change of position in time (translation), change of frequency (modulation) and change of size (dilation) over a prototype signal. In this section we discuss some conditions that make a frame to be generated when these operations are applied to a prototype waveform.

### 1.10.5.1 Translation, modulation and dilation operators

There are several ways to construct frames from operations on a prototype signal, some of them are based on translations, modulations and dilations of a function  $g(t) \in L^2(\mathbb{R})$  (the space of square integrable functions) [6].

**Definition 10.8.** *Translation by  $a \in \mathbb{R}$ :*

$$T_a : L^2(\mathbb{R}) \rightarrow L^2(\mathbb{R}), \quad T_a g(t) = g(t - a). \quad (10.49)$$

□

**Definition 10.9.** *Modulation by  $b \in \mathbb{R}$ :*

$$E_b : L^2(\mathbb{R}) \rightarrow L^2(\mathbb{R}), \quad E_b g(t) = g(t)e^{2\pi jb t}. \quad (10.50)$$

□

**Definition 10.10.** *Dilation by  $c \in \mathbb{R} - \{0\}$ :*

$$D_c : L^2(\mathbb{R}) \rightarrow L^2(\mathbb{R}), \quad D_c g(t) = \frac{1}{\sqrt{|c|}} g\left(\frac{t}{c}\right). \quad (10.51)$$

□

### 1.10.5.2 Common frame constructions

The most common approaches to construct frames from a prototype are:

- A frame in  $L^2(\mathbb{R})$  constructed by translations of a given function  $g(t) \in L^2(\mathbb{R})$ , through

$$\{T_{na}g(t)\}_{n \in \mathbb{Z}}, \quad \text{with } a > 0, \quad (10.52)$$

is called a *frame of translates* [6];

- A *Weyl-Heisenberg* or *Gabor frame* is a frame in  $L^2(\mathbb{R})$  constructed from a fixed function  $g(t) \in L^2(\mathbb{R})$ , by means of

$$\{E_{mb}T_{na}g(t)\}_{m,n \in \mathbb{Z}}, \quad \text{with } a, b > 0. \quad (10.53)$$

Such frame is also called a *Gabor System* or a *Windowed Fourier Frame* [4–6, 42] due to its connection to time-frequency analysis techniques;

- A frame constructed by dilations and translations of a prototype (mother) function  $g(t) \in L^2(\mathbb{R})$  by

$$\{T_{nac^j}D_{c^j}g(t)\}_{j,n \in \mathbb{Z}} = \left\{ c^{\frac{-j}{2}} g\left(c^{-j}t - na\right) \right\}_{j,n \in \mathbb{Z}}, \quad \text{with } c > 1, \text{ and } a > 0. \quad (10.54)$$

is called a *wavelet frame* [4–7].

In the following subsections we enumerate some conditions for obtaining frames in the above ways and some examples of their applications or relevance.

### 1.10.5.3 Frames of translates

Digital signal processing is heavily based on signal sampling, that is, the capability of sampling a function (whose independent variable may not be time) using regular intervals and reconstructing the signal from the samples [4, 6, 31, 43]. A sample corresponds to a value that in turn represents an evaluation/measurement of the function/signal. The operation of sampling can be modelled as the projection of the function/signal over a pre-defined element. Regular sampling corresponds to translating the element into different positions regularly sampled and taking a sample (measurement/projection) at the correspondent position. Although the following results employ time as the independent variable it could be any other.

**Definition 10.11.** A *frame of translates* is a frame for  $L^2(\mathbb{R})$  obtained through operations  $\{T_{na}g(t)\}_{n \in \mathbb{Z}}$ , on a fixed function  $g(t)$  with  $a > 0$ .  $\square$

Which conditions should hold on  $g(t)$  in order to  $\{T_{na}g(t)\}_{n \in \mathbb{Z}}$  being a frame? In this case it can be shown that [6]  $\{T_{na}g(t)\}_{n \in \mathbb{Z}}$  is a frame with bounds  $A$  and  $B$  if and only if

$$aA \leq G(\omega) \leq aB, \quad \omega \in [0, 1] - \mathcal{N}, \quad \mathcal{N} = \{\gamma \in [0, 1] : G(\omega) = 0\}. \quad (10.55)$$

Frames of translates are intimately related with sampling. The example below highlights their connection with Shannon Sampling Theorem [43].

**Example 10.9.** In this example one employs the Shannon Sampling Theorem [43, 44]. Let a band limited function of time  $s(t)$  be sampled using a train of impulses at a rate  $1/T$ . Assume that the signal bandwidth is  $W$ . If  $T < \frac{1}{2W}$ , one can reconstruct the signal using

$$s(t) = \sum_n s(nT) \frac{\sin[(t - nT)\frac{\pi}{T}]}{(t - nT)\frac{\pi}{T}}. \quad (10.56)$$

This is so because the infinite set of sinc pulses centered at  $nT$  provides a basis/frame of the  $W$  Hz band-limited space.

Define  $R$  as the “amount of over-sampling”

$$R = \frac{1}{2WT}, \quad \text{for } R \geq 1, \quad (10.57)$$

One notes that the Nyquist rate [31] implies  $2WT = 1$  and  $R \geq 1$  makes  $1/T \geq 2W$ . One has that [44]

$$s(t) = \frac{1}{R} \sum_n s(nT) \frac{\sin[(t - nT)\frac{\pi}{RT}]}{(t - nT)\frac{\pi}{RT}}. \quad (10.58)$$

Note that for  $R \geq 1$ , two sinc pulses centered at  $kT$  and  $lT$  ( $k, l \in \mathbb{Z}$ ) not just overlap, but are actually not orthogonal. Indeed, the set of  $T$  temporally-spaced sinc pulses is an overcomplete basis of the  $W$ -bandlimited signal space, in the case  $R \geq 1$ . That is, the sinc pulses centered at  $nT$  with  $R > 1$  are not linearly independent. However, the infinite set of sinc pulses above is shown to be a tight frame and  $R$  is interpreted as a redundancy factor for the frame [10,44]. One notes that for  $R = 1$  (10.58) equates (10.56) where the signal samples occur where the sinc pulses equate one (for  $t = nT$ ) or zero (other cases). However, as  $R$  increases the sinc pulse centered at  $nT$  gets wider and is not zero anymore for  $t - nT = kT$ ,  $k \in \mathbb{Z}^*$ .  $\square$

#### 1.10.5.4 Gabor frames

While the introduction of the frame concept remounts to 1952 [1], according to Christensen [6], the first mention of what are now called Gabor or Weyl-Heisenberg frames can be traced back even before that to the work of Gabor on communications [23] in 1946 and to the book of von Neumann on quantum mechanics originally published in 1932 [45].

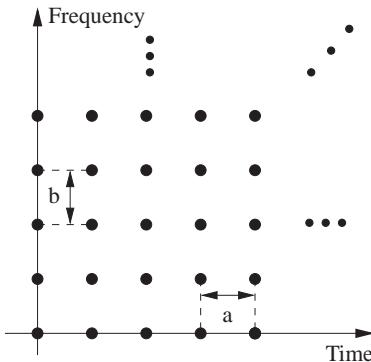

Let us simplify the idea of Gabor and simply state that its vision was to represent a signal  $s(t)$  by means of

$$s(t) = \sum_m \sum_n \tilde{c}_{m,n} E_{mb} T_{na} g(t). \quad (10.59)$$

The function  $g(t)$  is chosen to be a Gaussian due to its time-frequency concentration [19,21,46]. This representation can provide an analysis of the time frequency content around the points  $(na, mb)$  in the time-frequency plane. The resemblance between this idea and the frame definition sparks, and then a straightforward definition emerges.

**Definition 10.12.** A *Gabor frame* is a frame for  $L^2(\mathbb{R})$  obtained through operations  $\{E_{mb} T_{na} g(t)\}_{m,n \in \mathbb{Z}}$ , on a fixed function  $g(t)$  with  $a, b > 0$ .  $\square$

Now, one has the problem of guaranteeing that the set  $\{E_{mb} T_{na} g(t)\}_{n,m \in \mathbb{Z}}$  is capable of representing any signal  $s(t) \in L^2(\mathbb{R})$ , i.e., is the set  $\{E_{mb} T_{na} g(t)\}_{n,m \in \mathbb{Z}}$  a frame of  $L^2(\mathbb{R})$ ? In addition, how does one compute the set  $\{\tilde{c}_{m,n}\}_{n,m \in \mathbb{Z}^2}$  that allows the synthesis of a signal using Eq. (10.59)? The answer to the later question lies in the concept of inverse frame. But, we will start from the first question: for a given  $g(t)$ , when  $\{E_{mb} T_{na} g(t)\}_{m,n \in \mathbb{Z}}$  is a frame? The answer depends on a complicated interplay between  $g(t)$ ,  $a$  and  $b$ . For example in [47] a set of non-intuitive conditions was shown to hold on  $a$  and  $b$  to generate a Gabor System based on the characteristic function. In what follows, several results collected from the frame literature are presented, which provide either sufficient or necessary conditions for  $\{E_{mb} T_{na} g(t)\}_{m,n \in \mathbb{Z}}$  to constitute a frame.

**FIGURE 10.2**

Gabor system elements location in the time-frequency plane.

For  $\{E_{mb}T_{na}g(t)\}_{m,n \in \mathbb{Z}}$  to compose a frame it is necessary that  $ab \leq 1$  [4–6]. That is, if  $ab > 1$  a frame will not be obtained; however, the assumption  $ab \leq 1$  does not guarantee the generation of a frame for any  $g(t)$ , see for example [47]. It should be observed that  $ab$  is a measure of the density of the frame in the time-frequency plane [4,5,19–21,42]; the smaller  $ab$  is the denser is the frame. Figure 10.2 illustrates this concept.

If  $\{E_{mb}T_{na}g(t)\}_{m,n \in \mathbb{Z}}$  constitutes a frame then the frame bounds necessarily satisfy [6]

$$\forall t \in \mathbb{R}, \quad A \leq \frac{1}{b} \sum_n |g(t - na)|^2 \leq B \quad (10.60)$$

$$\forall \omega \in \mathbb{R}, \quad A \leq \frac{1}{b} \sum_k \left| \hat{g} \left( \omega - k \frac{b}{2\pi} \right) \right|^2 \leq B. \quad (10.61)$$

A well known sufficient condition for  $\{E_{mb}T_{na}g(t)\}_{m,n \in \mathbb{Z}}$  to be a frame is presented in [14]. Let  $a, b > 0$ ,  $g(t) \in L^2(\mathbb{R})$ , denote  $g^*(t)$  the complex conjugate of  $g(t)$  and suppose that  $\exists A, B > 0$  such that

$$A \leq \sum_{n \in \mathbb{Z}} |g(t - na)|^2 \leq B \quad \forall t \in \mathbb{R} \text{ and} \quad (10.62)$$

$$\sum_{k \neq 0} \left\| \sum_{n \in \mathbb{Z}} T_{na}g(t) T_{na+\frac{k}{b}} g^*(t) \right\|_\infty < A, \quad (10.63)$$

then  $\{E_{mb}T_{na}g(t)\}_{m,n \in \mathbb{Z}}$  is a Gabor frame for  $L^2(\mathbb{R})$ .

A more general sufficient condition for the generation of a frame  $\{E_{mb}T_{na}g(t)\}_{m,n \in \mathbb{Z}}$  for  $a, b > 0$  given and  $g(t) \in L^2(\mathbb{R})$  is [6,48]: if

$$B := \frac{1}{b} \sup_{t \in [0,a]} \sum_{k \in \mathbb{Z}} \left| \sum_{n \in \mathbb{Z}} g(t-na) g^* \left( t-na - \frac{k}{b} \right) \right| < \infty, \text{ and} \quad (10.64)$$

$$A := \frac{1}{b} \inf_{t \in [0,a]} \left[ \sum_{n \in \mathbb{Z}} |g(t-na)|^2 - \sum_{k \neq 0} \left| \sum_{n \in \mathbb{Z}} g(t-na) g^* \left( t-na - \frac{k}{b} \right) \right|^2 \right] > 0 \quad (10.65)$$

then  $\{E_{mb}T_{na}g(t)\}_{m,n \in \mathbb{Z}}$  is a frame for  $L^2(\mathbb{R})$  with frame bounds  $A, B$ . Note that this result shows that if  $g(t)$  has a limited support  $[0, 1/x]$  then for any set  $ab \leq 1$  and  $b < x$  a Gabor frame is obtained.

Other conditions for the generation of Gabor frames exist (see for example [4–6,27]). In [49] an extension of the results in Eqs. (10.64) and (10.65) for irregularly sampled time-frequency parameters (when the set  $(an, bm)$  is replaced by any pair  $(a_{n,m}, b_{n,m}) \in [na, (n+1)a] \times [mb, (m+1)b]$ ) is provided.

In subSection 1.10.6.2, we discuss the use of such frames for time-frequency analysis by means of the Gaborgram and in Section 1.10.6.3 we present an example of “how to find” the inverse frame to a Gabor frame. In Section 1.10.6.4 a condition for constructing Gabor frames in discrete spaces from its continuous counterpart is stated.

### 1.10.5.5 Wavelet frames

Wavelet analysis asks if translated and scaled versions of function  $\psi(t)$  can be employed for representing a signal  $s(t) \in L(\mathbb{R})$ . In this sense, the signal is to be represented using functions like

$$\psi_{c,a}(t) = \frac{1}{\sqrt{c}} \psi \left( \frac{t-a}{c} \right). \quad (10.66)$$

If one thinks about the signal projections over different  $\psi_{c,a}(t)$  to represent the signal, the similarity with the Gabor “time-frequency” approach is unavoidable. One applies operations to a fixed prototype function and use the resulting modified versions of the prototype to express the signal. Discrete pairs  $(a, c)$  define how the prototype function has been modified and thus provide what signal characteristics are being analyzed.

If one employs a continuum of  $(a, c)$  pairs, one has the so-called *Continuous Wavelet Transform* [4,5,7,50]

$$W_\psi(a, c) = \langle f(t), \psi_{c,a}(t) \rangle = \int f(t) \frac{1}{\sqrt{c}} \psi \left( \frac{t-a}{c} \right) dt. \quad (10.67)$$

One can compute the inverse wavelet transform using

$$f(t) = K_\psi \int_0^\infty \int W_\psi(a, c) \frac{1}{\sqrt{c}} \psi \left( \frac{t-a}{c} \right) da \frac{dc}{c^2} \quad (10.68)$$

In the equations above, we have considered that  $\psi(t)$  is real and  $K_\psi$  is a constant that depends on  $\psi(t)$  [4, 51, 52]. It is worthy to say that, similarly, the Gabor frame can be linked to the so-called *Short Time Fourier Transform* [4, 21].

In the case of wavelet frames, we are concerned with the case of a discrete set of pairs  $(a, c)$ . In this sense in 1910 [53], Haar has shown that for the function

$$\psi(t) = \begin{cases} 1, & 0 \leq t < 1/2, \\ 1, & 1/2 \leq t < 1, \\ 0, & \text{otherwise} \end{cases} \quad (10.69)$$

the set of dilated and translated versions

$$\psi_{j,k}(t) = 2^{j/2}\psi(2^j t - k), \quad j, k \in \mathbb{Z},$$

what means that  $\psi_{j,k}(t) = T_k D_{2^{-j}}\{f(t)\}$

(10.70)

is a basis for  $L^2(\mathbb{R})$ .

A more throughout study of such possibilities occurred in the beginning of the 1980s. Calderon in 1964 [51] and Grossman and Morlet in 1985 [52] introduced the *Wavelet Transform*. In continuation, the first *wavelet frame* construction appeared in 1986 in [12]. Great effort was dedicated to the study of wavelets due to their multi-resolution analysis [4, 5, 7, 13, 50]. A recent book [54] collects some relevant papers for wavelet analysis theory.

One should note that in Eqs. (10.66)–(10.70), the order in which the translation and dilation operation are applied differs from the one previously presented in Section 1.10.5.2. Therefore, for clarity, we now define what is meant by a Wavelet Frame.

**Definition 10.13.** For  $c > 1$ ,  $a > 0$  and  $g \in L^2(\mathbb{R})$ , a frame constructed by dilations and translations as

$$\{T_{nac^j}D_{c^j}g(t)\}_{j,n \in \mathbb{Z}} = \left\{c^{\frac{j}{2}}g(c^j t - na)\right\}_{j,n \in \mathbb{Z}} \quad (10.71)$$

is called a wavelet frame. □

In [5] both necessary and sufficient conditions are provided to construct wavelet frames. For example, if  $\{T_{nac^j}D_{c^j}g(t)\}_{j,n \in \mathbb{Z}} = \left\{c^{\frac{j}{2}}g(c^j t - na)\right\}_{j,n \in \mathbb{Z}}$  is a frame with frame bounds  $A$  and  $B$  then necessarily [55]

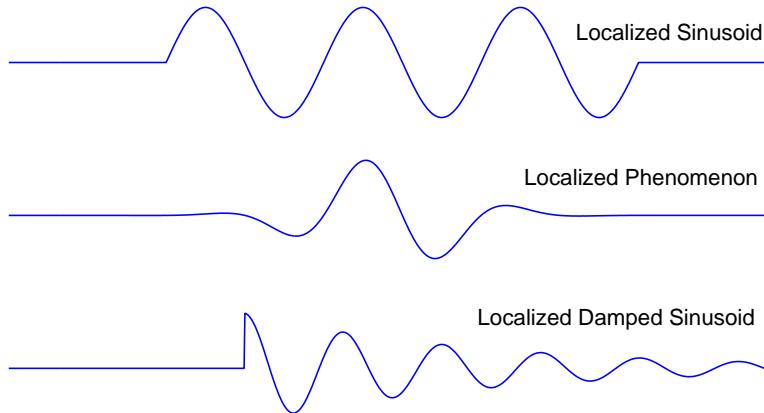

$$A \leq \frac{1}{a} \sum_{j \in \mathbb{Z}} \left| \hat{g}(c^j \omega) \right|^2 \leq B, \quad (10.72)$$

where  $\hat{g}(\omega)$  is the Fourier transform of  $g(t)$ .

A sufficient condition to generate a wavelet frame [6] is: suppose that  $c > 1$ ,  $a > 0$  and  $g(t) \in L^2(\mathbb{R})$  are given, if

$$B := \frac{1}{b} \sup_{|\omega| \in [1, c]} \sum_{j,n \in \mathbb{Z}} \left| \hat{g}(c^j \omega) \hat{g}(c^j \omega + \frac{n}{a}) \right| < \infty, \quad \text{and} \quad (10.73)$$

$$A := \frac{1}{b} \inf_{|\omega| \in [1, c]} \left[ \sum_{n \in \mathbb{Z}} \left| \hat{g}(c^j \omega) \right|^2 - \sum_{n \neq 0} \sum_{j \in \mathbb{Z}} \left| \hat{g}(c^j \omega) \hat{g}(c^j \omega + \frac{n}{a}) \right| \right] > 0 \quad (10.74)$$

**FIGURE 10.3**

Examples of fixed functions that can be used to construct frames.

then  $\{T_{nacj} D_{c^j} g(t)\}_{j,n \in \mathbb{Z}}$  is a frame for  $L^2(\mathbb{R})$  with bounds  $A, B$  given by the expressions above.

In [49] an extension of this condition for irregularly sampled time-scale parameters, when the set  $(an, c^j)$  is replaced by any pair  $(a_{n,j}, c_{n,j}) \in [c^j an, c^j a(n+1)] \times [c^j, c^{j+1}]$ , is provided.

### 1.10.5.6 Finite vector spaces

When considering finite vector spaces  $\mathbb{H}^N$  the simpler solution is to truncate or box-window the elements of the discrete space frame; however, this simple approach alters the frame bounds [56]. An alternative is to consider that the vector space is generated from an  $N$ -length section of an  $N$ -periodic  $l^2(\mathbb{Z})$  space, where the translation operator is a circular shift. The circular shift of a signal does not change the vector norm; this way the frame in  $\mathbb{H}^N$  has the same frame bounds as the frame in the  $N$ -periodic  $l^2(\mathbb{Z})$ .

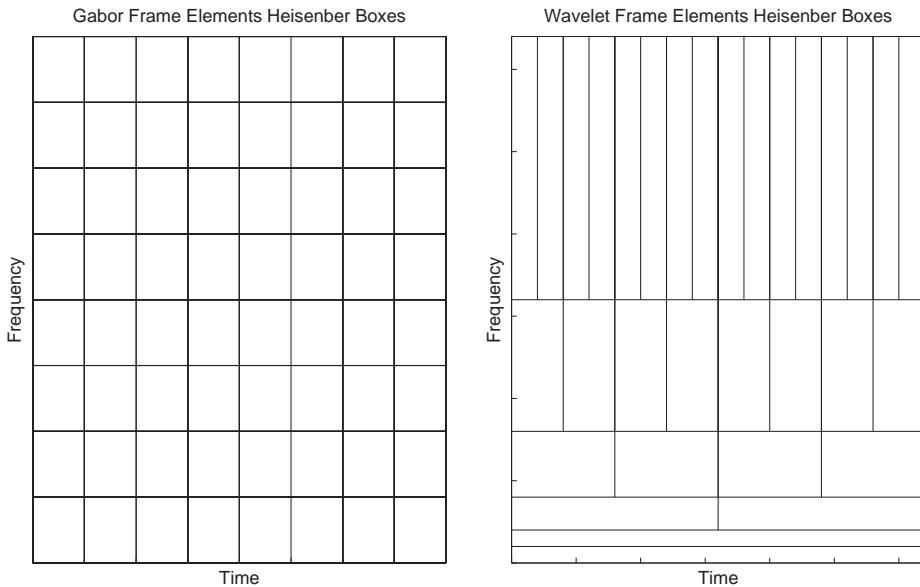

---

## 1.10.6 Some remarks and highlights on applications

### 1.10.6.1 Signal analysis

We have discussed the construction of different frames from a fixed prototype function. We have also presented examples that span the possibility of signal representation, analysis and synthesis using functions with prescribed characteristics. These are some of the main features of frames that are relevant for signal processing applications: detection of signal features, analyzing and synthesizing signals using a set of pre-defined signals. Frames bring freedom when compared to basis as the number of elements to be employed in the analysis-synthesis process can be larger than the signal space dimension.

In the literature, there is a large number of examples of different frame constructions using a fixed prototype signal; we have presented some in previous sections. Figure 10.3 illustrates different functions with different characteristics that can be used in this framework. These figures illustrate possible fixed functions to be employed to detect localized phenomena in a signal.

**FIGURE 10.4**

Heisenberg boxes in the time-frequency plane for Gabor (left) and wavelet (right) frames.

The Gabor and wavelet approaches commonly used for building frames from a fixed function were discussed. In some cases, the density in time, frequency or scale of the phenomena to be analyzed or detected in the signal [24,25,57] may be such that techniques for reducing the number of frame elements may be handy [58].

**Example 10.10.** As the reader may have already noticed, Wavelet frames can be used in a similar way to Gabor frames for time-frequency analysis. However, in this case a better phrasing would be *time-scale analysis*. Figure 10.4 depicts the different tilings of the time-frequency plane obtained by these approaches. These tilings depict the Heisenberg boxes [4] of the frame elements—these boxes roughly correspond to the time-frequency plane area where most of the elements' energy is concentrated. □

### 1.10.6.2 Gaborgram

In the beginning of Section 1.10.5.4 we have presented the idea of Gabor. That was representing a signal  $s(t)$  by means of

$$s(t) = \sum_m \sum_n c_{m,n} E_{mb} T_{na} g(t) = \sum_m \sum_n c_{m,n} e^{jmb} g(t - na). \quad (10.75)$$

As it can be noticed, this equation assumes that there is a representation for any  $s(t)$  using several  $g_{mb,na}(t) = E_{mb} T_{na} g(t)$ . We have seen that for these to be true it is enough for the set  $\{E_{mb} T_{na} g(t)\}_{m,n}$  to be a frame. What is commonly referred to as the Gaborgram is the plot of the coefficients  $c_{m,n}$  using the lattice presented in Figure 10.2. As discussed above a similar concept can be used for Wavelet Frames.

We have also seen that to compute the  $\{c_{m,n}\}_{m,n}$ , the inverse frame to  $\{E_{mb}T_{na}g(t)\}_{m,n}$  must be used. The next section illustrates how to obtain the inverse frame in the case of an exponential function. A Gabor frame of damped sinusoids is inspired on the connection among transients and damped sinusoids in physical systems.

### 1.10.6.3 Inverse gabor frame

The power of Gabor system for signal analysis and synthesis is not difficult to perceive. The problem is how to find the coefficients  $c_{m,n}$  that provide the reconstruction

$$s(t) = \sum_m \sum_n c_{m,n} E_{mb} T_{na} g(t) = \sum_m \sum_n c_{m,n} e^{jmb} g(t - na). \quad (10.76)$$

The inverse frame elements  $\{\tilde{g}(t)\}_{m,n}$  can be used. In this case one has that

$$s(t) = \sum_m \sum_n \langle c, \tilde{g}_{m,n}(t) \rangle E_{mb} T_{na} g(t). \quad (10.77)$$

Daubechies [13] has shown that, for Gabor frames, the inverse frame must be such that

$$\tilde{g}_{m,n}(t) = E_{mb} T_{na} \tilde{g}(t). \quad (10.78)$$

And one has that

$$s(t) = \sum_m \sum_n \langle c, E_{mb} T_{na} \tilde{g}(t) \rangle E_{mb} T_{na} g(t). \quad (10.79)$$

However, one still has to find  $\tilde{g}(t)$ . Equation (10.79) provides a biorthogonality condition (which is the “frame decomposition” formulas discussed in Section 1.10.3.1). In that sense, in [59] it is shown that Eq. (10.79) leads to

$$\frac{1}{ab} \int g(t) \tilde{g}\left(t - \frac{n}{b}\right) e^{-j2\pi m \frac{t}{a}} dt = \delta(n)\delta(m), \quad (10.80)$$

where  $\delta(x)$  denotes the impulse of  $x$ . In [59] it is also discussed that Eq. (10.80) accepts more than one solution in the oversampled case ( $ab < 1$ ) [27].

**Example 10.11.** In [24] the problem of building a Gabor system/frame based on the one sided exponential is presented. In this case, one has that

$$g(t) = \begin{cases} \sqrt{2\alpha} e^{-\alpha t}, & t \geq 0 \\ 0, & \text{otherwise} \end{cases} \quad (10.81)$$

Using the Zak Transform [47, 60] in [24] it is derived that for large oversampling ( $ab < 1$ )

$$\tilde{g}(t) \approx \begin{cases} -ke^{-\alpha(t+\frac{2}{b})}, & -1 \leq tb < 0 \\ ke^{-\alpha t}, & 0 \leq tb < 1 \\ 0, & \text{otherwise} \end{cases} \quad (10.82)$$

Where  $k$  is a constant that depends on  $a, b$  and  $\alpha$  [24].

Figure 10.5 illustrates the  $\tilde{g}(t)$  for different cases of  $a$  and  $b$ . In order to just focus on the waveform of  $\tilde{g}(t)$ , we ignore here the value of the constant  $k$  and make all functions scaled so that  $\max_t \tilde{g}(t) = 1$ .  $\square$

### 1.10.6.4 Gabor frames in discrete spaces

Obviously, due to the time-shift frequency-shift structure of Gabor frames, these have a broad range of applications for signal processing. Since most algorithms take place in a discrete space we should evaluate how to construct Gabor frames in this space.

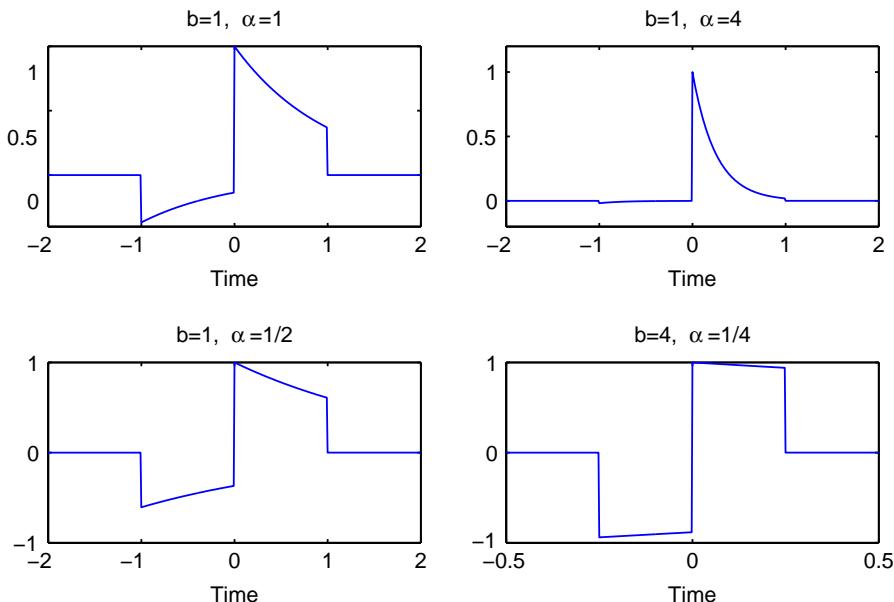

Frames in discrete spaces ( $l^2(\mathbb{Z})$ ) can be obtained by time-sampling the elements of frames in  $L^2(\mathbb{R})$  [6]. If  $g(t) \in L^2(\mathbb{R})$  is such that

$$\lim_{\epsilon \rightarrow 0} \sum_{k \in \mathbb{Z}} \frac{1}{\epsilon} \int_{-\frac{1}{2}\epsilon}^{\frac{1}{2}\epsilon} |g(k+t) - g(k)|^2 dt = 0, \quad (10.83)$$

and if  $\{E_{m/Q} T_{n/P} g(t)\}_{m,n \in \mathbb{Z}}$  with  $Q, P \in \mathbb{N}$  is a frame for  $L^2(\mathbb{R})$  with frame bounds  $A$  and  $B$ , then  $\{E_{m/Q} T_{n/P} \mathbf{g}_D\}_{n \in \mathbb{Z}, m=0,1,\dots,M-1}$  is a frame for  $l^2(\mathbb{Z})$  with frame bounds  $A$  and  $B$  [6]. The vector  $\mathbf{g}_D$  is the discretized version of  $g(t)$  with one sample per time unit, i.e.,  $\mathbf{g}_D = \{g(j)\}_{j \in \mathbb{Z}}$ .

### 1.10.6.5 Fast analysis and synthesis operators for gabor frames

Gabor or Weyl-Heisenberg frames in  $N$ -dimensional spaces are also interesting because one can find fast algorithms to compute their analysis and synthesis operators. Now, we consider that the number of “points” of the Weyl-Heisenberg frame in the frequency axis is such that  $Q = N/r$ ,  $Q, r \in \mathbb{N}$  and

**FIGURE 10.5**

Inverse Gabor frame prototype function of the one sided exponential—Biorthogonal function  $\tilde{g}(t)$  to  $g(t) = \sqrt{2\alpha} e^{-\alpha t} u(t)$ , for different values of  $\alpha$ .

also that the number of points in the time axis  $P \in \mathbb{N}$  (the same restrictions were employed in Section 1.10.6.4 above. These restrictions actually lead to  $a = 1/Q$  and  $b = N/P$  in Eq. (10.59). In this case, the  $c_{n,m}$  are defined for  $n \in \{0 \dots P - 1\}$  and  $m \in \{0 \dots Q - 1\}$  and are given by

$$c_{n,m} = \langle \mathbf{x}, E_{m \frac{1}{Q}} T_{n \frac{N}{P}} \mathbf{g} \rangle = \sum_{l=0}^{N-1} \mathbf{x}[l] e^{\frac{-j2\pi lm}{Q}} T_{n \frac{N}{P}} \mathbf{g}[l]. \quad (10.84)$$

Defining

$$\mathbf{f}_{n \frac{N}{P}}[k] = \mathbf{x}[k] T_{n \frac{N}{P}} \mathbf{g}[k] = \mathbf{x}[k] \mathbf{g}\left[\left(k - n \frac{N}{P}\right) \bmod N\right] \quad (10.85)$$

$$\mathbf{f}_{n \frac{N}{P}} = \left[ \mathbf{f}_{n \frac{N}{P}}[0], \dots, \mathbf{f}_{n \frac{N}{P}}[N-1] \right] \quad (10.86)$$

we obtain

$$c_{n,m} = \langle \mathbf{x}, E_{m \frac{1}{Q}} T_{n \frac{N}{P}} \mathbf{g} \rangle = \sum_{l=0}^{N-1} \mathbf{f}_{n \frac{N}{P}}[l] e^{\frac{-j2\pi lm}{Q}}. \quad (10.87)$$

For  $Q = N/r, r \in \mathbb{N}$  we obtain

$$c_{n,m} = \langle \mathbf{x}, E_{m \frac{1}{Q}} T_{n \frac{N}{P}} \mathbf{g} \rangle = \sum_{l=0}^{N-1} \mathbf{f}_{n \frac{N}{P}}[l] e^{\frac{-j2\pi l}{N} mr} = DFT\{\mathbf{f}_{n \frac{N}{P}}\}[mr], \quad (10.88)$$

where  $DFT\{\mathbf{x}\}[k]$  is the  $k^{th}$  sample of the Discrete Fourier Transform of  $\mathbf{x}$ , which can be computed using fast algorithms (FFT) [31].

Using the result in Eq. (10.88) the analysis operator (which was discussed in Section 1.10.4.2) of such Weyl-Heisenberg frames is given by

$$\mathbf{T}^*\{\cdot\} : \mathbb{H}^N \rightarrow \mathbb{C}^{PQ}, \quad (10.89)$$

$$\mathbf{T}^*\{\mathbf{x}\} : c_{n,m} = \{\langle \mathbf{x}, E_{m \frac{1}{Q}} T_{n \frac{N}{P}} \mathbf{g} \rangle\}, n \in [0, P-1], m \in [0, Q-1] \quad (10.90)$$

$$c_{n,m} = FFT\{\mathbf{f}_{n \frac{N}{P}}\}[mr], \mathbf{f}_{n \frac{N}{P}}[k] = \mathbf{x}[k] \mathbf{g}\left[\left(k - n \frac{N}{P}\right) \bmod N\right] \quad (10.91)$$

Similarly, for the synthesis operator of such frames we have that

$$\begin{aligned} \mathbf{T}\{\cdot\} : \mathbb{C}^{PQ} &\rightarrow \mathbb{H}^N, \\ \mathbf{T}\{c_{n,m}\} = [\mathbf{t}[0], \dots, \mathbf{t}[N-1]] &= \sum_{n=0}^{P-1} \sum_{m=0}^{Q-1} c_{n,m} E_{m \frac{1}{Q}} T_{n \frac{N}{P}} \mathbf{g}. \end{aligned} \quad (10.92)$$

The last equation is the sum of  $PQ$   $N$ -length vectors and can be computed using the Inverse Discrete Fourier Transform as below

$$\mathbf{t}[l] = \sum_{n=0}^{P-1} \sum_{m=0}^{Q-1} c_{n,m} e^{j \frac{2\pi ml}{Q}} \mathbf{f}_{n \frac{N}{P}}[l] = \sum_{n=0}^{P-1} \mathbf{f}_{n \frac{N}{P}}[l] \sum_{m=0}^{Q-1} c_{n,m} e^{j \frac{2\pi}{N} lmr}. \quad (10.93)$$

Denoting  $c_n(m) = c_{n,m}$  we can define

$$\mathbf{c}_n = [c_n[0], c_n[1], \dots, c_n[Q-1]], \quad (10.94)$$

and its up-sampled version

$$U(\mathbf{c}_n)[k] = \begin{cases} c_n[k/r], & k/r \in \{0, 1, \dots, Q-1\} \\ 0, & \text{otherwise} \end{cases} \quad (10.95)$$

Thus, the synthesis operator is such that

$$\begin{aligned} t[l] &= \sum_{n=0}^{P-1} f_{n \frac{N}{P}}[l] \sum_{m=0}^{Q-1} U(\mathbf{c}_n)[mr] e^{j \frac{2\pi}{N} lmr} \\ &= \sum_{n=0}^{P-1} f_{n \frac{N}{P}}[l] IFFT\{U(\mathbf{c}_n)\}[l]. \end{aligned} \quad (10.96)$$

Figure 10.6 presents a way to compute the expansion coefficients or the reconstructed signal when a frame is used either as an analysis or as a synthesis operator. Note that in the outputs of each FFT block, in Figure 10.6, there is a serial to parallel converter, while at the IFFT inputs a parallel to serial converter exists. Figure 10.6 shows that all the frame coefficients can be obtained using  $PN(1 + \log_2(N))$  operations, which can be reduced if one takes into account that just  $Q$  FFT/IFFT coefficients need to be computed at each FFT/IFFT branch.

### 1.10.6.6 Time-frequency content analysis using frame expansions

As we have seen in several cases, frames provide a powerful tool for signal analysis. This is specially true when one considers Gabor and Wavelet frames. These provide a natural tiling of the time-frequency plane. We now discuss how can a signal expansion be mapped into a time-frequency plot.

The Wigner-Ville distribution (WD) is probably one of the most well-known and widely used tools for time-frequency analysis of signals. The WD of a signal  $x(t)$  is defined as [4, 18, 20, 61]

$$WD_x(t, f) = \int_{-\infty}^{+\infty} x\left(t + \frac{\tau}{2}\right) x^*\left(t - \frac{\tau}{2}\right) e^{-2\pi j f \tau} d\tau, \quad (10.97)$$

Some applications have used the WD of signal decompositions in order to analyze the time-frequency content of signals [4, 20]. The Wigner-Ville distribution of a signal  $x(t)$ ,  $WD_x(t, f)$ , is a “measure” of the energy density in the signal in both time ( $t$ ) and frequency ( $f$ ) simultaneously. However, it is just meaningful when regions of the time-frequency plane are considered, that is as local averages, and it can not be considered at a given time-frequency point  $(t', f')$  due to uncertainty principle [4, 20]. In addition, the WD of a signal has another drawback since it is not restricted to be positive, a mandatory characteristic for an energy density.

In Section 1.10.3, we have seen that a signal  $x$  can be decomposed into a frame  $\{g_k\}_{k \in \mathcal{K}}$  or into its dual  $\{\tilde{g}_k\}_{k \in \mathcal{K}}$ , and reconstructed by means of

$$x = \sum_{k \in \mathcal{K}} \langle x, \tilde{g}_k \rangle g_k = \sum_{k \in \mathcal{K}} \langle x, g_k \rangle \tilde{g}_k. \quad (10.98)$$

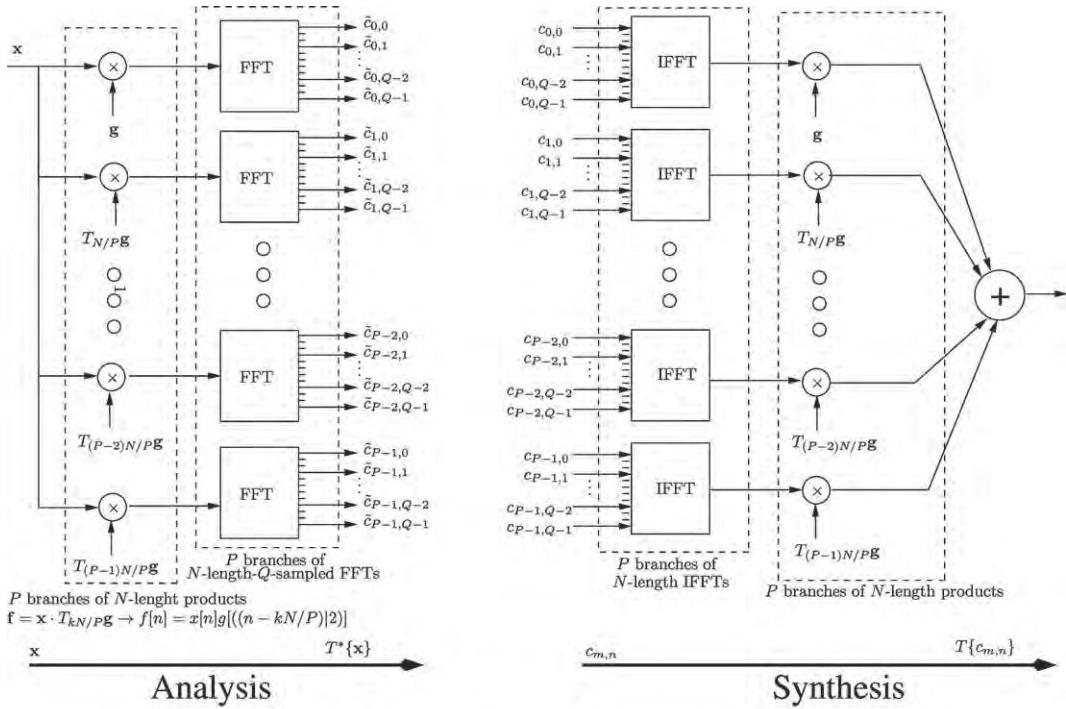

FIGURE 10.6

Weyl-Heisenberg fast analysis and synthesis using FFTs and IFFTs.

Once  $x$  is decomposed into the frame coefficients  $\langle x, \tilde{g}_k \rangle$ , its time-frequency content can be analyzed using

$$WD_{\tilde{x}}(t, f) = \sum_{k \in \mathcal{K}} \langle x(t), \tilde{g}_k(t) \rangle WD_{g_k}(t, f). \quad (10.99)$$

Using approaches like this, the inference of signal characteristics from signal decompositions is a common and powerful tool for signal analysis, detection and estimation. Specifically, in the case of time-frequency analysis, such approaches avoids the cross terms that appear when the original signal is directly analyzed [4, 18–22, 42, 61].

However, as we have seen the coefficients  $\langle x(t), \tilde{g}_k(t) \rangle$  used above may be obtained with a  $\tilde{g}_k(t)$  that does not, neither physically, nor visually and nor in its time-frequency content, resembles the associated  $g_k(t)$ . That is why in general this approach is left aside for others.

For instance, in [42] the time-frequency content of signals is estimated using the Matching Pursuits (MP) signal decomposition algorithm - a step based decomposition algorithm that iterates for successively obtaining better signal approximations [62]. The approximation is accomplished by

selecting the dictionary element that best matches the signal. This match is evaluated by projecting the signal on the dictionary elements. The best matching element is scaled by its correspondent projection and subtracted from the signal generating a residual error. The process is then applied to the residual error iteratively. This algorithm is considered to be greedy [63–65], in the sense that it minimizes the approximation error at each iteration. However, this may not be optimal as a sequence of iterations occur, and due to this fact several variants for the MP have been presented [65–68].

Although the dictionary employed in the MP is not required to be a frame, it has been a common procedure to employ a frame [58, 69, 70] as a dictionary. This is so because this choice guarantees the analysis and synthesis of any signal. In general, a mix of Gabor and Wavelet frames is employed to build the dictionary used together with the MP [42]. Doing this, the dictionary elements are placed in different locations in the time-frequency plane and the several scales provide different concentrations for the energy of the elements in time and frequency. It is common to employ a dictionary formed by Gaussian functions in different scales with different time and frequency shifts. One then obtains the MP expansion of signal  $x(t)$  into the Gabor dictionary

$$x(t) \approx \sum_{n=1}^M \gamma_n g_{i(n)}(t), \quad (10.100)$$

where the  $i(n)$  indexes the element selected for approximating the residual error in the decomposition step  $n$ . From this representation the time-frequency content of  $x(t)$  is analyzed by means of

$$\sum_{n=1}^M \gamma_n W D_{g_{i(n)}}(t, f). \quad (10.101)$$

In [71] the same approach is used, but using a modified version of the MP to obtain the signal expansion. Note the resemblance between the approach in Eq. (10.99) and the ones in Eqs. (10.100) and (10.101).

## 1.10.7 Conclusion

In this chapter we have made an overview of frames. We started by introducing the concept of overcomplete decompositions, highlighting its main characteristics. We then commented on the dual frames, and how frames can be employed to perform analysis and synthesis of signals. After this, we provided formal definitions of the frame operator, inverse frames and frame bounds. We then formalized the use of frames in discrete and finite dimensional spaces. Shifting into more practical matters, we showed how to generate frames from a prototype function, by using translations, modulations and dilations. From this, we analyzed the widely used frames of translates, Gabor frames and wavelet frames. We then described some applications in signal analysis, including the Gaborgram, and presented a way to compute it more efficiently using the Fast Fourier Transform. We finished the chapter by presenting ways to compute time-frequency analysis using decompositions and the matching pursuits algorithm.

## 1.11.1 Introduction

This chapter considers the topic of parametric estimation, which is an important engineering concept that is often used for modeling signals and systems. When a complex signal or system is encountered, it is often desirable to construct a model for the signal or system in question such that it can be readily analyzed. For an input-output system, this may be to understand its behavior, its potential weaknesses, or its stability to bounded inputs. For signals of interest, this may be to understand the content of the signal, such as to determine the words that were spoken in an acoustic signal containing a recording of human speech. In many such cases, models for the signals or systems of interest are sought that can be practically analyzed without excess computation. As in Occam's razor, a parsimonious model is better than a needlessly complicated one. A good model would be one that is sufficiently rich to enable insights into the salient characteristics of the signals or systems under study, but not any more so than necessary. By using parametric models, whose behavior is uniquely determined by a finite set of parameters, the complexity of the model can often be controlled by limiting the number of parameters. In this chapter, we focus on the estimation of such model parameters under a variety of scenarios. Using both statistical and deterministic formulations, rational models (linear models with a finite number of poles and zeros) are considered in both the batch and online recursive formulations. Such autoregressive and moving average models form the basis for our initial investigation, after which we explore advanced topics, such as spectrum estimation, prediction, and filtering, as well as a number of nonlinear parametric modeling techniques.

The background assumed in this chapter is a working knowledge of discrete-time signals and systems, some basic probability theory including knowledge of stationary random processes, and the mathematical skills of a senior level undergraduate student in electrical engineering or a similar discipline. An exemplary treatment of these topics includes the texts by Oppenheim et al. [1], Rabiner and Gold [2], and Rabiner and Schafer [3]. These texts cover discrete-time signal and system theory, with the latter covering some random processes. Additional material on probability and stochastic processes as applied to the problems in this chapter can be found in [4,5].

## 1.11.2 Deterministic and stochastic signals

In this chapter, we will consider discrete-time signals through a number of different lenses with the goal of developing parametric models for signals and systems that are useful in a variety of engineering contexts.

In order to proceed, we will often make use of two distinct models for signals in our discussions. The first, and perhaps the simplest formulation, is to assume that the signals of interest are deterministic, that is, that the signal values  $x[n]$  can take on any finite real value and there are no probabilities or other constraints to these values. This might be a useful way for us to capture the inability of our modeling methods to provide any other meaningful measure to the data we observe than the simple statement that the data can take on any values.

In this light, we will often use measures of performance such as the accumulated square error of an estimate  $\hat{x}[n]$  for a signal  $x[n]$  over a block of samples,  $n = 0, \dots, N$ ,

$$E_{LS} = \sum_{n=0}^N (x[n] - \hat{x}[n])^2, \quad (11.1)$$

or we may formulate this as an integral square error measured in the frequency domain,

$$E_{IS} = \frac{1}{2\pi} \int_{-\pi}^{\pi} |X_d(\omega) - \hat{X}(\omega)|^2 d\omega, \quad (11.2)$$

as a means of capturing the degree to which the approximating time domain signal  $\hat{x}[n]$  or frequency domain estimate  $\hat{X}(\omega)$  match or model the deterministic signal of interest  $x[n]$  or  $X_d(\omega)$ .

As a simple example, suppose that we have measured a signal  $x[n]$  that corresponds to the daily temperature of the water in a local pond. If we wanted to compute a good approximating signal,  $\hat{x}[n] = c$ , i.e., a signal whose value remains constant over the entire interval, and we use the accumulated square error over the collected data signal as a measure of performance, we could write

$$E_{LS} = \sum_{n=0}^N (x[n] - c)^2 \quad (11.3)$$

and seek to find the value of that minimizes the total accumulated square error over the observation interval. Differentiating  $E_{LS}$  with respect to  $c$ , and setting the result equal to zero, we obtain,

$$\frac{\partial E_{LS}}{\partial c} = -2 \sum_{n=0}^N (x[n] - c), \quad (11.4)$$

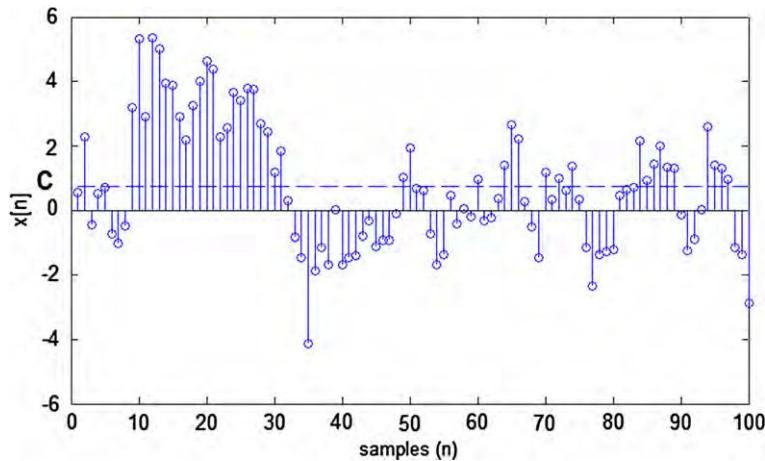

$$0 = -2 \sum_{n=0}^N (x[n] - c), \quad (11.5)$$

which can be solved for the minimizing value of  $c$ , yielding

$$c = \frac{1}{N+1} \sum_{n=0}^N x[n]. \quad (11.6)$$

This is the well-known result that the sample-average of a sequence is the best approximating value for the sequence, if we restrict the set of possible approximating signals to those that take on only a single constant value.

Figure 11.1 shows the result of approximating a signal  $x[n]$  with another signal that takes on only a single constant value. The signal in this example has an average value of  $c$  over the interval shown.

**FIGURE 11.1**

Approximating a signal with a constant value.

As a result, the best approximating constant valued signal, in terms of minimizing the squared approximation error over the interval shown, is the mean of the signal,  $c$ .

Another approach that we will often pursue is the use of stochastic (random) signal models in our development. Random signal models enable the use of probabilistic methods to model some of the uncertainty, or relative uncertainty, in the evolution of a time-series or a given signal or system model. As a result, we may choose measures of performance that are similar in spirit to those of our deterministic signal analyses, but for which we make explicit use of a probabilistic model for the signals of interest. In statistical signal processing, square-error methods are often used, again for their mathematical tractability as well as our ability to capture much of the behavior of the signals of interest with a relatively small number of statistical quantities. Specifically, we will often use a model for random signals that makes use of the so-called second-order statistics of the signal of interest [6]. Specifically, for a discrete-time random signal,  $x[n]$ , to have a complete statistical characterization of the signal would require knowledge of the probability density function for all possible probabilistic quantities such as  $f_x(x[n_1], x[n_2], x[n_3], \dots, x[n_k])$  for all possible  $n_1, n_2, n_3, \dots, n_k$ , and for all possible  $k$ . This complete statistical knowledge may be available for certain signal or system models, however, in general such a complete characterization is either not available or not appropriate.

As a result, we will often use second-order statistical models for random signals of interest by assuming that we either have knowledge of, or can make estimates of, the following two quantities. Specifically, the mean-value of the signal is defined as

$$m_x[n] = E\{x[n]\}, \quad (11.7)$$

where the  $E\{ \}$  denotes the statistical expectation operation which is taken with respect to the complete stochastic characterization of the random signal  $x[n]$ . The covariance function of the signal is defined as

$$\begin{aligned} C_x[m, n] &= E\{(x[m] - m_x[m])(x[n] - m_x[n])^*\}, \\ C_x[m, n] &= E\{(x[m]x[n]^*)\} - m_x[m]m_x[n]^*, \end{aligned} \quad (11.8)$$

where, again, the expectation is taken with respect to the complete stochastic characterization of the random signal, and the second term in the definition is conjugated, if the random signal is complex valued.

When the random signal  $x[n]$  is *wide-sense stationary* (WSS), then both the mean-value of the signal and also the covariance function take on a special form [1,6]. Specifically, for wide-sense stationary random signals, the mean-value of the signal is not a function of time, i.e.,  $m_x[n] = m_x$ , and the covariance function is only a function of the difference in times between the two samples, i.e.,

$$C_x[m, n] = C_x[0, n - m] \triangleq C_x[n - m], \quad (11.9)$$

where, with a slight abuse of notation, the same name is given to both the general and the wide-sense stationary covariance functions. In general terms, a random signal is stationary if the statistical properties of the signal do not depend on the specific time (of day, of the year, etc.) but rather samples of the signal have correlation (or other statistical dependence) that is merely a function of how close in time the samples are taken with respect to one another.

Returning to our earlier example of representing a signal, now a random signal, by a single constant estimate of that signal, we might seek to minimize the following mean square error, rather than the accumulated square error as before,

$$\begin{aligned} E_{MS} &= E\{(x[n] - \hat{x}[n])^2\}, \\ E_{MS} &= E\{(x[n] - c)^2\}, \end{aligned} \quad (11.10)$$

where, once again we seek a single value of the constant to represent the signal over the region of interest. If the signal  $x[n]$  is stationary, then we can find a simple solution to this estimation problem by differentiating with respect to the parameter as follows:

$$\begin{aligned} \frac{\partial E_{MS}}{\partial c} &= -E\{2(x[n] - c)\}, \\ 0 &= -2E\{x[n]\} + 2c, \\ c &= m_x. \end{aligned} \quad (11.11)$$

This provides the stochastic version of the deterministic least squares estimation problem, whereby the minimum mean square error (MMSE) constant estimate of a wide-sense stationary random signal is given by the mean of the signal.

### 1.11.3 Parametric models for signals and systems

There are a wide variety of ways in which a signal can be represented, or *modeled* using the tools of signal processing and random processes. In this section, we will consider models that are *parametric* in that they contain a number of free parameters that can be adjusted to optimize a given criterion of interest, such as the least square or mean square error metrics described previously. Perhaps the simplest such models are the so-called *autoregressive* (AR) and *moving average* (MA) models that use as free parameters, the coefficients of the numerator and denominator polynomials of a rational transfer function that is driven by a deterministic or random process.

In contrast to such parametric signal models, methods that attempt to model or approximate a given signal without the use of such a global parametric model are often called *non-parametric* signal models. A few examples of non-parametric methods for estimating a signal of interest include estimates of histograms for signal values, piecewise constant or piecewise linear signal models, truncated Fourier series models, and nearest neighbor models. We will not explore such non-parametric methods in this chapter.

### 1.11.3.1 Autoregressive (AR) models

A discrete-time signal  $x[n]$  is an autoregressive (AR) process of order  $p$  if it can be written in the form [6]

$$x[n] + a_1x[n - 1] + \cdots + a_px[n - p] = w[n], \quad (11.12)$$

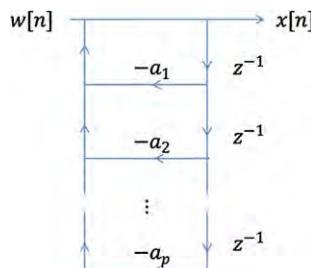

where  $a_1, \dots, a_p$  are parameters of the AR model and the signal  $w[n]$  is a zero mean white noise process of variance  $\sigma^2$ , i.e., we have that  $C_w[m] = \sigma^2\delta[m]$ . By rearranging the order of the terms in the definition, we can write the autoregressive process recursively, as

$$x[n] = -a_1x[n - 1] - a_2x[n - 2] - \cdots - a_px[n - p] + w[n], \quad (11.13)$$

which shows that a  $p$ th order autoregressive process can be written as a linear combination of the  $p$  most recent values of the signal plus a term that is statistically independent of the past values of the process; this is the so-called innovations sequence, and represents the new information, or the unpredictable components in the random signal (see Figure 11.2).

Another way to view autoregressive signals is by recognizing that the definition of the process also represents a convolution of the input sequence  $x[n]$  with the autoregressive parameters, such that the output signal is the innovations sequence, i.e.,

$$\sum_{k=0}^p a_k x[n - k] = w[n], \quad (11.14)$$

**FIGURE 11.2**

Autoregressive process flow diagram.

where we set  $a_0 = 1$ . The significance of this can be seen if we slightly rearrange terms, yielding

$$x[n] - \underbrace{\left( -\sum_{k=1}^p a_k x[n-k] \right)}_{\hat{x}[n]} = w[n] \quad (11.15)$$

in which we can view the summation as an estimate of the signal  $x[n]$ , given by its most recent  $p$  parameters, i.e., we have

$$x[n] - \hat{x}[n] = w[n]. \quad (11.16)$$

By writing the process in this form, we see that the sequence  $x[n]$  is rather unique in that it can be best estimated by its most recent past values and that after this *predictable component* is subtracted off, all that remains is a white-noise sequence that is independent of the past values. The term “autoregressive” comes from the ability to write the sequence  $x[n]$  using a “regression model” over its own past values, i.e., using a finite linear combination of its own past values.

By using the linear regression, or auto-regression model for the sequence  $x[n]$ , we see that there is an input-output relationship between the sequences  $w[n]$  and  $x[n]$  that is, we can view the creation of the sequence  $x[n]$  by processing the sequence  $w[n]$  with a linear, time-invariant filter. Ignoring that the sequences  $x[n]$  and  $w[n]$  may be random for now, and considering only the input-output relationship between them, we can take the  $z$ -transform of both sides (assuming for now that the sequences are deterministic, or given), we have

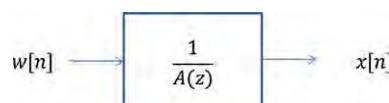

$$x(z) + \sum_{k=1}^p a_k z^{-k} X(z) = W(z), \quad (11.17)$$

$$x(z) \left( 1 + \sum_{k=1}^p a_k z^{-k} \right) = W(z), \quad (11.18)$$

$$x(z) = \left( \frac{1}{1 + \sum_{k=1}^p a_k z^{-k}} \right) W(z). \quad (11.19)$$

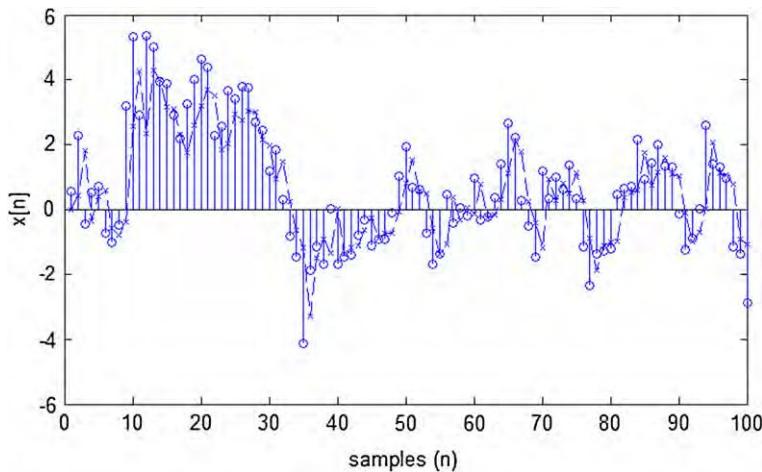

This input-output relationship implies that we can view the sequence  $x[n]$  as being generated by filtering the sequence  $w[n]$  with an “all-pole” filter, since the transfer function  $H(z) = X(z)/W(z)$ , relating  $X(z)$  and  $W(z)$  can be written as a rational transfer function where the numerator polynomial is given by  $B(z) = 1$ , and the denominator polynomial is given by  $A(z) = 1 + \sum_{k=1}^p a_k z^{-k}$  (see Figure 11.3).

This input-output interpretation of an AR process provides two interesting ways to view the relationship between the signals  $x[n]$  and  $w[n]$ . Specifically, we can use the relationship  $X(z) = H(z)W(z)$ ,

**FIGURE 11.3**

Input-output transfer function perspective of the autoregressive model.

**FIGURE 11.4**

Tracking colored noise with an AR model.

to look at the signal  $x(n)$  as being *generated* by filtering a white-noise signal  $w[n]$  with an all-pole filter. This provides us with a simple way to generate random processes (or deterministic signals) with a spectral shape that can be parametrically controlled through the coefficients of  $A[z]$ . An alternative viewpoint arises from writing the signal in the so-called “prediction error form” [3,6] whereby we have  $x[n] - \hat{x}[n] = w[n]$ . By writing it this way, we can view the signal  $x[n]$  as being filtered using the prediction error filter with transfer function  $A(z)$ , such that the output is the white-noise signal  $w[n]$ . In this sense, the predictable component of  $x[n]$  can be completely removed by the FIR prediction error filter with transfer function  $A(z)$ , leaving only the “innovation” sequence, or unpredictable component,  $x[n] - \hat{x}[n] = w[n]$ .

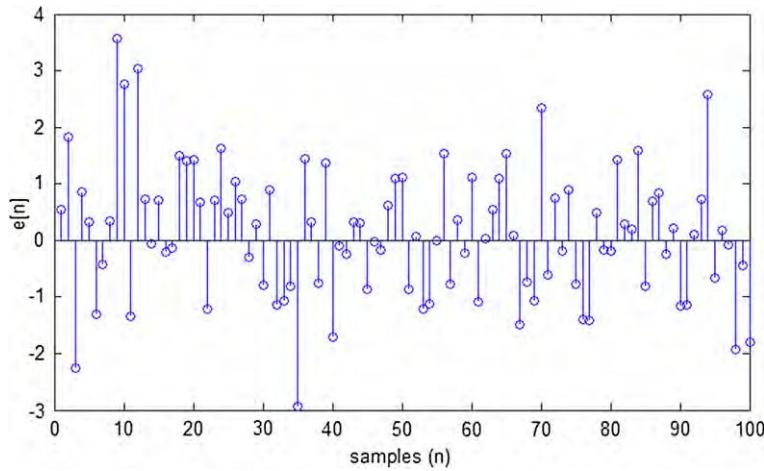

One application of the AR model is to use the parametric model for prediction of the sequence  $x[n]$ . For example, one might attempt to predict the next value of a colored noise signal with an AR model. Figure 11.4 shows the input  $w[n]$  and output  $x[n]$  of an FIR prediction filter that is designed to track the input using only past values of the input. The signal used in Figure 11.1 is reused in Figure 11.4.

Since colored noise can be generated by filtering a white-noise signal, we can view the signal of interest as if it were originally generated by filtering such a white-noise signal. Thus, we expect that the error between the predicted and measured signals will be a white-noise sequence. Figure 11.5 shows the prediction error sequence, which indeed appears uncorrelated from sample to sample, i.e., white.

### 1.11.3.2 Moving average (MA) models

A discrete-time signal  $x[n]$  is called a moving average (MA) process of order  $q$  if it can be written in the form [3,6]

$$x[n] = b_0 w[n] + b_1 w[n-1] + \cdots + b_q w[n-q], \quad (11.20)$$

**FIGURE 11.5**

Prediction error from estimating colored noise using an AR model.

where  $b_0, \dots, b_q$  are parameters of the MA model and the signal  $w[n]$  is a white noise process, i.e., we have that  $C_w[m] = \sigma^2 \delta[m]$ . Since the sequence  $x[n]$  can be viewed as a linear combination of the most recent values of the sequence then it is called a “moving average.” From this structure, whenever the sequence  $x[n]$  is given as the output of an FIR filter whose input is a white-noise sequence, then we can refer to as a moving average sequence. More generally, even when the input is not a white-noise sequence, the process of filtering with an FIR filter can be viewed as taking a “moving average” of the input. Financial models often use 50-day and 100-day moving averages as indicators of trends in various stock prices and indices. In such a context,  $q$  and  $b_k$  are usually taken such that  $b_k = \frac{1}{q+1}$ ,  $k = 0, \dots, q$ , such that  $x[n] = \frac{1}{q+1} \sum_{k=0}^q w[n-k]$ , i.e., the arithmetic mean of the most recent  $q+1$  values of  $w[n]$ .

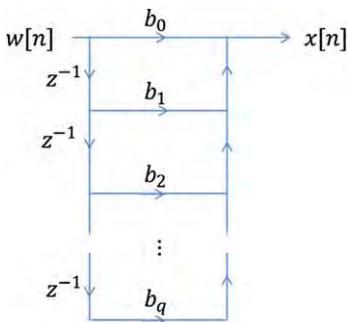

Viewing the relationship between the sequences  $x[n]$  and  $w[n]$  with a signal flowgraph model, in Figure 11.6a, we see that  $x[n]$  can be viewed as an FIR filtered version of the sequence  $w[n]$ . Similarly, we can view this in Figure 11.6b, via an input-output transfer function relationship between the two sequences.

### 1.11.3.3 Autoregressive moving average (ARMA) models

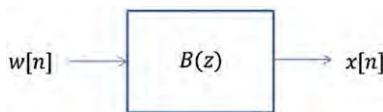

A discrete-time signal  $x[n]$  is an autoregressive moving average (ARMA) process of order  $q, p$  if it can be written in the form [3, 6]

$$x[n] + a_1 x[n-1] + \cdots + a_p x[n-p] = b_0 w[n] + \cdots + b_q w[n-q], \quad (11.21)$$

where  $a_1, \dots, a_p, b_0, \dots, b_q$  are parameters of the ARMA model and the signal  $w[n]$  is a white noise process, i.e., we have that  $C_w[m] = \sigma^2 \delta[m]$ . We can once again relate the sequences  $x[n]$  and  $w[n]$

**FIGURE 11.6a**

Moving average flowgraph model.

**FIGURE 11.6b**

Transfer function perspective of the MA model relating  $x[n]$  and  $w[n]$ .

through a transfer function relationship, such as

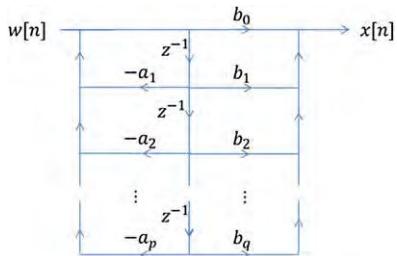

$$X(z) = \left( \frac{\sum_{k=0}^q b_k z^{-k}}{1 + \sum_{k=1}^p a_k z^{-k}} \right) W(z). \quad (11.22)$$

This input-output relationship implies that we can view the sequence  $x[n]$  as being generated by filtering the sequence  $w[n]$  with a rational function, i.e., a “pole-zero” filter with finite order numerator and denominator polynomials, where the numerator polynomial is given by  $B(z) = \sum_{k=0}^q b_k z^{-k}$ , and the denominator polynomial is given by  $A(z) = 1 + \sum_{k=1}^p a_k z^{-k}$ . It is usually assumed that the rational function is “strictly proper,” which means that the numerator order is strictly less than that of the denominator, i.e.,  $q < p$ . For this reason, we may refer to the sequence as an ARMA( $p$ ) process, rather than ARMA( $q, p$ ). Figures 11.7a and 11.7b illustrate the flowgraph and transfer function perspective of the ARMA model relating the sequences  $x[n]$  and  $w[n]$ .

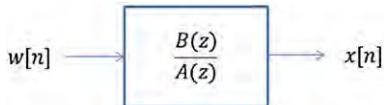

#### 1.11.3.4 Parametric modeling for system function approximation

One of the primary reasons that parametric models are used is to obtain finite-order (rational system) approximations to systems that we encounter in real-world engineering problems. Whether the data of interest are taken from a mechanical system, an electrical device, a digital communications link, or even a financial or economic model, we often seek input-output relationships that can explain the behaviors we observe such that we might be able to better understand them, or even hope to control them.

There are a number of ways in which input-output behavior can be modeled though two are perhaps most common. One is based on observations of input-output pairs in the time domain, from which

**FIGURE 11.7a**

ARMA flowgraph model.

**FIGURE 11.7b**

Transfer function perspective of the ARMA model relating  $x[n]$  and  $w[n]$ .

an explanation of such behavior is sought. Another other comes from attempts to fit a given system function or frequency response that either arose from a more detailed physical model, or which was measured using instrumentation, such as a spectrum analyzer in response to a variety of probe signals. These two approaches can certainly be linked, through the Fourier transform, and we will move back and forth between the two domains depending on the methods at hand. For example, given a frequency response  $H(e^{j\omega})$  that we sought to model, we could readily transform this into the input-output pair  $x[n] = \delta[n]$ ,  $y[n] = h[n]$ , defining the impulse response of the system as the response of the system to an impulse as input, using the definition of the discrete-time Fourier transform [1],

$$H(e^{j\omega}) = \sum_{n=-\infty}^{\infty} h[n]e^{-j\omega n}, \quad (11.23)$$

$$h[n] = \frac{1}{2\pi} \int_{-\pi}^{\pi} H(e^{j\omega})e^{j\omega n} dw. \quad (11.24)$$

In general, direct ARMA modeling is difficult, since the formulation of the optimization of interest is highly nonlinear in the parameters of the model. For example, given a frequency response  $H(e^{j\omega})$ , the deterministic least squares optimal ARMA( $q, p$ ) model satisfies the following minimization

$$\min_{\{a_k\}_{k=1}^p \{b_k\}_{k=0}^q} \frac{1}{2\pi} \int_{-\pi}^{\pi} \left| H(e^{j\omega}) - \frac{\sum_{k=0}^q b_k e^{-jk\omega}}{1 + \sum_{k=1}^p a_k e^{-jk\omega}} \right|^2 d\omega, \quad (11.25)$$

which is highly nonlinear in the parameters of the ARMA model. This can be rewritten in the time domain, by application of Parseval's relation [1], which equates energy calculated in the time domain

with that calculated in the frequency domain, yielding,

$$\min_{\{a_k\}_{k=1}^p \{b_k\}_{k=0}^q} \sum_{n=-\infty}^{\infty} \left| h[n] - \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{\sum_{k=0}^q b_k e^{-jk\omega}}{1 + \sum_{k=1}^p a_k e^{-jk\omega}} e^{j\omega n} d\omega \right|^2, \quad (11.26)$$

which is equally cumbersome.

This problem formulation is difficult due to the manner in which the AR parameters of interest are nonlinearly related to the optimization criterion. If we were only concerned with a MA estimate and wanted to use this least-squares criterion, then the time-domain formulation can provide a simple solution, whereby

$$\min_{\{b_k\}_{k=0}^q} \sum_{n=-\infty}^{\infty} \left| h[n] - \frac{1}{2\pi} \int_{-\pi}^{\pi} \sum_{k=0}^q b_k e^{-jk\omega} e^{j\omega n} d\omega \right|^2, \quad (11.27)$$

which can be rewritten

$$\min_{\{b_k\}_{k=0}^q} \sum_{n=-\infty}^{\infty} \left| h[n] - \sum_{k=0}^q b_k \delta[n-k] \right|^2, \quad (11.28)$$

yielding the simple, though somewhat unsatisfying, solution,

$$b_k = h[k], \quad k = 0, \dots, q. \quad (11.29)$$

This is nothing more than a simple truncation approximation to the desired impulse response for the system of interest. If a more elaborate response is desired, for example, one that is IIR, then poles are necessary, in addition to the zeros of the approximating transfer function, and an AR or ARMA model should be considered. This again would lead to the nonlinearities we just encountered.

An approach that had proven useful for AR modeling is one that takes the engineering approach to problem solving, that is, if a problem is difficult to solve directly, attempt to change it into one that is more readily solvable. In this light, we will see how the nonlinear optimization for the AR formulation can be transformed into a linear optimization through a clever insight. First, we recall the form of the AR model for the transfer function, namely,

$$H(z) = \frac{1}{1 + \sum_{k=1}^p a_k z^{-k}}. \quad (11.30)$$

Beginning with this expression and taking the inverse z-transform, we see that the impulse response of the modeled system must satisfy

$$h[n] + \sum_{k=1}^p a_k h[n-k] = \delta[n]. \quad (11.31)$$

Now given a desired (or measured) impulse response, which we will denote,  $h_d[n]$ , we could attempt to minimize the deviation of this expression from that which is expected from this recursion and replace the nonlinear optimization above with the simpler form

$$\min_{\{a_k\}_{k=1}^p} \sum_{n=-\infty}^{\infty} \left| h_d[n] + \sum_{k=1}^p a_k h_d[n-k] \right|^2, \quad (11.32)$$

which is a quadratic minimization in the parameters of interest and therefore admits a closed-form solution! Specifically, denoting the quadratic error term in the minimization above as  $E$  we can write

$$0 = \frac{\partial E}{\partial a_\ell} = 2 \sum_{n=-\infty}^{\infty} \left( h_d[n] + \sum_{k=1}^p a_k h_d[n-k] \right) h_d[n-\ell], \quad \ell = 1, \dots, p, \quad (11.33)$$

which comprise a set of linear equations in  $a_\ell$ ,  $\ell = 1, \dots, p$ . We can write these equations more compactly by exchanging the order of summation, as

$$\sum_{k=1}^p a_k \underbrace{\sum_{n=-\infty}^{\infty} h_d[n-k] h_d[n-\ell]}_{\hat{R}_{h_d h_d}[k-\ell]} = - \underbrace{\sum_{n=-\infty}^{\infty} h_d[n] h_d[n-\ell]}_{\hat{R}_{h_d h_d}[\ell]}, \quad \ell = 1, \dots, p. \quad (11.34)$$

We have made use of the definition which is often called the deterministic auto-correlation sequence for the sequence. We can then summarize the set of equations in matrix form, sometimes referred to as the Normal Equations [3,6],

$$R\vec{a} = -\vec{r}, \quad (11.35)$$

or

$$\begin{bmatrix} \hat{R}_{h_d h_d}[0] & \dots & \hat{R}_{h_d h_d}[p-1] \\ \vdots & \ddots & \vdots \\ \hat{R}_{h_d h_d}[p-1] & \dots & \hat{R}_{h_d h_d}[0] \end{bmatrix} \begin{bmatrix} a_1 \\ \vdots \\ a_p \end{bmatrix} = - \begin{bmatrix} \hat{R}_{h_d h_d}[1] \\ \vdots \\ \hat{R}_{h_d h_d}[p] \end{bmatrix}, \quad (11.36)$$

which has the solution,

$$\vec{a} = -R_{-1}\vec{r}. \quad (11.37)$$

The matrix  $R$  has special structure that makes solving such linear equations not only straightforward, but also fast. Namely,  $R$  is known as a symmetric Toeplitz matrix, for which fast linear equation solvers can be readily obtained [3,6]. This special structure, together with the right hand side of the linear equations led to a particularly fast algorithm for its solution, known as the Levinson-Durbin recursion [3]. If we were to replace the least-squares enforcement of the prediction error criterion with a mean square error criterion, i.e., we sought to minimize the mean square error

$$\min_{\{a_k\}_{k=1}^p} E \left\{ \left| h_d[n] + \sum_{k=1}^p a_k h_d[n-k] \right|^2 \right\}, \quad (11.38)$$

we would naturally arrive at a similar form for its solution, namely, we would have

$$R\vec{a} = -\vec{r} \quad (11.39)$$

or

$$\begin{bmatrix} R_{h_d h_d}[0] & \dots & R_{h_d h_d}[p-1] \\ \vdots & \ddots & \vdots \\ R_{h_d h_d}[p-1] & \dots & R_{h_d h_d}[0] \end{bmatrix} \begin{bmatrix} a_1 \\ \vdots \\ a_p \end{bmatrix} = - \begin{bmatrix} R_{h_d h_d}[1] \\ \vdots \\ R_{h_d h_d}[p] \end{bmatrix}, \quad (11.40)$$

which has the solution,

$$\vec{a} = -R^{-1}\vec{r}, \quad (11.41)$$

where, the only difference in our solution lies in replacing the deterministic auto-correlation with the statistical auto-correlation,  $R_{h_d h_d}[\ell] = E\{h_d[n]h_d[n - \ell]\}$ , where the expectation is taken over the distribution of the random sequence  $h_d[n]$ . This approach to autoregressive modeling is often called “linear prediction” or “linear predictive modeling” due to the use of the prediction error form that is used to make the optimization problem linear in the parameters of interest [3,6,7].

Returning to the ARMA modeling problem, there are a number of ways of incorporating zeros into the modeling problem while still using the much simpler prediction-error formulation developed so far. Perhaps the simplest is to just use the zeros to match the first values of the impulse response exactly, that is to first solve for the denominator coefficients as above (predictive AR modeling) and then select

$$b_\ell = h_d[\ell] + \sum_{k=1}^p a_k h_d[\ell - k], \quad k = 0, \dots, q, \quad (11.42)$$

which follows from the system function relation

$$H_d(z) = \left( \frac{\sum_{k=0}^q b_k z^{-k}}{1 + \sum_{k=1}^p a_k z^{-k}} \right). \quad (11.43)$$

This two-step process, namely (1) determine the AR parameters using linear predictive modeling, followed by (2) select the MA parameters by exactly matching the first  $q$  samples of the impulse response is often called Prony’s method [3,7]. In general, this method provides a reasonable set of AR parameters; however the MA parameters are not particularly well-modeled. That is, if a system were known to have a given ARMA form, and its parameters were to be estimated from noisy observations using Prony’s method, the AR parameters would likely well-match the true underlying system, however the MA parameters would likely be a poor match.

An improvement over this approach is to once again use a least squares, or MMSE criterion to obtain the MA parameters in a modified two-step approach. The first of the two steps remains the same, that is, use the predictive-least squares (or MMSE) approach to find the AR parameters according to the Normal equations as before. However, now that a set of AR parameters are given, the sequence  $v[n]$  is defined as follows:

$$v[n] = - \sum_{k=1}^p a_k v[n - k] + \delta[n], \quad (11.44)$$

i.e.,  $v[n]$  is defined to be the impulse response of the AR model derived in step (1). Now, the goal is to minimize the discrepancy between the desired impulse response  $h_d[n]$  and the output of the cascade of the AR model and the MA model, such that the sequence  $v[n]$  passed through the FIR filter with transfer function  $B(z)$  is close to the desired impulse response. Specifically, we select the MA coefficients to minimize the following criterion,

$$\min_{\{b_k\}_{k=0}^q} \sum_{n=-\infty}^{\infty} \left| h_d[n] + \sum_{k=0}^q b_k v[n - k] \right|^2, \quad (11.45)$$

which is once again a quadratic minimization admitting a closed-form solution. The linear equations reduce to

$$\sum_{k=0}^q b_k \underbrace{\sum_{n=-\infty}^{\infty} v[n-k]v[n-\ell]}_{\hat{R}_{vv}[k-\ell]} = - \underbrace{\sum_{n=-\infty}^{\infty} h_d[n]v[n-\ell]}_{\hat{R}_{h_dv}[\ell]}, \quad \ell = 0, \dots, q, \quad (11.46)$$

which admits the solution,

$$\vec{b} = - \begin{bmatrix} R_{vv}[0] & \dots & R_{vv}[q] \\ \vdots & \ddots & \vdots \\ R_{vv}[q] & \dots & R_{vv}[0] \end{bmatrix}^{-1} \begin{bmatrix} R_{h_dv}[0] \\ \vdots \\ R_{h_dv}[q] \end{bmatrix}, \quad (11.47)$$

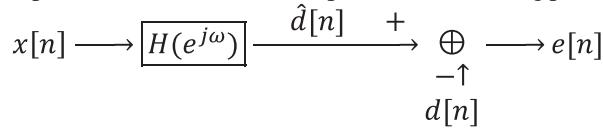

$$\vec{b} = -(R_{vv})^{-1} \vec{r}_{hv}, \quad (11.48)$$

where, we denote

$$R_{vv} = \begin{bmatrix} R_{vv}[0] & \dots & R_{vv}[q] \\ \vdots & \ddots & \vdots \\ R_{vv}[q] & \vdots & R_{vv}[0] \end{bmatrix}, \quad \vec{r}_{hv} = \begin{bmatrix} R_{h_dv}[0] \\ \vdots \\ R_{h_dv}[q] \end{bmatrix}. \quad (11.49)$$

### 1.11.3.5 Parametric modeling for joint process estimation

One of the classical signal estimation and modeling problems that makes use of parametric estimation methods like those developed here, include the adaptive filtering and joint process estimation problem [2]. Most generally, these problems can be viewed as a parametric modeling problem depicted as follows:

where the parameters of a model for  $H(e^{j\omega})$  are adjusted to minimize the discrepancy  $e[n] = (d[n] - \hat{d}[n])$  in a suitable manner [8]. When the parameters of the model are adjusted in an online (sequential) manner, such that the filter parameters  $\{h[k]\}_{k=0}^p$  are updated after each observation of the desired signal, this is commonly referred to as “adaptive filtering” [8]. When a batch of data  $\{x[k]\}_{k=0}^N$  is observed and the parameters  $\{h[k]\}_{k=0}^p$  are selected based on this entire set of observations, this problem is commonly referred to as batch or block processing. We will first consider the stochastic case, where the discrepancy to be minimized takes the form

$$\{h_{\text{MMSE}}[k]\}_{k=0}^p = \arg \min_{\{h[k]\}_{k=0}^p} \epsilon \{(d[n] - \hat{d}[n])^2\}. \quad (11.50)$$

Writing out this minimization using the parameters of the model, leads to

$$\{h_{\text{MMSE}}[k]\}_{k=0}^p = \arg \min_{\{h[k]\}_{k=0}^p} \epsilon_{\text{MMSE}} = E \left\{ \left( d[n] - \sum_{k=0}^p h[k]x[n-k] \right)^2 \right\}. \quad (11.51)$$

To proceed, we consider that the sequences  $x[n]$  and  $d[n]$  are wide-sense stationary stochastic processes, with zero mean and covariance functions [6]

$$C_x[n, n - m] = E\{x[n]x[n - m]\} = R_x[m] = R_x[-m], \quad (11.52)$$

$$C_d[n, n - m] = E\{d[n]d[n - m]\} = R_d[m] = R_d[-m], \quad (11.53)$$

$$C_{xd}[n, n - m] = E\{x[n]d[n - m]\} = R_{xd}[m] = R_{dx}[-m]. \quad (11.54)$$

We can now solve for the minimizing set of parameters by differentiating this quadratic expression with respect to each of the unknown parameters, which leads to

$$0 = \frac{\partial \epsilon_{\text{MMSE}}}{\partial h[\ell]} = -2E \left\{ \left( d[n] - \sum_{k=0}^p h[k]x[n - k] \right) x[n - \ell] \right\}, \quad \ell = 0, \dots, p. \quad (11.55)$$

Rearranging terms, we arrive at

$$0 = E\{d[n]x[n - \ell]\} - \sum_{k=0}^p h[k]E\{x[n - k]x[n - \ell]\}, \quad \ell = 0, \dots, p, \quad (11.56)$$

$$E\{d[n]x[n - \ell]\} = \sum_{k=0}^p h[k]E\{x[n - k]x[n - \ell]\}, \quad \ell = 0, \dots, p, \quad (11.57)$$

$$R_{dx}[\ell] = \sum_{k=0}^p h[k]R_{xx}[k - \ell], \quad \ell = 0, \dots, p, \quad (11.58)$$

which can be recognized as another form of the auto-correlation normal equations we have seen previously for AR modeling. We have

$$\begin{bmatrix} R_{xx}[0] & \dots & R_{xx}[p] \\ \vdots & \ddots & \vdots \\ R_{xx}[p] & \dots & R_{xx}[0] \end{bmatrix} \begin{bmatrix} h[0] \\ \vdots \\ h[p] \end{bmatrix} = \begin{bmatrix} R_{dx}[0] \\ \vdots \\ R_{dx}[p] \end{bmatrix}, \quad (11.59)$$

which has the solution,

$$\begin{bmatrix} h_{\text{MMSE}}[0] \\ \vdots \\ h_{\text{MMSE}}[p] \end{bmatrix} = \begin{bmatrix} R_{xx}[0] & \vdots & R_{xx}[p] \\ \vdots & \ddots & \vdots \\ R_{xx}[p] & \vdots & R_{xx}[0] \end{bmatrix}^{-1} \begin{bmatrix} R_{dx}[0] \\ \vdots \\ R_{dx}[p] \end{bmatrix}, \quad (11.60)$$

$$\vec{h}_{\text{MMSE}} = R^{-1} \vec{p}, \quad (11.61)$$

taking a similar form to the AR modeling case. Once again, since the matrix to be inverted is an auto-correlation matrix, and is symmetric, positive semidefinite, and Toeplitz, there exist fast, and numerically

stable algorithms for solving for the MMSE-optimal parameters [6,8]. This set of parameters minimizes the mean square error, and is hence called the MMSE-optimal set of model parameters. They are also often referred to as the Wiener solution, or the Wiener filter [8].

A deterministic formulation of the problem could be made, using the least-squares criterion, which would again lead to a set of equations in a similar form, specifically, defining the error criterion to be

$$\{h_{LS}[k]\}_{k=0}^p = \arg \min_{\{h[k]\}_{k=0}^p} \epsilon_{LS} = \sum_{n=-\infty}^{\infty} \left( d[n] - \sum_{k=0}^p h[k]x[n-k] \right)^2. \quad (11.62)$$

This leads to

$$\sum_{n=-\infty}^{\infty} d[n]x[n-\ell] = \sum_{k=0}^p h[k] \sum_{n=-\infty}^{\infty} x[n-k]x[n-\ell], \quad \ell = 0, \dots, p, \quad (11.63)$$

$$\hat{R}_{dx}[\ell] = \sum_{k=0}^p h[k] \hat{R}_{xx}[k-\ell], \quad \ell = 0, \dots, p, \quad (11.64)$$

where  $\hat{R}_{dx}[\ell]$  and  $\hat{R}_{xx}[\ell]$  are defined using summations over the observed data, rather than taking a statistical expectation. The resulting set of normal equations are identical, with the statistical auto- and cross-correlation functions replaced by their deterministic counterparts, arriving at the solution,

$$\begin{bmatrix} h_{LS}[0] \\ \vdots \\ h_{LS}[p] \end{bmatrix} = \begin{bmatrix} \hat{R}_{xx}[0] & \dots & \hat{R}_{xx}[p] \\ \vdots & \ddots & \vdots \\ \hat{R}_{xx}[p] & \vdots & \hat{R}_{xx}[0] \end{bmatrix}^{-1} \begin{bmatrix} \hat{R}_{dx}[0] \\ \vdots \\ \hat{R}_{dx}[p] \end{bmatrix}, \quad (11.65)$$

$$\vec{h}_{LS} = \vec{R}^{-1} \hat{\vec{p}}. \quad (11.66)$$

### 1.11.3.6 Sequential parametric modeling

In certain signal processing problems, the observations may arrive sequentially and the application may require immediate output based on only the available data. In other applications, different model parameters may be suitable for different parts of the observations such that parameters are updated in time for better fit. A common approach to consolidate these is to produce the estimated parameters in a sequential manner. Unlike the previous approaches where we have the batch data  $\{x[k]\}_{k=0}^N$ , the parameters  $\{x[k]\}_{k=0}^p$  are selected based on only currently available data  $\{x[k]\}_{k=-\infty}^n$ . As in the previous sections, a deterministic formulation of the problem could be made, using the least-squares criterion, based only on the available data as

$$\{h_{LS}[k, n]\}_{k=0}^p = \operatorname{argmin}_{\{h[k]\}_{k=0}^p} \sum_{t=-\infty}^n \left( d[t] - \sum_{k=0}^p h[k]x[t-k] \right)^2. \quad (11.67)$$

The estimated parameters are now function of time and updated as new observations arrive. To emphasize the most recent data in the estimate, the least-squares criterion is often defined over a window of observations or a weighted least squares problem is formulated, such as

$$\{h_{LS}[k, n]\}_{k=0}^p = \underset{\{h[k]\}_{k=0}^p}{\operatorname{argmin}} \sum_{t=-\infty}^n \lambda_{n-t} \left( d[t] - \sum_{k=0}^p h[k]x[t-k] \right)^2, \quad (11.68)$$

where the emphasized window length is intrinsically set with weighting parameter  $0 < \lambda \leq 1$ , e.g., when  $\lambda = 0.9$  the most recent data is emphasized in that any samples that are more than  $(\frac{1}{1-\lambda}) = 10$  samples old are weighted by  $1/e$  or less, as compared with the most recent data sample. The sequential and weighted least-squares criterion leads to a similar set of normal equations

$$\begin{bmatrix} h_{LS}[0, n] \\ \vdots \\ h_{LS}[p-n] \end{bmatrix} = \begin{bmatrix} \hat{R}_{xx}[0, n] & \dots & \hat{R}_{xx}[p, n] \\ \vdots & \ddots & \vdots \\ \hat{R}_{xx}[p, n] & \dots & \hat{R}_{xx}[0, n] \end{bmatrix}^2 \begin{bmatrix} \hat{R}_{dx}[0, n] \\ \vdots \\ \hat{R}_{dx}[p, n] \end{bmatrix}, \quad (11.69)$$

$$\vec{h}_{LS}[n] = \hat{R}[n]^{-1} \hat{p}[n]. \quad (11.70)$$

However, here, the sample auto-correlation matrix and cross-correlation vector are calculated using only the available data, and hence, are time varying,

$$\hat{R}_{xx}[k-\ell, n] = \sum_{t=-\infty}^n \lambda^{n-t} x[t-k]x[t-\ell], \quad \ell = 0, \dots, p, \quad (11.71)$$

$$\hat{R}_{dx}[\ell, n] = \sum_{t=-\infty}^n \lambda^{n-t} d[t]x[t-\ell], \quad \ell = 0, \dots, p. \quad (11.72)$$

Although successful in most signal processing applications, this online processing requires calculating the sample correlation matrix, cross-correlation vector and performing inversion for each new sample, which may be computationally infeasible for some applications. However, by recognizing the time recursions in

$$\hat{R}_{xx}[k-\ell, n+1] = \lambda \hat{R}_{xx}[k-\ell, n] + x[n+1-k]x[n+1-\ell], \quad \ell = 0, \dots, p, \quad (11.73)$$

$$\hat{R}_{dx}[\ell, n+1] = \lambda \hat{R}_{dx}[\ell, n] + d[n+1]x[n+1-\ell], \quad \ell = 0, \dots, p, \quad (11.74)$$

and using the matrix inversion lemma [8], we can solve the corresponding estimation problem in a recursive form such that the estimated model parameters at time  $n+1$  can be readily obtained from the estimated parameters at time  $n$  as

$$e[n] = d[n] - \hat{d}[n], \quad (11.75)$$

$$\vec{g}[n] = p[n] \vec{x}[n] \{ \lambda + \vec{x}[n]^T p[n] \vec{x}[n] \}^{-1}, \quad (11.76)$$

$$p[n+1] = \lambda^{-1} p[n] - \vec{g}[n] \vec{x}[n]^T \lambda^{-1} p[n], \quad (11.77)$$

$$\vec{h}[n+1] = \vec{h}[n] + \vec{g}[n] e[n] \quad (11.78)$$

yielding the “recursive least squares” (RLS) algorithm [8], where  $P[n] = \hat{R}[n]^{-1}$ . While there exist more computationally efficient lattice implementations of this update without the matrix inversion lemma, the RLS algorithm is shown to be numerically more stable [8].

We observe from this recursive update that the corresponding estimated parameter vector  $\vec{h}[n]$  at time  $n$  is basically updated by an additive vector, called the gain vector, times the estimation error to yield the parameters at time  $n + 1$  as

$$\vec{h}[n + 1] = \vec{h}[n] + \vec{g}[n]e[n], \quad (11.79)$$

where the gain vector is the inverse correlation matrix multiplied by the data vector  $\vec{x}[n]$  with certain power scaling. A common approach in signal processing to reduce the computational complexity of this update is to replace the scaled inverse correlation matrix by the inverse of the trace of the correlation matrix

$$\vec{h}[n + 1] = \vec{h}[n] + \frac{1}{\text{Trace}(\hat{R}[n])}\vec{x}[n]e[n]. \quad (11.80)$$

Subsequently, the inverse of the trace, which corresponds to the power in the stochastic process, is further replaced by a positive constant  $\mu > 0$  as

$$\vec{h}[n + 1] = \vec{h}[n] + \mu\vec{x}[n]e[n], \quad (11.81)$$

yielding the celebrated least mean squares (LMS) adaptive algorithm [9].

When the underlying stochastic model is known, i.e., the cross and auto-correlation functions are known, the parameters that minimize the MSE are evaluated by solving the normal equations

$$\vec{h}_{\text{MMSE}} = R^{-1}\vec{p}. \quad (11.82)$$

The same normal equations can be iteratively solved by applying a gradient descent algorithm [8] to the mean square error cost function, yielding a recursive update

$$\vec{h}^{(k+1)} = \vec{h}^{(k)} - \mu \nabla_{\vec{h}^{(k)}} E[e^2[n]], \quad (11.83)$$

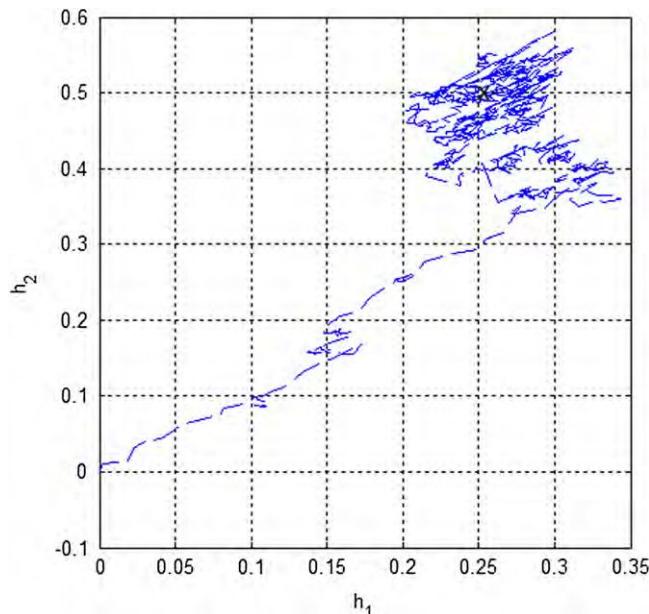

$$\vec{h}^{(k+1)} = \vec{h}^{(k)} - \mu(\vec{p} - R \vec{h}^{(k)}), \quad (11.84)$$

which converges to  $\vec{h}_{\text{MMSE}}$  as  $k$  increases provided that  $\mu$  is selected appropriately [8,9]. If the underlying  $R$  and  $p$  are not known, then the same iteration can be carried in time domain by replacing the expected variables by their temporal values, in other words by replacing  $E[e^2[n]]$  with  $e^2[n]$ , to yield

$$\vec{h}^{[n+1]} = \vec{h}[n] - \mu \nabla_{\vec{h}[n]} e^2[n], \quad (11.85)$$

$$\vec{h}^{[n+1]} = \vec{h}^{[n]} - \mu(\vec{x}[n]e[n]), \quad (11.86)$$

which yields the stochastic interpretation of the LMS algorithm. Hence, the LMS algorithm can be considered a gradient descent algorithm, where a “stochastic” gradient is used in the update instead of the true gradient as shown in Figure 11.8 [8].

**FIGURE 11.8**

Graphical depiction of the convergence of the stochastic gradient (LMS) algorithm, depicted for a two tap filter initialized at  $h = [0, 0]$ .

### 1.11.3.7 Universal model order estimation

Even when a parametric model is known to be appropriate for a particular application, e.g., an AR, ARMA or MA model, we still need to decide on the number of parameters in the corresponding parametric model. Determination of the proper number of parameters to use for a parametric model is known to be a difficult problem and has a rich history in a number of applications in signal processing, machine learning and communications [8, 10]. If the complete statistical properties of the underlying signals were known, then increasing the number of parameters would have only increased the modeling power, i.e., more parameters are better. However, since the model parameters should be learned from a limited amount of training data, this can cause over fitting, especially in short-data regimes, and lead to poor extrapolation outside of the training set, i.e., too many parameters can be bad. To avoid such over fitting problems, much of the early work in the model order determination literature focused on methods that are based on assumed probabilistic models, such as the minimum description length (MDL) or the Akaike information criterion (AIC) [6, 11]. These methods establish a balance between modeling power of the parameters using certain maximum likelihood, or information theoretic measures, while penalizing the number of parameters using certain regularization terms. For example, for AR modeling with white Gaussian noise, the leading term of the penalty term in the MDL for a model of order  $p$  and a signal length  $n$  is given by  $\frac{p}{2} \log(n)$ . Hence, for a signal  $d[t]$  according to the original definition of

MDL, the model order is selected by minimizing

$$\min_p \left\{ \min_{\{h[k]\}_{k=0}^p} \sum_{t=1}^n \left( d[t] - \sum_{k=1}^p h[k]d[t-k] \right)^2 + \left( \frac{p}{2} \right) \log(n) \right\}. \quad (11.87)$$

While these statistical approaches have been widely used in different signal processing applications, they require considerable statistical information on the signals of interest and can be fragile to operating in regimes in which the signals, for example, do not behave according to the assumed statistical model.

However, recent work in the machine learning and information theory communities have applied a new approach to tackling the model order selection problem [12, 13]. As an example, in the universal model order selection approach, instead of making hard decisions at each instant based on an assumed statistical model, one uses a performance based mixture of all models of different orders in an attempt to perform as well as or better than the best model in the mixture. The resulting algorithms then successfully navigate the short-data record regime by placing more emphasis on lower order models, while achieving the ultimate precision of higher order models as the data record grows to accommodate them. The elegance of the universal mixture methods is that this occurs naturally by monitoring the performance of each model on the data observed so far and placing more emphasis on the results of better performing models in an online manner.

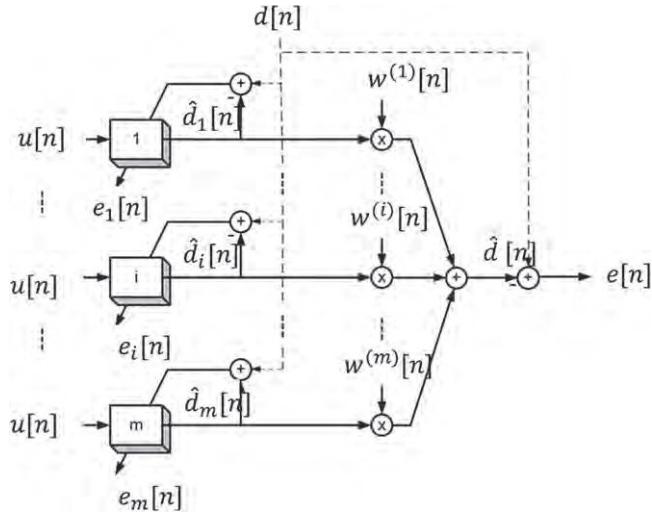

This model combination approach is successfully applied to model order selection in the context of RLS adaptive filtering when several different linear predictors, e.g., AR models, are used for prediction, regression or estimation. Clearly, the order of linear predictor heavily depends on the available amount of data and assumed statistical models. Here, instead of fixing a particular model order, one can use an explicit adaptive convex combination of different order linear predictors  $\hat{x}_p[n]$ , up to some order  $M$ , as

$$\hat{x}[n] = \sum_{p=1}^M \mu_p[n] \hat{x}_p[n], \quad (11.88)$$

where the corresponding adaptive combination weights  $\mu_p[n]$  are calculated intuitively as  $\mu_p[n] \sim \exp(-\sum_{t=1}^n (x(t) - \hat{x}_p[t])^2)$ , i.e., based on the performance of the predictor on the observed data so far. An example weighted mixture that combines  $m$  adaptive filters is shown in Figure 11.9. The output is simply calculated as a performance-weighted mixture. For these applications, an efficient lattice filter structure can be used to not only implement each of the elements of the competing class, but to also construct the universal predictor output all with complexity that is only linear in the largest model order in the competing class of models [9]. Such a model combination is shown to achieve, for any  $n$  [12]

$$\frac{1}{n} \sum_{n=1}^N (x[n] - \hat{x} - \hat{x}[n])^2 \leq \min_{p < M} \frac{1}{n} \sum_{n=1}^N (x[n] - \hat{x}_p[n])^2 + \frac{1}{n} \ln(M). \quad (11.89)$$

The ability to asymptotically achieve the performance of the best model order in the set of models gives rise to the term “universal filter” and hence such methods are often called “universal” methods.

**FIGURE 11.9**

Adaptively combining the outputs of multiple adaptive filters.

### 1.11.3.8 Universal linear predictor

In parameter estimation, the universal algorithms approach can be generalized to construct estimators that are, in a deterministic sense, min-max optimal [13]. As an example, once again let us focus on AR parameter estimation under the deterministic total square estimation error. However, instead of constructing sequential normal equations, as in the previous section, we hypothetically implement all of the continuum of AR models for each  $\vec{h} \in R^P$  and construct a sequential estimate based on a performance-weighted mixture of all these AR models as in the previous section. By taking an implicit performance-weighted mixture over the outputs of all adaptive filters  $\vec{h} \in R^P$  and using a priori Gaussian weighting  $p(\hat{h})$ , the integral

$$\int_{R^P} \vec{h}^T \vec{x}[n] p(\vec{h}) \sum_{t=1}^{n-1} e^2[t] d\vec{h}, \quad (11.90)$$

analogous to the weighted combination in the previous section, can be evaluated in closed form and leads to a diagonally loaded RLS adaptive filtering algorithm [12]

$$\vec{h}_{uni}[n] = \vec{R}[n-1]^{-1} \hat{\vec{p}}[n]. \quad (11.91)$$

However, in this new recursive update, we have  $\hat{R}[n-1] = \sum_{t=1}^{n-1} \vec{x}[t]\vec{x}^T + \delta I$ . Hence, the diagonal loading term is the missing ingredient that takes the standard RLS adaptive filtering algorithm from being simply universal to attaining the min-max optimal performance [13]. When applied to any bounded and arbitrary sequence, this universal recursive algorithm yields the min-max optimal performance bound

for any  $N$  as

$$\frac{1}{n} \sum_{n=1}^N (x[n] - \vec{h}_{uni}[n]^T \vec{x}[n])^2 \leq \min_{\vec{h}} \frac{1}{n} \sum_{n=1}^N (d[n] - \vec{h}^T \vec{x}[n])^2 + \frac{1}{n} O(p \ln N). \quad (11.92)$$

This is min-max optimal, in that no other approach can achieve a lower “regret” than the  $\frac{1}{n} O(p \ln N)$  term above [14].

### 1.11.3.9 Universality with respect to classes that vary in space: nonlinear classes/piecewise in space

Linear AR, MA, or ARMA models discussed in the previous sections are extensively used in signal processing due to their tractability and adequate accuracy in modeling [9]. Recently, nonlinear models and those based on piecewise linear and locally linear approximations have gained significant attention as they capture the salient characteristics of many physical phenomena. Nonlinear parametric estimation methods, for example, Volterra filters [8] have proven attractive for a number of applications. By removing structural constraints on linearity, nonlinear models are perhaps more appropriate for a variety of data exhibiting saturation effects, threshold phenomena or other nonlinear behavior.

Piecewise linear modeling can be viewed as a natural extension to linear modeling, in which the space spanned by past observations is partitioned into a union of disjoint regions over each of which an affine model is fitted. In each region, a linear model can be estimated, and as the number of regions grows, the piecewise linear model can better approximate any smoothly varying nonlinear estimator. As an example to a piecewise linear estimator, suppose the space of past observations  $\vec{x}[n] \in R^p$  is partitioned into  $k$  disjoint regions  $R^p = \bigcup_{k=1}^K V_k$ . Based on this partitioning, the observations can be divided into  $k$  disjoint sets, where  $k$  different normal equations are written as

$$\vec{R}_k = \sum_{n=1}^N \vec{x}[n] \vec{x}[n]^T I_k(\vec{x}[n]), \quad (11.93)$$

$$\vec{p}_k = \sum_{n=1}^N d[n] \vec{x}[n]^T I_k(\vec{x}[n]), \quad (11.94)$$

and  $I_k(\vec{x}[n])$  is the indicator function of the  $k$ th region, i.e.,  $I_k(\vec{x}[n]) = 1$  if  $\vec{x}[n] \in V_k$ , for each region. This partitioning of the observations yields a linear estimator,

$$\vec{h}_k = \hat{R}_k^{-1} \hat{p}_k, \quad (11.95)$$

$k = 1, \dots, k$ , at each region, yielding a piecewise linear model. A similar formulation is possible when the data arrives sequentially, however, in that case, the AR parameters are estimated sequentially using time dependent normal equations. As an example, for sequential processing, we can run  $k$  different LMS algorithms, one for each region, to get an adaptive piecewise linear model trained as

$$\vec{h}_k[n+1] = \vec{h}_k[n] + \mu e_k[n] \vec{x}[n] I_k(\vec{x}[n]), \quad (11.96)$$

where  $e_k[n] = d[n] - \vec{h}_k[n]^T \vec{x}[n]$ . These types of piecewise linear models have been referred to in the signal processing literature as “nonlinear autoregressive models” and in the signal processing and statistics literature as “self-exciting threshold auto regressive models,” and have been used in modeling a wide range of data in fields ranging from population biology to econometrics to glottal flow in voiced speech [15].

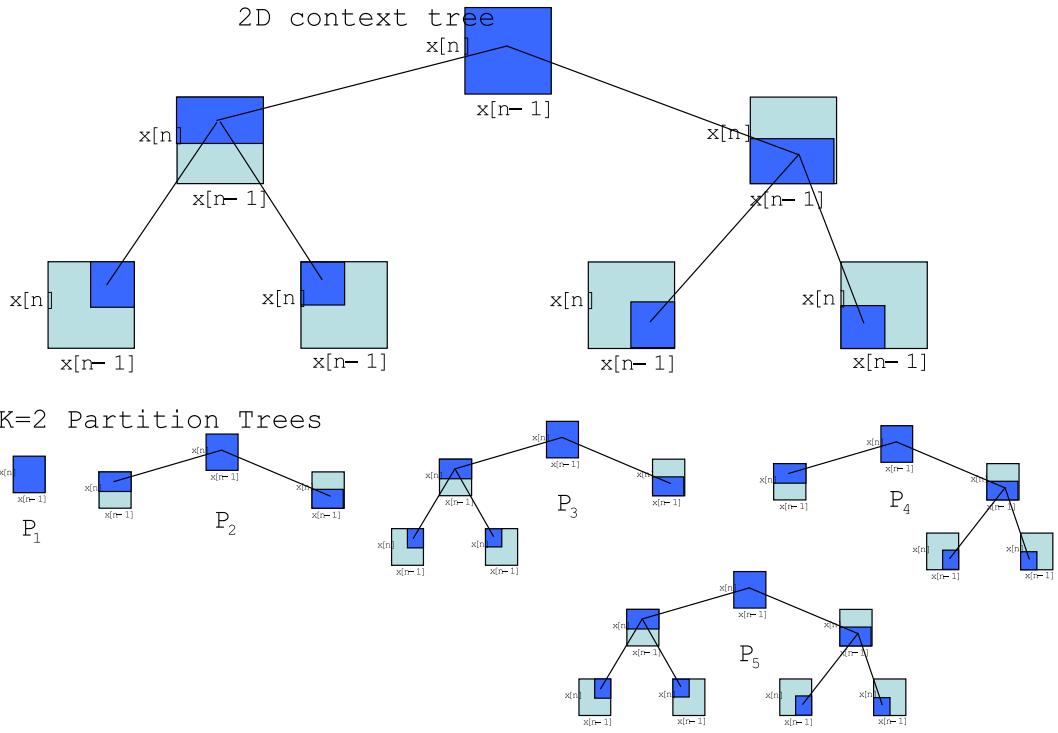

To fully exploit the potential modeling power of piecewise linear estimators, we need to be cautious while selecting the number of regions and boundaries of these regions. Piecewise linear models can approximate a wide class of nonlinear models, which satisfy certain regularity conditions. As the number of regions increases, we point out that the normal equations are calculated using a finite number of observations assigned to each region, which on a per-region basis, necessarily decreases with the number of regions. Hence, over fitting may occur if there are not enough observations assigned to a particular region. Clearly, how the boundaries are selected also affects the effectiveness of the piecewise linear models and how the observations are assigned to particular regions. These design considerations are especially severe in sequential processing, where the observations can only accumulate in time and available data is sparse in the initial phase of the adaptation.

One solution to avoid possible over fitting is to include the boundaries of regions as design parameters along with the corresponding AR parameters. Along these lines, recently, context tree based methods have been used to compactly represent a doubly exponential number of partitions of the space of past observations and provide an elegant way to design the partition of the past observations together with the AR parameters.

An example context tree is given in Figure 11.10 which partitions the space of past observations, where the depth of this context tree is 2, i.e.,  $K = 2$  [16]. For a context tree of depth  $K = 2$ , we have four leaves, where each leaf is assigned to a region of the space of past observations. Subsequently, each node on the context tree is assigned to a region that is the union of regions assigned to its children nodes. Using this context tree, we can define different partitions of the space of past observations as the union of regions assigned to nodes and the leaves. A context tree of depth can define a doubly exponential number of different partitions, e.g., in Figure 11.10, we present five different partitions of the space constructed by the context of depth  $K = 2$ . We represent a partition of the space of past observations as  $P_k = \{V_{k,1}, \dots, V_{k,K_k}\}$ , where  $\mathbf{U}_{j=1}^{K_k} V_{k,j}$  and each  $V_{k,j}$  assigned to a node on the context tree. Each of these partitions can be used to construct a piecewise linear model since they define complete partitions of the space of past observations. Some of the partitions are coarser and require fewer data samples to accurately calculate their linear estimators, while, as an example, the partition corresponding to the leaves has the finest partitioning and requires substantially more data for training. However, if there is sufficient data, then the finest partition naturally achieves the best modeling accuracy.

By using the context tree weighting method, we can construct a sequential piecewise AR model that hypothetically constructs all the piecewise linear estimators corresponding to all of these different partitions. This context tree based estimator achieves the performance of the best piecewise region with the corresponding sequential estimated parameters in each node as

$$\sum_{n=1}^N (x[n] - \vec{h}_{ctw}^T[n] \vec{x}[n])^2 \leq \min_k \left\{ \sum_{n=1}^N (x[n] - \vec{h}_{P_k}^T[t] \vec{x}[n])^2 + C(P_k) \right\}, \quad (11.97)$$

**FIGURE 11.10**

A context tree of depth  $K = 2$ , which has  $K = 4$  leaves and 3 inner nodes. This tree can represent five different partitions,  $P_1, \dots, P_5$ , where each partition defines a different piecewise linear estimator.

where  $C(P_k)$  is a certain constant that depends on the partition  $P_k$ ,  $\vec{h}_{P_k}[n]$  are the sequentially estimated AR parameters by the piecewise estimator assigned to the  $P_k$  partition. As an example, if the LMS algorithms are used in each node to train the corresponding linear models in different regions, then we have  $\vec{h}_{P_k}[n] = \vec{h}_{V_{k,j}}[n]$  if  $\vec{x}[n] \in V_{k,j}$ , and

$$\vec{h}_{V_{k,j}}[n+1] = \vec{h}_{V_{k,j}}[n] + \mu e_{V_{k,j}}[n] \vec{x}[n] I_{V_{k,j}}(\vec{x}[n]). \quad (11.98)$$

We can use different adaptation methods, e.g., the RLS algorithm instead of the LMS algorithm, in each node or region such that only the update equation should be changed accordingly. This implies that the context tree algorithm can uniformly achieve the performance of the best partition that can be represented on the context tree for any bounded deterministic signal, where the computational complexity of this algorithm is only in the order of the depth of the context tree.

### 1.11.3.10 Universality with respect to classes that vary in time

For non-stationary data models or time varying environments, the best choice of an adaptive estimator as well as the structure of this best estimator may change over time. As an example, different order AR models are needed to accurately model voiced and unvoiced time segments of a speech signal [3]. While RLS algorithm is known to converge faster than the LMS algorithm, since it minimizes a true least square error criterion, the LMS algorithm is known to better track certain non-stationary data [8]. In classical adaptive filtering, this kind of time variation is usually overcome by incorporating windowing or weighting by defining appropriate cost functions as done in the previous sections.

Recently, the universal model combination approaches gave rise to a host of model combination methods, where several different sequential estimation methods are combined in order to outperform the best in the combination [12]. In this sense, instead of using windowing or weighting, the best of choice of algorithms are intrinsically selected by the underlying data based on the performance so far. For example, by using a combination of adaptive algorithms that are fast tracking along with others that have superior steady state mean square error performance, one can strike a balance and achieve the tracking performance of the fast-converging adaptive filter, while maintaining the superior steady state performance of the slower, more precise adaptive filter counterpart.

Hence, rather than pushing the time variation into a known statistical model or adaptation, one can try to exploit the time varying nature of the best choice of algorithm for any given realization. As an example, given the batch data we can partition the observations in time into contiguous segments

$$\{\vec{x}[1], \dots, \vec{x}[n_1 - 1]\} \{\vec{x}[n_1], \dots, \vec{x}[n_2 - 1]\} \dots \{\vec{x}[n_k], \dots, \vec{x}[N]\} \quad (11.99)$$

and construct independent normal equations using

$$\hat{R}_k = \sum_{n=n_{k-1}+1}^{n_k} \vec{x}[n] \vec{x}[n]^T, \quad (11.100)$$

$$\hat{p}_k = \sum_{n=n_{k-1}+1}^{n_k} x[n] \vec{x}[n], \quad (11.101)$$

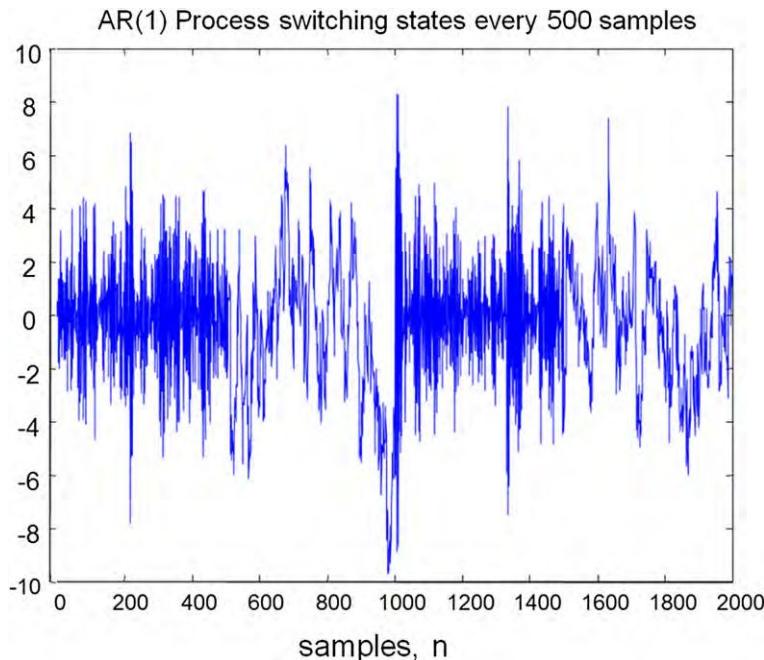

where  $n_0 = 0$ . This yields  $K$  independent AR models one for each contiguous segment as

$$\vec{h}_k = \hat{R}_k^{-1} \hat{p}_k, \quad (11.102)$$

$$\vec{h}[n] = \vec{h}_k, \quad n_{k-1} + 1 \leq n \leq n_k. \quad (11.103)$$

Since each normal equation only depends on the observations belonging to a specific segment, this adaptive processing can readily track variations in time. However, the best partition, i.e., how to optimally divide the observations in time can only be chosen after observing the whole data. Hence, we cannot construct a sequential version of such optimization and are forced to resort to windowing or weighting to emulate such piecewise partition in time.

However, inspired by the universal source coding methods, rather than trying to find the best partition (possible best switching points) or the best number of transitions, we can construct a sequential adaptive algorithm that simply achieves the performance of the best partition directly and simultaneously for all

**FIGURE 11.11**

A time-varying AR(1) model used as input to the predictor that permits switching among different linear predictors in time.

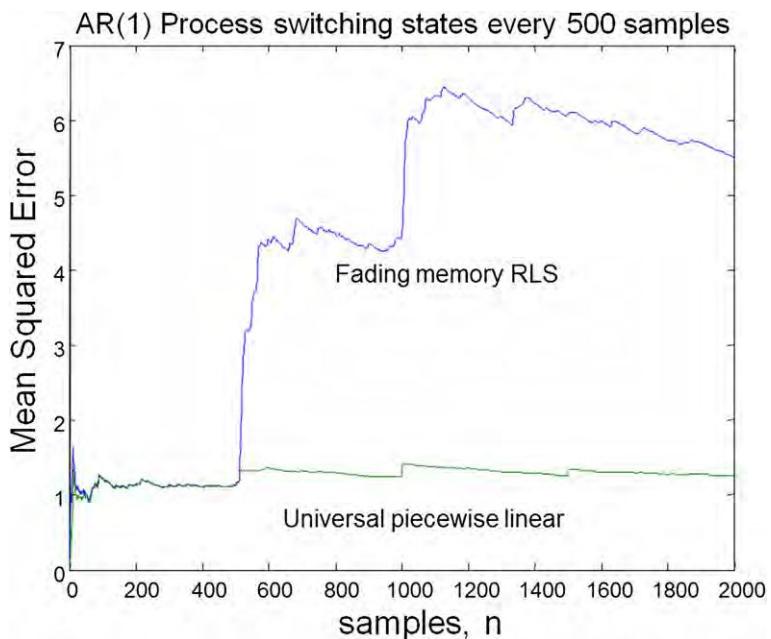

different partitions and for any possible observation sequence. This switching approach has been successfully applied by a number of researchers in a variety of problems, including tracking the best among a fixed class of algorithms as well as tracking the best from parametrically-continuous classes of algorithms [13]. By using transition diagrams, we can construct sequential algorithms that asymptotically achieve the performance of the best switching algorithm, i.e.,

$$\sum_{n=1}^N (x[n] - \vec{h}_{ctw}^T[n] \vec{x}[n])^2 \leq \min_{n_1, \dots, n_K, \vec{h}_1, \dots, \vec{h}_K} \left\{ \sum_{k=0}^K \sum_{n=n_k+1}^{n_k} (x[n] - \vec{h}_k^T \vec{x}[n])^2 + L(K) \right\} \quad (11.104)$$

tuned to the underlying sequence of observations without any stochastic assumptions, where  $L(K)$  is a constant that only depends on the number of contiguous segments.

The performance of a universal linear predictor that switches in time is demonstrated with the following example.

In this example, we are tracking a process similar to a speech sample such that the state of the process switches states abruptly every 500 samples, as shown in Figure 11.11. The state of the process at each segment is represented by an AR model driven by a Gaussian noise [8]. Figure 11.12 shows the mean

**FIGURE 11.12**

Mean square prediction error exhibited by (i) a fading memory RLS linear predictor and (ii) the universal piecewise constant (in time) linear predictor.

square error that results when we attempt to track the process using a fading memory RLS algorithm versus that obtained using a universal piecewise linear algorithm.

It can be seen that the universal piecewise linear algorithm recovers from the state transitions much more quickly, since it competes against the best switching pattern, while the fading memory RLS algorithm cannot recover in the short-data regime between transitions. Therefore, in such a situation, a universal piecewise linear model gives superior performance relative to the standard single filter model.

### 1.12.1 Introduction

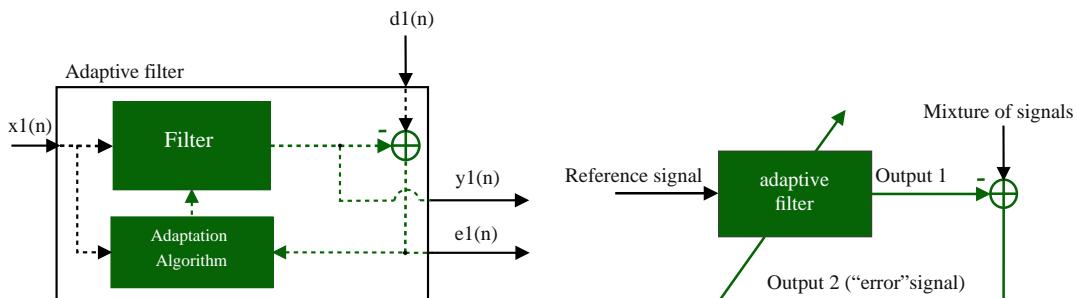

Adaptive filters are employed in situations in which the environment is constantly changing, so that a fixed system would not have adequate performance. As they are usually applied in real-time applications, they must be based on algorithms that require a small number of computations per input sample.

These algorithms can be understood in two complementary ways. The most straightforward way follows directly from their name: an adaptive filter uses information from the environment and from the very signal it is processing to change itself, so as to optimally perform its task. The information from the environment may be sensed in real time (in the form of a so-called desired signal), or may be provided *a priori*, in the form of previous knowledge of the statistical properties of the input signal (as in blind equalization).

On the other hand, we can think of an adaptive filter also as an algorithm to separate a mixture of two signals. The filter must have some information about the signals to be able to separate them; usually this is given in the form of a reference signal, related to only one of the two terms in the mixture. The filter has then two outputs, corresponding to each signal in the mixture (see Figure 12.1). As a byproduct of separating the signals, the reference signal is processed in useful ways. This way of viewing an adaptive filter is very useful, particularly when one is learning the subject.

In the following sections we give an introduction to adaptive filters, covering from basic principles to the most important recent developments. Since the adaptive literature is vast, and the topic is still an active area of research, we were not able to treat all interesting topics. Along the text, we reference important textbooks, classic papers, and the most promising recent literature. Among the many very good textbooks on the subject, four of the most popular are [1–4].

We start with an application example, in the next section. In it, we show how an adaptive filter is applied to cancel acoustic echo in hands-free telephony. Along the text we return frequently to this example, to illustrate new concepts and methods. The example is completed by an overview of how adaptive filters work, in which we use only deterministic arguments and concepts from basic linear systems theory, in Section 1.12.1.2. This overview shows many of the compromises that arise in adaptive filter design, without the more complicated math. Section 1.12.1.3 gives a small glimpse of the wide variety of applications of adaptive filters, describing a few other examples. Of course, in order to fully understand the behavior of adaptive filters, one must use estimation theory and stochastic processes,

**FIGURE 12.1**

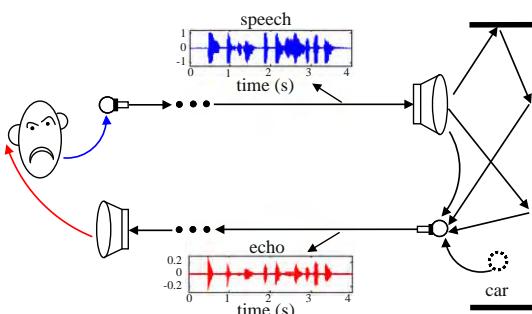

Inputs and outputs of an adaptive filter. Left: detailed diagram showing inputs, outputs and internal variable. Right: simplified diagram.

which is the subject of Sections 1.12.2 and 1.12.3. The remaining sections are devoted to extensions to the basic algorithms and recent results.

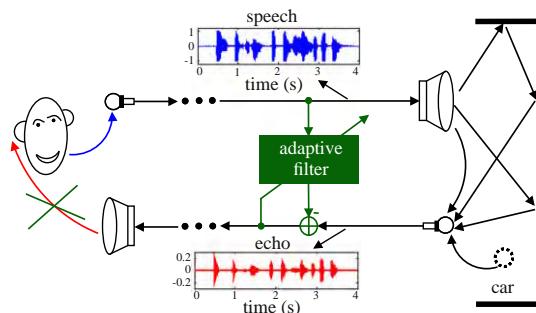

Adaptive filter theory brings together results from several fields: signal processing, matrix analysis, control and systems theory, stochastic processes, and optimization. We tried to provide short reviews for most of the necessary material in separate links (“boxes”), that the reader may follow if needed.

### 1.12.1.1 Motivation—acoustic echo cancellation

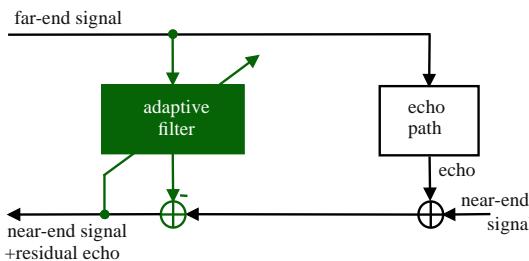

Suppose that you are talking with a person who uses a hands-free telephone inside a car. Let us assume that the telephone does not have any acoustic echo canceler. In this case, the sound of your voice will reach the loudspeaker, propagate inside the car, and suffer reflections every time it encounters the walls of the car. Part of the sound can be absorbed by the walls, but part of it is reflected, resulting in an echo signal. This signal is fed back to the microphone and you will hear your own voice with delay and attenuation, as shown in Figure 12.2.

**FIGURE 12.2**

Echo in hands-free telephony. Click [speech.wav](#) to listen to a speech signal and [echo.wav](#) to listen to the corresponding echo signal.

**FIGURE 12.3**

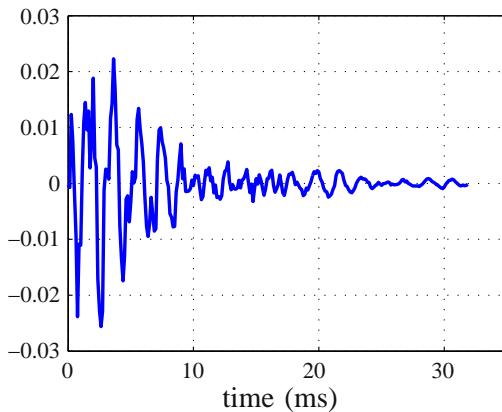

Acoustic echo cancellation using an adaptive filter.

**FIGURE 12.4**

General echo canceler configuration.

The echo signal depends on the acoustic characteristics of each car and also on the location of the loudspeaker and microphone. Furthermore, the acoustic characteristics can change during a phone call, since the driver may open or close a window, for example. In order to follow the variations of the environment, the acoustic echo must be canceled by an adaptive filter, which performs on-line updating of its parameters through an algorithm. Figure 12.3 shows the insertion of an adaptive filter in the system of Figure 12.2 to cancel the echo signal. In this configuration, the adaptive filter must identify the echo path and provide at its output an estimate of the echo signal. Thus, a synthesized version of the echo is subtracted from the signal picked up by the car microphone. In an ideal scenario, the resulting signal will be free of echo and will contain only the signal of interest. The general set-up of an echo canceler is shown in Figure 12.4. The *near-end* signal (near with respect to the echo canceler) may be simply noise when the person inside the car is in silence, as considered in Figures 12.2 and 12.3, or it can be a signal of interest, that is, the voice of the user in the car.

You most likely have already heard the output of an adaptive echo canceler. However, you probably did not pay attention to the initial period, when you can hear the adaptive filter learning the echo impulse response, if you listen carefully. We illustrate this through a simulation, using a measured impulse response of 256 samples (sampled at 8 kHz), and an echo signal produced from a recorded

**FIGURE 12.5**

Measured impulse response (256 samples).

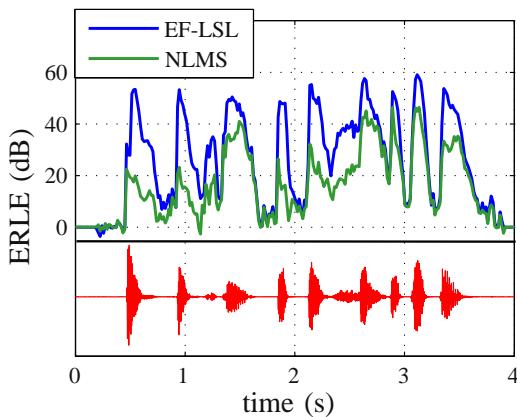

voice signal. The measured impulse response is shown in Figure 12.5. In the first example, the near-end signal is low-power noise (more specifically, white Gaussian noise with zero mean and variance  $\sigma^2 = 10^{-4}$ ). Listen to [e\\_nlms.wav](#), and pay attention to the beginning. You will notice that the voice (the echo) is fading away, while the adaptive filter is learning the echo impulse response. This file is the output of an echo canceler adapted using the *normalized least-mean squares algorithm (NLMS)*, which is described in Section 1.12.3.2.

Listen now to [e\\_lsl.wav](#) in this case the filter was adapted using the modified *error-feedback least-squares lattice algorithm (EF-LSL)* [5], which is a low-cost and stable version of the *recursive least-squares algorithm (RLS)* described in Section 1.12.3.3. Now you will notice that the echo fades away much faster. This fast convergence is characteristic of the EF-LSL algorithm, and is of course a very desirable property. On the other hand, the NLMS algorithm is simpler to implement and more robust against imperfections in the implementation. An adaptive filtering algorithm must satisfy several requirements, such as convergence rate, tracking capability, noise rejection, computational complexity, and robustness. These requirements are conflicting, so that there is no best algorithm that will outperform all the others in every situation. The many algorithms available in the literature are different compromises between these requirements [1–3].

Figure 12.6 shows 4 s of the echo signal, prior to cancellation (bottom) and a measure of the quality of echo cancellation, the so-called *echo return loss enhancement (ERLE)* (top). The ERLE is defined as the ratio

$$\text{ERLE} = \frac{\text{Power of original echo}}{\text{Power of residual echo}}.$$

The higher the ERLE, the better the performance of the canceler. The ERLE drops when the original echo is small (there is nothing to cancel!), and increases again when the echo is strong. The figure shows that EF-LSL performs better than NLMS (but at a higher computational cost).

**FIGURE 12.6**

Echo return loss enhancement for NLMS ( $\tilde{\mu} = 0.5$ ,  $\delta = 10^{-5}$ ,  $M = 256$ ) and EF-LSL ( $\lambda = 0.999$ ,  $\delta = 10^{-5}$ ) algorithms. Bottom trace: echo signal prior to cancellation. The meaning of the several parameters is explained in Sections 1.12.3.1, 1.12.3.2, and 1.12.3.3.

Assuming now that the near-end signal is another recorded voice signal (Click [DT\\_echo.wav](#) to listen to this signal), we applied again the EF-LSL algorithm to cancel the echo. This case simulates a person talking inside the car. Since the speech of this person is not correlated to the far-end signal, the output of the adaptive filter converges again to an estimate of the echo signal. Thus, a synthesized version of the echo is subtracted from the signal picked up by the car microphone and the resulting signal converges to the speech of the person inside the car. This result can be verified by listening to the file [e\\_1s1DT.wav](#).

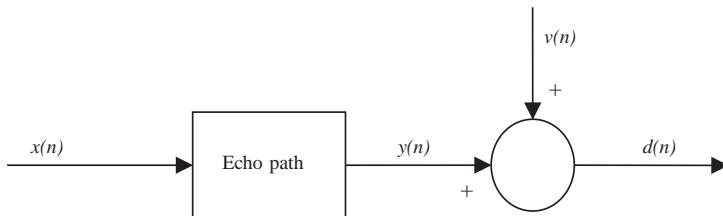

This is a typical example of use of an adaptive filter. The environment (the echo impulse response) changes constantly, requiring a constant re-tuning of the canceling filter. Although the echo itself is not known, we have access to a reference signal (the clean speech of the far-end user). This is the signal that is processed to obtain an estimate of the echo. Finally, the signal captured by the near-end microphone (the so-called *desired* signal) is a mixture of two signals: the echo, plus the near-end speech (or ambient noise, when the near-end user is silent). The task of the adaptive filter can be seen as to separate these two signals.

We should mention that the name desired signal is somewhat misleading, although widespread in the literature. Usually we are interested in separating the “desired” signal into two parts, one of which is of no interest at all!

We proceed now to show how an algorithm can perform this task, modeling all signals as periodic to simplify the arguments.

### 1.12.1.2 A quick tour of adaptive filtering

Before embarking in a detailed explanation of adaptive filtering and its theory, it is a good idea to present the main ideas in a simple setting, to help the reader create intuition. In this section, we introduce the least-mean squares (LMS) algorithm and some of its properties using only deterministic arguments and basic tools from linear systems theory.

**FIGURE 12.7**

A model for the echo.

#### 1.12.1.2.1 Posing the problem

Consider again the echo-cancellation problem, seen in the previous section (see Figure 12.7). Let  $y(n)$  represent the echo,  $v(n)$  represent the voice of the near-end user, and  $x(n)$  the voice of the far-end user (the reference).  $d(n)$  represents the signal that would be received by the far-end user without an echo canceler (the mixture, or desired signal).

The echo path represents the changes that the far-end signal suffers when it goes through the digital-to-analog (D/A) converter, the loudspeaker, the air path between the loudspeaker and the microphone (including all reflections), the microphone itself and its amplifier, and the analog-to-digital (A/D) converter. The microphone signal  $d(n)$  will always be a mixture of the echo  $y(n)$  and an unrelated signal  $v(n)$ , which is composed of the near-end speech plus noise. Our goal is to remove  $y(n)$  from  $d(n)$ . The challenge is that we have no means to measure  $y(n)$  directly, and the echo path is constantly changing.

#### 1.12.1.2.2 Measuring how far we are from the solution

How is the problem solved, then? Since we cannot measure  $y(n)$ , the solution is to estimate it from the measurable signals  $x(n)$  and  $d(n)$ . This is done as follows: imagine for now that all signals are periodic, so they can be decomposed as Fourier series

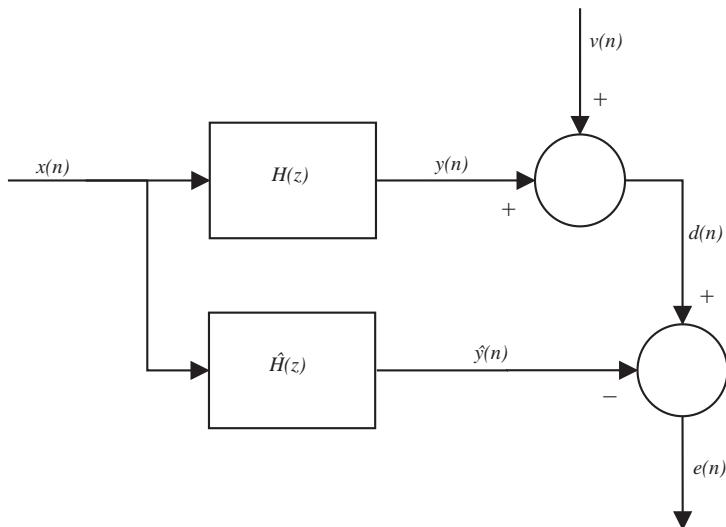

$$x(n) = \sum_{k=1}^{K_0} A_k \cos(k\omega_0 n + \varphi_k), \quad v(n) = \sum_{\ell=1}^{K_1} B_\ell \cos(\ell\omega_1 n + \theta_\ell), \quad (12.1)$$

for certain amplitudes  $A_k$  and  $B_\ell$ , phases  $\varphi_k$  and  $\theta_\ell$ , and frequencies  $\omega_0$  and  $\omega_1$ . The highest frequencies appearing in  $x(n)$  and  $v(n)$  must satisfy  $K_0\omega_0 < \pi$ ,  $K_1\omega_1 < \pi$ , since we are dealing with sampled signals (Nyquist criterion). We assume for now that the echo path is fixed (not changing), and can be modeled by an unknown linear transfer function  $H(z)$ . In this case,  $y(n)$  would also be a periodic sequence with fundamental frequency  $\omega_0$ ,

$$y(n) = \sum_{k=1}^{K_0} C_k \cos(k\omega_0 n + \psi_k),$$

with  $C_k e^{j\psi_k} = H(e^{jk\omega_0}) A_k e^{j\varphi_k}$ . The signal picked by the microphone is then

$$d(n) = y(n) + v(n) = \sum_{k=1}^{K_0} C_k \cos(k\omega_0 n + \psi_k) + \sum_{\ell=1}^{K_1} B_\ell \cos(\ell\omega_1 n + \theta_\ell).$$

**FIGURE 12.8**

Echo canceler.

Since we know  $x(n)$ , if we had a good approximation  $\hat{H}(z)$  to  $H(z)$ , we could easily obtain an approximation  $\hat{y}(n)$  to  $y(n)$  and subtract it from  $d(n)$ , as in Figure 12.8.

How could we find  $\hat{H}(z)$  in real time? Recall that only  $d(n)$ ,  $x(n)$ ,  $\hat{y}(n)$ , and  $e(n)$  can be observed. For example, how could we know that we have the exact filter, that is, that  $\hat{H}(z) = H(z)$ , by looking only at these signals? To answer this question, take a closer look at  $e(n)$ . Let the output of  $\hat{H}(z)$  be

$$\begin{aligned}
 \hat{y}(n) &= \sum_{k=1}^{k_0} \hat{C}_k \cos(k\omega_0 n + \hat{\psi}_k), \quad \text{and thus} \\
 e(n) &= d(n) - \hat{y}(n) = y(n) - \hat{y}(n) + v(n) \\
 &= \sum_{k=1}^{K_0} [C_k \cos(k\omega_0 n + \psi_k) - \hat{C}_k \cos(k\omega_0 n + \hat{\psi}_k)] \\
 &\quad + \sum_{\ell=1}^{K_1} B_\ell \cos(\ell\omega_1 n + \theta_\ell) \\
 &= \sum_{k=1}^{K_0} \tilde{C}_k \cos(k\omega_0 n + \tilde{\psi}_k) + \sum_{\ell=1}^{K_1} B_\ell \cos(\ell\omega_1 n + \theta_\ell),
 \end{aligned} \tag{12.2}$$

where  $\tilde{C}_k e^{j\tilde{\psi}_k} = C_k e^{j\psi_k} - \hat{C}_k e^{j\hat{\psi}_k}$ ,  $k = 1, \dots, K_0$ .

Assuming that the cosines in  $x(n)$  and  $v(n)$  have no frequencies in common, the simplest approach is to measure the average power of  $e(n)$ . Indeed, if all frequencies  $k\omega_0$  and  $\ell\omega_1$  appearing in  $e(n)$  are different from one another, then the average power of  $e(n)$  is

$$P = \sum_{k=1}^{K_0} \frac{\tilde{C}_k^2}{2} + \sum_{\ell=1}^{K_1} \frac{B_\ell^2}{2}. \quad (12.3)$$

If  $\hat{y}(n) = y(n)$ , then  $P$  is at its minimum,

$$P_o = \min_{\hat{H}(z)} P = \sum_{\ell=1}^{K_1} \frac{B_\ell^2}{2},$$

which is the average power of  $v(n)$ . In this case,  $e(n)$  is at its optimum:  $e(n) = e_o(n) = v(n)$ , and the echo is completely canceled.

It is important to see that this works because the two signals we want to separate,  $y(n)$  and  $v(n)$ , are *uncorrelated*, that is, they are such that

$$\lim_{N \rightarrow \infty} \frac{1}{N+1} \sum_{-N/2}^{N/2} y(n)v(n) = \lim_{N \rightarrow \infty} \frac{1}{N+1} \sum_{-N/2}^{N/2} y(n)e_o(n) = 0. \quad (12.4)$$

This property is known as the *orthogonality condition*. A form of orthogonality condition will appear in general whenever one tries to minimize a quadratic function, as is the case here. This is discussed in more detail in Section 1.12.2.

The average power  $P$  could then be used as a measure of how good is our approximation  $\hat{y}(n)$ . The important point is that it is very easy to find a good approximation to  $P$ . It suffices to low-pass filter  $e^2(n)$ , for example,

$$\hat{P}(n) = \frac{1}{N} \sum_{k=0}^{N-1} e^2(n-k) \quad (12.5)$$

is a good approximation if the window length  $N$  is large enough.

The adaptive filtering problem then becomes an optimization problem, with the particularity that the cost function that is being minimized is not known exactly, but only through an approximation, as in (12.5). In the following sections, we discuss in detail the consequences of this fact.

It is also important to remark that the average error power is not the only possible choice for cost function. Although it is the most popular choice for a number of reasons, in some applications other choices are more adequate. Even posing the adaptive filtering problem as an optimization problem is not the only alternative, as shown by recent methods based on projections on convex sets [6].

### 1.12.1.2.3 Choosing a structure for the filter

Our approximation  $\hat{y}(n)$  will be built by minimizing the estimated average error power (12.5) as a function of the echo path model  $\hat{H}(z)$ , that is, our estimated echo path will be the solution of

$$\hat{H}_o(z) = \arg \min_{\hat{H}(z)} \hat{P}(n). \quad (12.6)$$

Keep in mind that we are looking for a real-time way of solving (12.6), since  $\widehat{P}(n)$  can only be obtained by measuring  $e(n)$  for a certain amount of time. We must then be able to implement the current approximation  $\widehat{H}(z)$ , so that  $\hat{y}(n)$  and  $e(n)$  may be computed.

This will impose practical restrictions on the kind of function that  $\widehat{H}(z)$  may be: since memory and processing power are limited, we must choose beforehand a structure for  $\widehat{H}(z)$ . Memory and processing power will impose a constraint on the maximum order the filter may have. In addition, in order to write the code for the filter, we must decide if it will depend on past outputs (IIR filters) or only on past inputs (FIR filters). These choices must be made based on some knowledge of the kind of echo path that our system is likely to encounter.

To explain how these choices can be made, let us simplify the problem a little more and restrict the far-end signal  $x(n)$  to a simple sinusoid (i.e., assume that  $K_0 = 1$ ). In this case,

$$y(n) = C_1 \cos(\omega_0 n + \varphi_1),$$

with  $C_1 e^{j\psi_1} = H(e^{j\omega_0}) A_1 e^{j\varphi_1}$ . Therefore,  $\widehat{H}(z)$  must satisfy

$$\left[ \widehat{H}(e^{j\omega}) = H(e^{j\omega}) \right]_{\omega=\omega_0} \quad (12.7)$$

only for  $\omega = \omega_0$ —the value of  $\widehat{H}(e^{j\omega})$  for other frequencies is irrelevant, since the input  $x(n)$  has only one frequency. Expanding (12.7), we obtain

$$\operatorname{Re}\{\widehat{H}(e^{j\omega_0})\} = \operatorname{Re}\{H(e^{j\omega_0})\}, \quad \operatorname{Im}\{\widehat{H}(e^{j\omega_0})\} = \operatorname{Im}\{H(e^{j\omega_0})\}. \quad (12.8)$$

The optimum  $\widehat{H}(z)$  is defined through two conditions. Therefore an FIR filter with just two coefficients would be able to satisfy both conditions for any value of  $H(e^{j\omega_0})$ , so we could define

$$\widehat{H}(z) = w_0 + w_1 z^{-1},$$

and the values of  $w_0$  and  $w_1$  would be chosen to solve (12.6). Note that the argument generalizes for  $K_0 > 1$ : in general, if  $x(n)$  has  $K_0$  harmonics, we could choose  $\widehat{H}(z)$  as an FIR filter with length  $2K_0$ , two coefficients per input harmonic.

This choice is usually not so simple: in practice, we would not know  $K_0$ , and in the presence of noise (as we shall see later), a filter with fewer coefficients might give better performance, even though it would not completely cancel the echo. The structure of the filter also affects the dynamic behavior of the adaptive filter, so simply looking at equations such as (12.7) does not tell the whole story. Choosing the structure for  $\widehat{H}(z)$  is one of the most difficult steps in adaptive filter design. In general, the designer must test different options, initially perhaps using recorded signals, but ultimately building a prototype and performing some tests.

#### 1.12.1.2.4 Searching for the solution

Returning to our problem, assume then that we have decided that an FIR filter with length  $M$  is adequate to model the echo path, that is,

$$\widehat{H}(z) = \sum_{k=0}^{M-1} w_k z^{-k}.$$

Our minimization problem (12.6) now reduces to finding the coefficients  $w_0, \dots, w_{M-1}$  that solve

$$\min_{w_0, \dots, w_{M-1}} \widehat{P}(n). \quad (12.9)$$

Since  $\widehat{P}(n)$  must be computed from measurements, we must use an iterative method to solve (12.9). Many algorithms could be used, as long as they depend only on measurable quantities ( $x(n)$ ,  $d(n)$ ,  $\hat{y}(n)$ , and  $e(n)$ ). We will use the steepest descent algorithm (also known as gradient algorithm) as an example now. Later we show other methods that also could be used. If you are not familiar with the gradient algorithm, see Box 1 for an introduction.

The cost function in (12.9) is

$$\widehat{P}(n) = \frac{1}{N} \sum_{k=0}^{N-1} e^2(n-k) = \frac{1}{N} \sum_{k=0}^{N-1} [d(n-k) - \hat{y}(n-k)]^2.$$

We need to rewrite this equation so that the steepest descent algorithm can be applied. Recall also that now the filter coefficients will change, so define the vectors

$$\mathbf{w}(n) = [w_0(n) \quad w_1(n) \quad \cdots \quad w_{M-1}(n)]^T,$$

and

$$\mathbf{x}(n) = [x(n) \quad x(n-1) \quad \cdots \quad x(n-M+1)]^T,$$

where  $(\cdot)^T$  denotes transposition. At each instant, we have  $\hat{y}(n) = \mathbf{w}^T(n)\mathbf{x}(n)$ , and our cost function becomes

$$\widehat{P}(n) = \frac{1}{N} \sum_{k=0}^{N-1} [d(n-k) - \mathbf{w}^T(n-k)\mathbf{x}(n-k)]^2, \quad (12.10)$$

which depends on  $\mathbf{w}(n), \dots, \mathbf{w}(n-N+1)$ . In order to apply the steepest descent algorithm, let us keep the coefficient vector  $\mathbf{w}(n)$  constant during the evaluation of  $\widehat{P}$ , as follows. Starting from an initial condition  $\mathbf{w}(0)$ , compute for  $n = 0, N, 2N, \dots$  (The notation is explained in Boxes 2 and 6.)

$$\mathbf{w}(n+N) = \mathbf{w}(n) - \alpha \left. \frac{\partial \widehat{P}(n+N-1)}{\partial \mathbf{w}^T} \right|_{\mathbf{w}=\mathbf{w}(n)}, \quad (12.11)$$

where  $\alpha$  is a positive constant, and  $\mathbf{w}(n+N-1) = \mathbf{w}(n+N-2) = \cdots = \mathbf{w}(n)$ . Our cost function now depends on only one  $\mathbf{w}(n)$  (compare with (12.10)):

$$\begin{aligned} \widehat{P}(n+N-1) &= \frac{1}{N} \sum_{k=0}^{N-1} [d(n+N-1-k) - \mathbf{w}^T(n)\mathbf{x}(n+N-1-k)]^2 \\ &= \frac{1}{N} \sum_{k=0}^{N-1} [d(n+k) - \mathbf{w}^T(n)\mathbf{x}(n+k)]^2, \quad n = 0, N, 2N, \dots \end{aligned} \quad (12.12)$$

We now need to evaluate the gradient of  $\widehat{P}$ . Expanding the expression above, we obtain

$$\widehat{P}(n+N-1) = \frac{1}{N} \sum_{k=0}^{N-1} \left[ d(n+k) - \sum_{\ell=0}^{M-1} w_\ell(n)x(n+k-\ell) \right]^2,$$

so

$$\begin{aligned}\frac{\partial \widehat{P}(n - N + 1)}{\partial w_m(n)} &= -\frac{2}{N} \sum_{k=0}^{N-1} [d(n+k) - \mathbf{w}^T(n)\mathbf{x}(n+k)] x(n+k-m) \\ &= -\frac{2}{N} \sum_{k=0}^{N-1} e(n+k)x(n+k-m),\end{aligned}$$

and

$$\frac{\partial \widehat{P}(n - N + 1)}{\partial \mathbf{w}^T} = -\frac{2}{N} \sum_{k=0}^{N-1} e(n+k)\mathbf{x}(n+k), n = 0, N, 2N, \dots \quad (12.13)$$

As we needed, this gradient depends only on measurable quantities,  $e(n+k)$  and  $\mathbf{x}(n+k)$ , for  $k = 0, \dots, N-1$ . Our algorithm for updating the filter coefficients then becomes

$$\mathbf{w}(n+N) = \mathbf{w}(n) + \mu \frac{1}{N} \sum_{k=0}^{N-1} e(n+k)\mathbf{x}(n+k), n = 0, N, 2N, \dots, \quad (12.14)$$

where we introduced the overall step-size  $\mu = 2\alpha$ .

We still must choose  $\mu$  and  $N$ . The choice of  $\mu$  is more complicated and will be treated in Section 1.12.1.2.5. The value usually employed for  $N$  may be a surprise: in almost all cases, one uses  $N = 1$ , resulting in the so-called *least-mean squares* (LMS) algorithm

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \mu e(n)\mathbf{x}(n), \quad (12.15)$$

proposed initially by Widrow and Hoff in 1960 [7] (Widrow [8] describes the history of the creation of the LMS algorithm). The question is, how can this work, if no average is being used for estimating the error power? An intuitive answer is not complicated: assume that  $\mu$  is a very small number so that  $\mu = \mu_0/N$  for a large  $N$ . In this case, we can approximate  $e(n+k)$  from (12.15) as follows.

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \frac{\mu_0}{N} e(n)\mathbf{x}(n) \approx \mathbf{w}(n), \quad \text{if } N \text{ is large.}$$

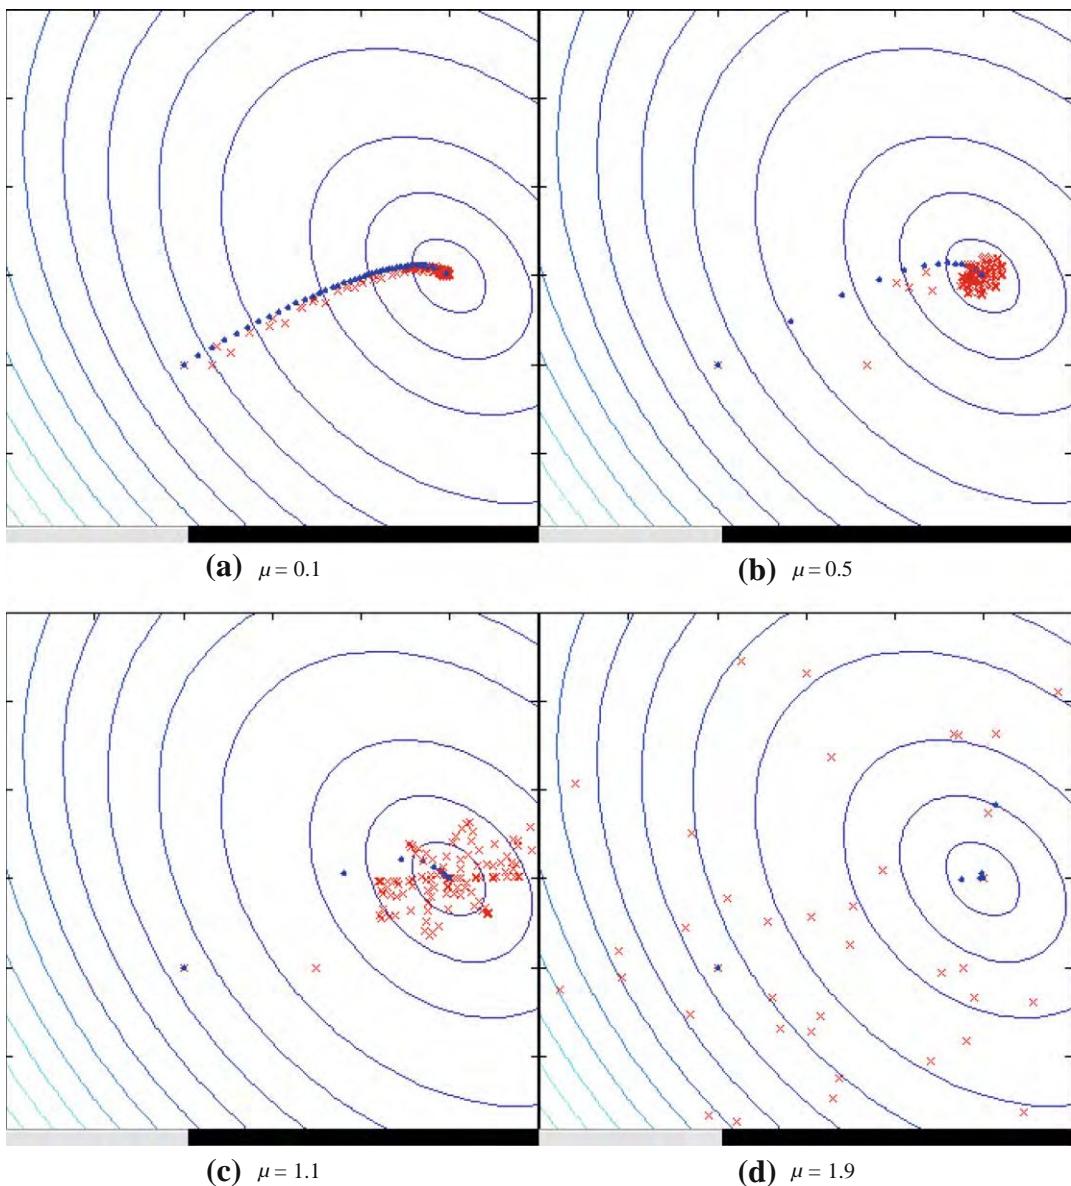

Since  $\mathbf{w}(n+1) \approx \mathbf{w}(n)$ , we have  $e(n+1) = d(n+1) - \mathbf{w}^T(n+1)\mathbf{x}(n+1) \approx d(n+1) - \mathbf{w}^T(n)\mathbf{x}(n+1)$ . Therefore, we could approximate

$$e(n+k) \approx d(n+k) - \mathbf{w}^T(n)\mathbf{x}(n+k), \quad k = 0, \dots, N-1,$$

so  $N$  steps of the LMS recursion (12.15) would result

$$\mathbf{w}(n+N) \approx \mathbf{w}(n) + \frac{\mu_0}{N} \sum_{k=0}^{N-1} [d(n+k) - \mathbf{w}^T(n)\mathbf{x}(n+k)] \mathbf{x}(n+k),$$

just what would be obtained from (12.14). The conclusion is that, although there is no explicit average being taken in the LMS algorithm (12.15), the algorithm in fact computes an implicit, approximate average if the step-size is small. This is exactly what happens, as can be seen in the animations in

**FIGURE 12.9**

LMS algorithm for echo cancelation with sinusoidal input. [Click](#) LMS video files to see animations on your browser.

Figure 12.9. These simulations were prepared with

$$x(n) = \cos(0.4\pi n + \varphi_1), \quad v(n) = 0.2 \cos(0.2\pi n + \theta_1),$$

where  $\varphi_1$  and  $\theta_1$  were chosen randomly in the interval  $[0, 2\pi]$ . Several step-sizes were used. The estimates computed with the LMS algorithm are marked by the crosses (red in the web version). The initial condition is at the left, and the theoretical optimum is at the right end of each figure. In the simulations, the true echo path was modeled by the fixed filter

$$H(z) = 1.5 + 0.5z^{-1}.$$

For comparison, we also plotted the estimates that would be obtained by the gradient algorithm using the exact value of the error power at each instant. These estimates are marked with small dots (blue in the web version).

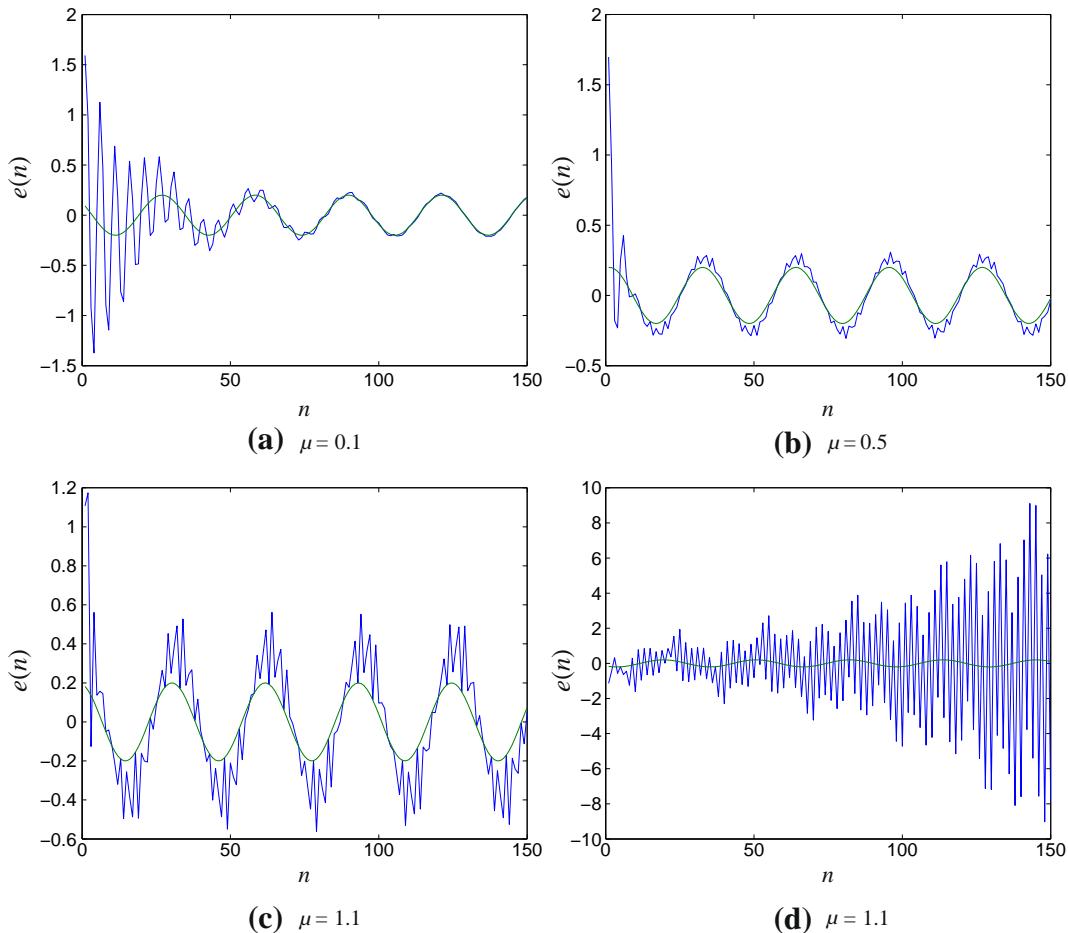

Note that when a small step-size is used, such as  $\mu = 0.1$  in Figure 12.9a, the LMS filter stays close to the dots obtained assuming exact knowledge of the error power. However, as the step-size increases, the LMS estimates move farther away from the dots. Although convergence is faster, the LMS estimates do not reach the optimum and stay there: instead, they hover around the optimum. For larger step-sizes, the LMS estimates can go quite far from the optimum (Figure 12.9b and c). Finally, if the step-size is too large, the algorithm will diverge, that is, the filter coefficients grow without bounds (Figure 12.9d).

#### 1.12.1.2.5 Tradeoff between speed and precision

The animations in Figure 12.9 illustrate an important problem in adaptive filters: even if you could magically choose as initial conditions the exact optimum solutions, the adaptive filter coefficients would not stay there! This happens because the filter does not know the exact value of the cost function it is trying to minimize (in this case, the error power): since  $\hat{P}(n)$  is an approximation, noise (and the near-end signal in our echo cancellation example) would make the estimated gradient non-zero, and the filter would wander away from the optimum solution. This effect keeps the minimum error power obtainable using the adaptive filter always a little higher than the optimum value. The difference between the (theoretical, unattainable without perfect information) optimum and the actual error power is known as *excess mean-square error* (EMSE), and the ratio between the EMSE and the optimum error is known as *misadjustment* (see Eqs. (12.171) and (12.174)).

For small step-sizes the misadjustment is small, since the LMS estimates stay close to the estimates that would be obtained with exact knowledge of the error power. However, a small step-size also means slow convergence. This trade-off exists in all adaptive filter algorithms, and has been an intense topic of research: many algorithms have been proposed to allow faster convergence without increasing the misadjustment. We will see some of them in the next sections.

The misadjustment is central to evaluate the performance of an adaptive filter. In fact, if we want to eliminate the echo from the near-end signal, we would like that after convergence,  $e(n) \approx v(n)$ . This is indeed what happens when the step-size is small (see Figure 12.10a). However, when the step-size is increased, although the algorithm converges more quickly, the performance after convergence is not very good, because of the wandering of the filter weights around the optimum (Figure 12.10b–d—in the last case, for  $\mu = 1.9$ , the algorithm is diverging.).

**FIGURE 12.10**

Compromise between convergence rate and misadjustment in LMS. Plots of  $e(n)x_n$  for several values of  $\mu$ .

We will stop this example here for the moment, and move forward to a description of adaptive filters using probability theory and stochastic processes. We will return to it during discussions of stability and model order selection.

The important message from this section is that an adaptive filter is able to separate two signals in a mixture by minimizing a well-chosen cost function. The minimization must be made iteratively, since the true value of the cost function is not known: only an approximation to it may be computed at each step. When the cost function is quadratic, as in the example shown in this section, the components of the mixture are separated such that they are in some sense orthogonal to each other.

---

**Box 1: Steepest descent algorithm**

---

Given a cost function

$$J(\mathbf{w}) = J(w_0, \dots, w_{M-1}),$$

with  $\mathbf{w} = [w_0, \dots, w_{M-1}]^T$  ( $(\cdot)^T$  denotes transposition), we want to find the minimum of  $J$ , that is, we want to find  $\mathbf{w}_o$  such that

$$\mathbf{w}_o = \arg \min_{\mathbf{w}} J(\mathbf{w}).$$

The solution can be found using the gradient of  $J(\mathbf{w})$ , which is defined by

$$\nabla_{\mathbf{w}} J(\mathbf{w}) = \frac{\partial J}{\partial \mathbf{w}^T} = \begin{bmatrix} \frac{\partial J}{\partial w_0} \\ \frac{\partial J}{\partial w_1} \\ \vdots \\ \frac{\partial J}{\partial w_{M-1}} \end{bmatrix}.$$

See Box 2 for a brief explanation about gradients and Hessians, that is, derivatives of functions of several variables.

The notation  $\partial J / \partial \mathbf{w}^T$  is most convenient when we deal with complex variables, as in Box 6. We use it for real variables for consistency.

Since the gradient always points to the direction in which  $J(\mathbf{w})$  increases most quickly, the steepest descent algorithm searches iteratively for the minimum of  $J(\mathbf{w})$  taking at each iteration a small step in the opposite direction, i.e., towards  $-\nabla_{\mathbf{w}} J(\mathbf{w})$ :

$$\mathbf{w}(n+1) = \mathbf{w}(n) - \frac{\mu}{2} \nabla_{\mathbf{w}} J(\mathbf{w}(n)), \quad (12.16)$$

where  $\mu$  is a step-size, i.e., a constant controlling the speed of the algorithm. As we shall see, this constant should not be too small (or the algorithm will converge too slowly) neither too large (or the recursion will diverge).

As an example, consider the quadratic cost function with  $M = 2$

$$J(\mathbf{w}) = 1 - 2\mathbf{w}^T \mathbf{r} + \mathbf{w}^T \mathbf{R} \mathbf{w}, \quad (12.17)$$

with

$$\mathbf{r} = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad \mathbf{R} = \begin{bmatrix} \frac{4}{3} & -\frac{2}{3} \\ -\frac{2}{3} & 4 \end{bmatrix}. \quad (12.18)$$

The gradient of  $J(\mathbf{w})$  is

$$\nabla_{\mathbf{w}} J(\mathbf{w}) = \frac{\partial J}{\partial \mathbf{w}^T} = -2\mathbf{r} + 2\mathbf{R}\mathbf{w}. \quad (12.19)$$

Of course, for this example we can find the optimum  $\mathbf{w}_o$  by equating the gradient to zero:

$$\nabla_{\mathbf{w}} J(\mathbf{w}_o) = \mathbf{0} \implies \mathbf{R}\mathbf{w}_o = \mathbf{r} \implies \mathbf{w}_o = \mathbf{R}^{-1}\mathbf{r} = \begin{bmatrix} 0.9877 \\ 0.4902 \end{bmatrix}. \quad (12.20)$$

Note that in this case the *Hessian* of  $J(\mathbf{w})$  (the matrix of second derivatives, see Box 2) is simply  $\nabla_{\mathbf{w}}^2 J = 2\mathbf{R}$ . As  $\mathbf{R}$  is symmetric with positive eigenvalues ( $\lambda_1 = 2$  and  $\lambda_2 = \frac{2}{3}$ ), it is positive-definite, and we can conclude that  $\mathbf{w}_o$  is indeed a minimum of  $J(\mathbf{w})$  (See Boxes 2 and 3. Box 3 lists several useful properties of matrices.)

Even though in this case we could compute the optimum solution through (12.20), we will apply the gradient algorithm with the intention of understanding how it works and which are its main limitations. From (12.16) and (12.17), we obtain the recursion

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \mu(\mathbf{r} - \mathbf{R}\mathbf{w}(n)). \quad (12.21)$$

The user must choose an initial condition  $\mathbf{w}(0)$ .

In Figure 12.11 we plot the evolution of the approximations computed through (12.21) against the level sets (i.e., curves of constant value) of the cost function (12.17). Different choices of step-size  $\mu$  are shown. In Figure 12.11a, a small step-size is used. The algorithm converges to the correct solution, but slowly. In Figure 12.11b, we used a larger step-size—convergence is now faster, but the algorithm still needs several iterations to reach the solution. If we try to increase the step-size even further, convergence at first becomes slower again, with the algorithm oscillating towards the solution (Figure 12.11c). For even larger step-sizes, such as that in Figure 12.11d, the algorithm diverges: the filter coefficients get farther and farther away from the solution.

It is important to find the maximum step-size for which the algorithm (12.21) remains stable. For this, we need concepts from linear systems and linear algebra, in particular eigenvalues, their relation to stability of linear systems, and the fact that symmetric matrices always have real eigenvalues (see Box 3).

The range of allowed step-sizes is found as follows. Rewrite (12.21) as

$$\mathbf{w}(n+1) = [\mathbf{I} - \mu\mathbf{R}] \mathbf{w}(n) + \mu\mathbf{r},$$

which is a linear recursion in state-space form ( $\mathbf{I}$  is the identity matrix).

Linear systems theory [9] tells us that this recursion converges as long as the largest eigenvalue of  $\mathbf{A} = \mathbf{I} - \mu\mathbf{R}$  has absolute value less than one. The eigenvalues of  $\mathbf{A}$  are the roots of

$$\det(\beta\mathbf{I} - (\mathbf{I} - \mu\mathbf{R})) = \det((\beta - 1)\mathbf{I} + \mu\mathbf{R}) = -\det((1 - \beta)\mathbf{I} - \mu\mathbf{R}) = 0.$$

Let  $1 - \beta = v$ . Then  $\beta$  is an eigenvalue of  $\mathbf{A}$  if and only if  $v = 1 - \beta$  is an eigenvalue of  $\mu\mathbf{R}$ . Therefore, if we denote by  $\lambda_i$  the eigenvalues of  $\mathbf{R}$ , the stability condition is

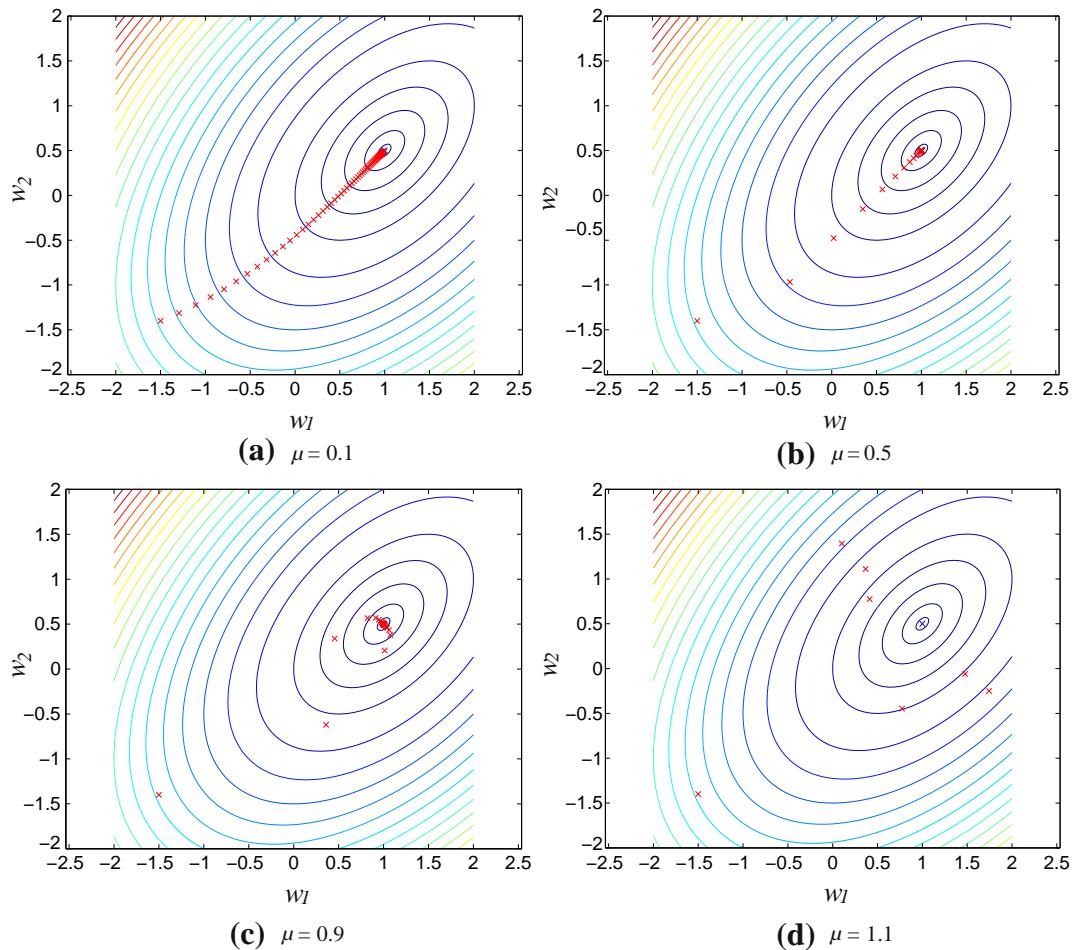

$$-1 < 1 - \mu\lambda_i < 1 \quad \forall i \Leftrightarrow 0 < \mu < \frac{2}{\lambda_i} \quad \forall i \Leftrightarrow 0 < \mu < \frac{2}{\max\{\lambda_i\}}.$$

The stability condition for our example is thus  $0 < \mu < 1$ , in agreement with what we saw in Figure 12.11.

The gradient algorithm leads to relatively simple adaptive filtering algorithms; however, it has an important drawback. As you can see in Figure 12.11a, the gradient does not point directly to the direction of the optimum. This effect is heightened when the level sets of the cost function are very elongated, as in Figure 12.12. This case corresponds to a quadratic function in which  $\mathbf{R}$  has one eigenvalue much smaller than the other. In this example, we replaced the matrix  $\mathbf{R}$  in (12.18) by

$$\mathbf{R}' = \frac{1}{9} \begin{bmatrix} 25 & 20 \\ 20 & 25 \end{bmatrix}.$$

This matrix has eigenvalues  $\lambda'_1 = 5$  and  $\lambda'_2 = \frac{5}{9}$ .

**FIGURE 12.11**

Performance of the steepest descent algorithm for different step-sizes. The crosses ( $x$ ) represent the successive approximations  $\mathbf{w}(n)$ , plotted against the level curves of (12.17). The initial condition is the point in the lower left.

Let us see why this is so. Recall from Box 3 that for every symmetric matrix there exists an orthogonal matrix  $\mathbf{U}$  (that is,  $\mathbf{U}^{-1} = \mathbf{U}^T$ ) such that

$$\mathbf{U}^T \mathbf{R} \mathbf{U} = \begin{bmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{bmatrix} \stackrel{\Delta}{=} \mathbf{\Lambda}, \quad (12.22)$$

where we defined the diagonal eigenvalue matrix  $\mathbf{\Lambda}$ .

Let us apply a change of coordinates to (12.19). The optimum solution to (12.17) is

$$\mathbf{w}_o = \mathbf{R}^{-1}\mathbf{r}.$$

Our first change of coordinates is to replace  $\mathbf{w}(n)$  by  $\tilde{\mathbf{w}}(n) = \mathbf{w}_o - \mathbf{w}(n)$  in (12.19). Subtract (12.19) from  $\mathbf{w}_o$  and replace  $\mathbf{r}$  in (12.19) by  $\mathbf{r} = \mathbf{R}\mathbf{w}_o$  to obtain

$$\tilde{\mathbf{w}}(n+1) = \tilde{\mathbf{w}}(n) - \mu \mathbf{R} \tilde{\mathbf{w}}(n) = [\mathbf{I} - \mu \mathbf{R}] \tilde{\mathbf{w}}(n). \quad (12.23)$$

Next, multiply this recursion from both sides by  $\mathbf{U}^T = \mathbf{U}^{-1}$

$$\mathbf{U}^T \tilde{\mathbf{w}}(n+1) = \mathbf{U}^T [\mathbf{I} - \mu \mathbf{R}] \underbrace{\mathbf{U} \mathbf{U}^T}_{=\mathbf{I}} \tilde{\mathbf{w}}(n) = [\mathbf{I} - \mu \Lambda] \mathbf{U}^T \tilde{\mathbf{w}}(n).$$

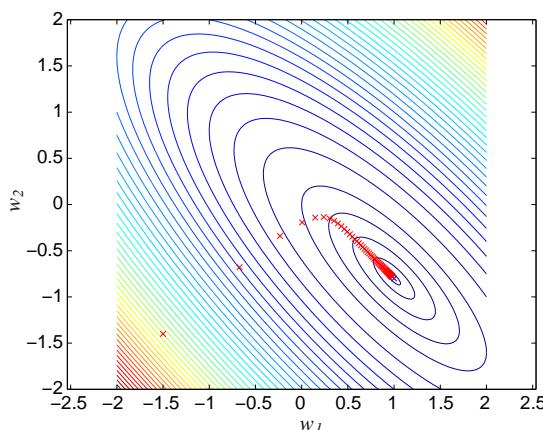

Defining  $\bar{\mathbf{w}}(n) = \mathbf{U}^T \tilde{\mathbf{w}}(n)$ , we have rewritten the gradient equation in a new set of coordinates, such that now the equations are uncoupled. Given that  $\Lambda$  is diagonal, the recursion is simply

$$\begin{bmatrix} \bar{w}_1(n+1) \\ \bar{w}_2(n+1) \end{bmatrix} = \begin{bmatrix} (1 - \mu \lambda_1) \bar{w}_1(n) \\ (1 - \mu \lambda_2) \bar{w}_2(n) \end{bmatrix}. \quad (12.24)$$

Note that, as long as  $|1 - \mu \lambda_i| < 1$  for  $i = 1, 2$ , both entries of  $\bar{\mathbf{w}}(n)$  will converge to zero, and consequently  $\mathbf{w}(n)$  will converge to  $\mathbf{w}_o$ .

The stability condition for this recursion is

$$|1 - \mu \lambda_i| < 1, i = 1, 2 \Rightarrow \mu < \frac{2}{\max\{\lambda_1, \lambda_2\}}.$$

**FIGURE 12.12**

Performance of the steepest descent algorithm for a problem with large ratio of eigenvalues. The crosses ( $\times$ ) represent the successive approximations  $\mathbf{w}(n)$ , plotted against the level curves of (12.17). The initial condition is the point in the lower left. Step-size  $\mu = 0.1$ .

When one of the eigenvalues is much larger than the other, say, when  $\lambda_1 \gg \lambda_2$ , the rate of convergence for the direction relative to the smaller eigenvalue becomes

$$1 > 1 - \mu\lambda_2 > 1 - 2\frac{\lambda_{\min}}{\lambda_{\max}} \approx 1,$$

and even if one of the coordinates in  $\tilde{\mathbf{w}}(n)$  converges quickly to zero, the other will converge very slowly. This is what we saw in Figure 12.12. The ratio  $\lambda_{\max}/\lambda_{\min}$  is known as the *eigenvalue spread* of a matrix.

In general, the gradient algorithm converges slowly when the eigenvalue spread of the Hessian is large. One way of solving this problem is to use a different optimization algorithm, such as the *Newton* or *quasi-Newton* algorithms, which use the inverse of the Hessian matrix, or an approximation to it, to improve the search direction used by the gradient algorithm.

Although these algorithms converge very quickly, they require more computational power, compared to the gradient algorithm. We will see more about them when we describe the RLS (*recursive least-squares*) algorithm in Section 1.12.3.3.

For example, for the quadratic cost-function (12.17), the Hessian is equal to  $2\mathbf{R}$ . If we had a good approximation  $\hat{\mathbf{R}}$  to  $\mathbf{R}$ , we could use the recursion

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \mu\hat{\mathbf{R}}^{-1}[\mathbf{r} - \mathbf{R}\mathbf{w}(n)]. \quad (12.25)$$

This class of algorithms is known as *quasi-Newton* (if  $\hat{\mathbf{R}}^{-1}$  is an approximation) or *Newton* (if  $\hat{\mathbf{R}}^{-1}$  is exact). In the Newton case, we would have

$$\mathbf{w}(n+1) = (1 - \mu)\mathbf{w}(n) + \mathbf{w}_o,$$

that is, the algorithm moves at each step precisely in the direction of the optimum solution. Of course, this is not a very interesting algorithm for a quadratic cost function as in this example (the optimum solution is used in the recursion!) However, this method is very useful when the cost function is not quadratic and in adaptive filtering, when the cost function is not known exactly.

## Box 2: Gradients

Consider a function of several variables  $J(\mathbf{w})$ , where

$$\mathbf{w} = \begin{bmatrix} w_0 \\ w_1 \\ \vdots \\ w_{M-1} \end{bmatrix}.$$

Its gradient is defined by

$$\nabla_{\mathbf{w}} J(\mathbf{w}) = \frac{\partial J}{\partial \mathbf{w}^T} = \begin{bmatrix} \frac{\partial J}{\partial w_0} \\ \frac{\partial J}{\partial w_1} \\ \vdots \\ \frac{\partial J}{\partial w_{M-1}} \end{bmatrix}.$$

The real value of the notation  $\partial J / \partial \mathbf{w}^T$  will only become apparent when working with functions of complex variables, as shown in Box 6. We also define, for consistency,

$$\frac{\partial J}{\partial \mathbf{w}} = \left[ \begin{array}{c} \frac{\partial J}{\partial w_0} \quad \frac{\partial J}{\partial w_1} \quad \cdots \quad \frac{\partial J}{\partial w_{M-1}} \end{array} \right].$$

As an example, consider the quadratic cost function

$$J(\mathbf{w}) = b - 2\mathbf{w}^T \mathbf{r} + \mathbf{w}^T \mathbf{R} \mathbf{w}. \quad (12.26)$$

The gradient of  $J(\mathbf{w})$  is (verify!)

$$\nabla_{\mathbf{w}} J(\mathbf{w}) = \frac{\partial J}{\partial \mathbf{w}^T} = -2\mathbf{r} + 2\mathbf{R}\mathbf{w}. \quad (12.27)$$

If we use the gradient to find the minimum of  $J(\mathbf{w})$ , it would be necessary also to check the second-order derivative, to make sure the solution is not a maximum or a saddle point. The second order derivative of a function of several variables is a matrix, the *Hessian*. It is defined by

$$\nabla_{\mathbf{w}}^2 J = \frac{\partial^2 J}{\partial \mathbf{w} \partial \mathbf{w}^T} = \left[ \begin{array}{c} \frac{\partial}{\partial \mathbf{w}} \left\{ \frac{\partial J}{\partial w_0} \right\} \\ \vdots \\ \frac{\partial}{\partial \mathbf{w}} \left\{ \frac{\partial J}{\partial w_{M-1}} \right\} \end{array} \right] = \left[ \begin{array}{ccc} \frac{\partial^2 J}{\partial w_0^2} & \cdots & \frac{\partial^2 J}{\partial w_0 \partial w_{M-1}} \\ \vdots & \ddots & \vdots \\ \frac{\partial^2 J}{\partial w_{M-1} \partial w_0} & \cdots & \frac{\partial^2 J}{\partial w_{M-1}^2} \end{array} \right]. \quad (12.28)$$

Note that for the quadratic cost-function (12.26), the Hessian is equal to  $\mathbf{R} + \mathbf{R}^T$ . It is equal to  $2\mathbf{R}$  if  $\mathbf{R}$  is symmetric, that is, if  $\mathbf{R}^T = \mathbf{R}$ . This will usually be the case here. Note that  $\mathbf{R} + \mathbf{R}^T$  is always symmetric: in fact, since for well-behaved functions  $J$  it holds that

$$\frac{\partial^2 J}{\partial w_i \partial w_j} = \frac{\partial^2 J}{\partial w_j \partial w_i},$$

the Hessian is usually symmetric.

Assume that we want to find the minimum of  $J(\mathbf{w})$ . The first-order conditions are then

$$\left. \frac{\partial J}{\partial \mathbf{w}} \right|_{\mathbf{w}_0} = \mathbf{0}.$$

The solution  $\mathbf{w}_0$  is a minimum of  $J(\mathbf{w})$  if the Hessian at  $\mathbf{w}_0$  is a positive semi-definite matrix, that is, if

$$\mathbf{x}^T \nabla_{\mathbf{w}}^2 J(\mathbf{w}_0) \mathbf{x} \geq 0$$

for all directions  $\mathbf{x}$ .

### Box 3: Useful results from Matrix Analysis

Here we list without proof a few useful results from matrix analysis. Detailed explanations can be found, for example, in [10–13].

**Fact 1 (Traces).** The *trace* of a matrix  $\mathbf{A} \in \mathcal{C}^{M \times M}$  is the sum of its diagonal elements:

$$\text{Tr}(\mathbf{A}) = \sum_{i=1}^M a_{ii}, \quad (12.29)$$

in which the  $a_{ii}$  are the entries of  $\mathbf{A}$ . For any two matrices  $\mathbf{B} \in \mathcal{C}^{M \times N}$  and  $\mathbf{C} \in \mathcal{C}^{N \times M}$ , it holds that

$$\text{Tr}(\mathbf{BC}) = \text{Tr}(\mathbf{CB}). \quad (12.30)$$

In addition, if  $\lambda_i$ ,  $i = 1, \dots, M$  are the eigenvalues of a square matrix  $\mathbf{A} \in \mathcal{C}^{M \times M}$ , then

$$\text{Tr}(\mathbf{A}) = \sum_{i=1}^M \lambda_i. \quad (12.31)$$

**Fact 2 (Singular matrices).** A matrix  $\mathbf{A} \in \mathcal{C}^{M \times M}$  is singular if and only if there exists a nonzero vector  $\mathbf{u}$  such that  $\mathbf{Au} = \mathbf{0}$ .

The *null space*, or *kernel*  $N(\mathbf{A})$  of a matrix  $\mathbf{A} \in \mathcal{C}^{M \times N}$  is the set of vectors  $\mathbf{u} \in \mathcal{C}^N$  such that  $\mathbf{Au} = \mathbf{0}$ . A square matrix  $\mathbf{A} \in \mathcal{C}^{M \times M}$  is nonsingular if, and only if,  $N(\mathbf{A}) = \{\mathbf{0}\}$ , that is, if its null space contains only the null vector.

Note that, if  $\mathbf{A} = \sum_{k=1}^K \mathbf{u}_k \mathbf{v}_k^H$ , with  $\mathbf{u}_k, \mathbf{v}_k \in \mathcal{C}^M$ , then  $\mathbf{A}$  cannot be invertible if  $K < M$ . This is because when  $K < M$ , there always exists a nonzero vector  $\mathbf{x} \in \mathcal{C}^M$  such that  $\mathbf{v}_k^H \mathbf{x} = 0$  for  $1 \leq k \leq K$ , and thus  $\mathbf{Ax} = \mathbf{0}$  with  $\mathbf{x} \neq \mathbf{0}$ .

**Fact 3 (Inverses of block matrices).** Assume the square matrix  $\mathbf{A}$  is partitioned such that

$$\mathbf{A} = \begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{bmatrix},$$

with  $\mathbf{A}_{11}$  and  $\mathbf{A}_{22}$  square. If  $\mathbf{A}$  and  $\mathbf{A}_{11}$  are invertible (nonsingular), then

$$\mathbf{A}^{-1} = \begin{bmatrix} \mathbf{I} & -\mathbf{A}_{11}^{-1} \mathbf{A}_{12} \\ \mathbf{0} & \mathbf{I} \end{bmatrix} \begin{bmatrix} \mathbf{A}_{11}^{-1} & \mathbf{0} \\ \mathbf{0} & \Delta^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ -\mathbf{A}_{21} \mathbf{A}_{11}^{-1} & \mathbf{I} \end{bmatrix},$$

where  $\Delta = \mathbf{A}_{22} - \mathbf{A}_{21} \mathbf{A}_{11}^{-1} \mathbf{A}_{12}$  is the *Schur complement* of  $\mathbf{A}_{11}$  in  $\mathbf{A}$ . If  $\mathbf{A}_{22}$  and  $\mathbf{A}$  are invertible, then

$$\mathbf{A}^{-1} = \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ -\mathbf{A}_{22}^{-1} \mathbf{A}_{21} & \mathbf{I} \end{bmatrix} \begin{bmatrix} \Delta'^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{A}_{22}^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{I} & -\mathbf{A}_{12} \mathbf{A}_{22}^{-1} \\ \mathbf{0} & \mathbf{I} \end{bmatrix},$$

where  $\Delta' = \mathbf{A}_{11} - \mathbf{A}_{12} \mathbf{A}_{22}^{-1} \mathbf{A}_{21}$ .

**Fact 4 (Matrix inversion Lemma).** Let  $A$  and  $B$  be two nonsingular  $M \times M$  matrices,  $D \in \mathcal{C}^{K \times K}$  be also nonsingular, and  $C, E \in \mathcal{C}^{M \times K}$  be such that

$$A = B + CDE^H. \quad (12.32)$$

The inverse of  $A$  is then given by

$$A^{-1} = B^{-1} - B^{-1}C(D^{-1} + E^H B^{-1}C)^{-1}E^H B^{-1}. \quad (12.33)$$

The lemma is most useful when  $K \ll M$ . In particular when  $K = 1$ ,  $D + E^H B^{-1}C$  is a scalar, and we have

$$A^{-1} = B^{-1} - \frac{B^{-1}CE^H B^{-1}}{D^{-1} + E^H B^{-1}C}.$$

**Fact 5 (Symmetric matrices).** Let  $A \in \mathcal{C}^{M \times M}$  be *Hermitian Symmetric* (or simply *Hermitian*), that is,  $A^H = (A^T)^* = A$ . Then, it holds that

1. All eigenvalues  $\lambda_i, i = 1, \dots, M$  of  $A$  are real.
2.  $A$  has a complete set of orthonormal eigenvectors  $u_i, i = 1, \dots, M$ . Since the eigenvectors are orthonormal,  $u_i^H u_j = \delta_{ij}$ , where  $\delta_{ij} = 1$  if  $i = j$  and 0 otherwise.
3. Arranging the eigenvectors in a matrix  $U = [u_1 \dots u_M]$ , we find that  $U$  is *unitary*, that is,  $U^H U = UU^H = I$ . In addition,

$$U^H A U = \Lambda = \begin{bmatrix} \lambda_1 & 0 & \dots & 0 \\ 0 & \lambda_2 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & \lambda_M \end{bmatrix}.$$

4. If  $A = A^T \in \mathcal{R}^{M \times M}$ , it is called simply *symmetric*. In this case, not only the eigenvalues, but also the eigenvectors are real.
5. If  $A$  is symmetric and invertible, then  $A^{-1}$  is also symmetric.

**Fact 6 (Positive-definite matrices).** If  $A \in \mathcal{C}^{M \times M}$  is Hermitian symmetric and moreover for all  $u \in \mathcal{C}^M$  it holds that

$$u^H A u \geq 0, \quad (12.34)$$

then  $A$  is *positive semi-definite*. Positive semi-definite matrices have non-negative eigenvalues:  $\lambda_i \geq 0$ ,  $i = 1, \dots, M$ . They may be singular, if one or more eigenvalue is zero.

If the inequality (12.34) is strict, that is, if

$$u^H A u > 0 \quad (12.35)$$

for all  $u \neq 0$ , then  $A$  is *positive-definite*. All eigenvalues  $\lambda_i$  of positive-definite matrices satisfy  $\lambda_i > 0$ . Positive-definite matrices are always nonsingular.

Finally, all positive-definite matrices admit a Cholesky factorization, i.e., if  $A$  is positive-definite, there is a lower-triangular matrix  $L$  such that  $A = LL^H$  [14].

**Fact 7 (Norms and spectral radius).** The *spectral radius*  $\rho(\mathbf{A})$  of a matrix  $\mathbf{A} \in \mathcal{C}^{M \times M}$  is

$$\rho(\mathbf{A}) = \max_{1 \leq i \leq M} |\lambda_i|, \quad (12.36)$$

in which  $\lambda_i$  are the eigenvalues of  $\mathbf{A}$ . The spectral radius is important, because a linear system

$$\mathbf{x}(n+1) = \mathbf{A}\mathbf{x}(n)$$

is stable if and only if  $\rho(\mathbf{A}) \leq 1$ , as is well known. A useful inequality is that, for any matrix norm  $\|\cdot\|$  such that for any  $\mathbf{A}, \mathbf{B} \in \mathcal{C}^{M \times M}$

$$\|\mathbf{AB}\| \leq \|\mathbf{A}\| \|\mathbf{B}\|,$$

it holds that

$$\rho(\mathbf{A}) \leq \|\mathbf{A}\|. \quad (12.37)$$

This property is most useful when used with norms that are easy to evaluate, such as the 1-norm,

$$\|\mathbf{A}\|_1 = \max_{1 \leq i \leq M} \sum_{j=1}^M |a_{ij}|,$$

where  $a_{ij}$  are the entries of  $\mathbf{A}$ . We could also use the infinity norm,

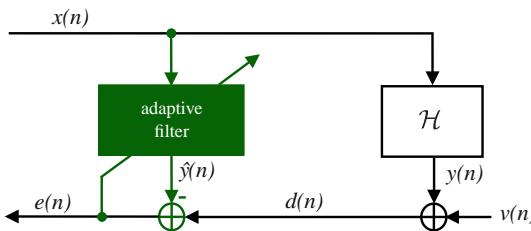

$$\|\mathbf{A}\|_\infty = \max_{1 \leq j \leq M} \sum_{i=1}^M |a_{ij}|.$$

### 1.12.1.3 Applications

Due to the ability to adjust themselves to different environments, adaptive filters can be used in different signal processing and control applications. Thus, they have been used as a powerful device in several fields, such as communications, radar, sonar, biomedical engineering, active noise control, modeling, etc. It is common to divide these applications into four groups:

1. interference cancellation;
2. system identification;
3. prediction; and
4. inverse system identification.

In the first three cases, the goal of the adaptive filter is to find an approximation  $\hat{y}(n)$  for the signal  $y(n)$ , which is contained in the signal  $d(n) = y(n) + v(n)$ . Thus, as  $\hat{y}(n)$  approaches  $y(n)$ , the signal  $e(n) = d(n) - \hat{y}(n)$  approaches  $v(n)$ . The difference between these applications is in what we are interested. In interference cancellation, we are interested in the signal  $v(n)$ , as is the case of acoustic echo cancellation, where  $v(n)$  is the speech of the person using the hands-free telephone (go back to Figures 12.4 and 12.7). In system identification, we are interested in the filter parameters, and in

**FIGURE 12.13**

Scheme for interference cancellation and system identification.  $x(n)$  and  $y(n)$  are correlated to each other.

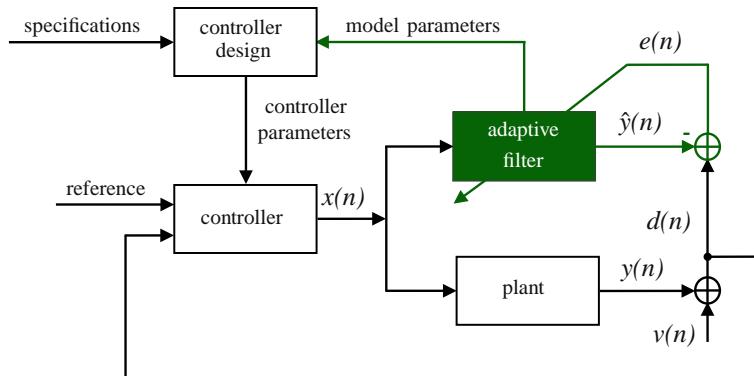

prediction, we may be interested in the signal  $v(n)$  and/or in the filter parameters. Note that in all these applications (interference cancellation, system identification and prediction), the signal  $e(n)$  is an approximation for  $v(n)$  and should not converge to zero, except when  $v(n) \equiv 0$ . In inverse system identification, differently from the other applications, the signal at the output of the adaptive filter must be as close as possible to the signal  $d(n)$  and thus, ideally, the signal  $e(n)$  should be zeroed. In the sequel, we give an overview of these four groups in order to arrive at a common formulation that will simplify our analysis of adaptive filtering algorithms in further sections.

#### 1.12.1.3.1 Interference cancellation

In a general interference cancellation problem, we have access to a signal  $d(n)$ , which is a mixture of two other signals,  $v(n)$  and  $y(n)$ . We are interested in one of these signals, and want to separate it from the other (the interference) (see Figure 12.13). Even though we do not know  $v(n)$  or  $y(n)$ , we have some information about  $y(n)$ , usually in the form of a reference signal  $x(n)$  that is related to  $y(n)$  through a filtering operation  $\mathcal{H}$ . We may know the general form of this operation, for example, we may know that the relation is linear and well approximated by an FIR filter with 200 coefficients. However, we do not know the parameters (the filter coefficients) necessary to reproduce it. The goal of the adaptive filter is to find an approximation  $\hat{y}(n)$  to  $y(n)$ , given only  $x(n)$  and  $d(n)$ . In the process of finding this  $\hat{y}$ , the adaptive filter will construct an approximation for the relation  $\mathcal{H}$ . A typical example of an interference cancellation problem is the echo cancellation example we gave in Section 1.12.1.1. In that example,  $x(n)$  is the far-end voice signal,  $v(n)$  is the near-end voice signal, and  $y(n)$  is the echo. The relation  $\mathcal{H}$  is usually well approximated by a linear FIR filter with a few hundred taps.

The approximation for  $\mathcal{H}$  is a by-product, that does not need to be very accurate as long as it leads to a  $\hat{y}(n)$  close to  $y(n)$ . This configuration is shown in Figure 12.13 and is called *interference cancellation*, since the interference  $y(n)$  should be canceled. Note that we do not want to make  $e(n) \equiv 0$ , otherwise we would not only be killing the interference  $y(n)$ , but also the signal of interest  $v(n)$ .

There are many applications of interference cancellation. In addition to acoustic and line echo cancellation, we can mention, for example, adaptive notch filters for cancellation of sinusoidal interference (a common application is removal of 50 or 60 Hz interference from the mains line), cancellation of the maternal electrocardiography in fetal electrocardiography, cancellation of echoes in long distance telephone circuits, active noise control (as in noise-canceling headphones), and active vibration control.

**FIGURE 12.14**

Scheme for plant identification in a control system.

### 1.12.1.3.2 System identification

In interference cancellation, the coefficients of the adaptive filter converge to an approximation for the true relation  $\mathcal{H}$ , but as mentioned before, this approximation is a by-product that does not need to be very accurate. However, there are some applications in which the goal is to construct an approximation as accurate as possible for the unknown relation  $\mathcal{H}$  between  $x(n)$  and  $y(n)$ , thus obtaining a model for the unknown system. This is called *system identification* or *modeling* (the diagram in Figure 12.13 applies also for this case). The signal  $d(n)$  is now composed of the output  $y(n)$  of an unknown system  $\mathcal{H}$ , plus noise  $v(n)$ . The reference signal  $x(n)$  is the input to the system which, when possible, is chosen to be white noise. In general, this problem is harder than interference cancellation, as we shall see in Section 1.12.2.1.5, due to some conditions that the reference signal  $x(n)$  must satisfy. However, one point does not change: in the ideal case, the signal  $e(n)$  will be equal to the noise  $v(n)$ . Again, we do not want to make  $e(n) \equiv 0$ , otherwise we would be trying to model the noise (however, the smaller the noise the easier the task, as one would expect).

In many control systems, an unknown dynamic system (also called as *plant* in control system terminology) is identified online and the result is used in a self-tuning controller, as depicted in Figure 12.14. Both the plant and the adaptive filter have the same input  $x(n)$ . In practical situations, the plant to be modeled is noisy, which is represented by the signal  $v(n)$  added to the plant output. The noise  $v(n)$  is generally uncorrelated with the plant input. The task of the adaptive filter is to minimize the error model  $e(n)$  and track the time variations in the dynamics of the plant. The model parameters are continually fed back to the controller to obtain the controller parameters used in the self-tuning regulator loop [15].

There are many applications that require the identification of an unknown system. In addition to control systems, we can mention, for example, the identification of the room impulse response, used to study the sound quality in concert rooms, and the estimation of the communication channel impulse response, required by maximum likelihood detectors and blind equalization techniques based on second-order statistics.

### 1.12.1.3.3 Prediction

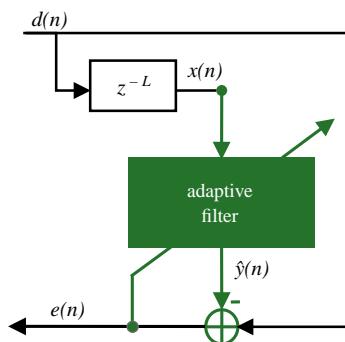

In *prediction*, the goal is to find a relation between the current sample  $d(n)$  and previous samples  $d(n-L), \dots, d(n-L-M+1)$ , as shown in Figure 12.15. Therefore, we want to model  $d(n)$  as a part  $y(n)$  that depends only on  $d(n-L), \dots, d(n-L-M+1)$ , and a part  $v(n)$  that represents new information. For example, for a linear model, we would have

$$d(n) = \underbrace{\sum_{k=0}^{M-1} h_k d(n-L-k)}_{y(n)} + v(n),$$

Thus, we in fact have again the same problem as in Figure 12.13. The difference is that now the reference signal is a delayed version of  $d(n)$ :  $x(n) = d(n-L)$ , and the adaptive filter will try to find an approximation  $\hat{y}(n)$  for  $y(n)$ , thereby separating the “predictable” part  $y(n)$  of  $d(n)$  from the “new information”  $v(n)$ , to which the signal  $e(n) = d(n) - \hat{y}(n)$  should converge. The system  $\mathcal{H}$  in Figure 12.13 now represents the relation between  $d(n-L)$  and the predictable part of  $d(n)$ .

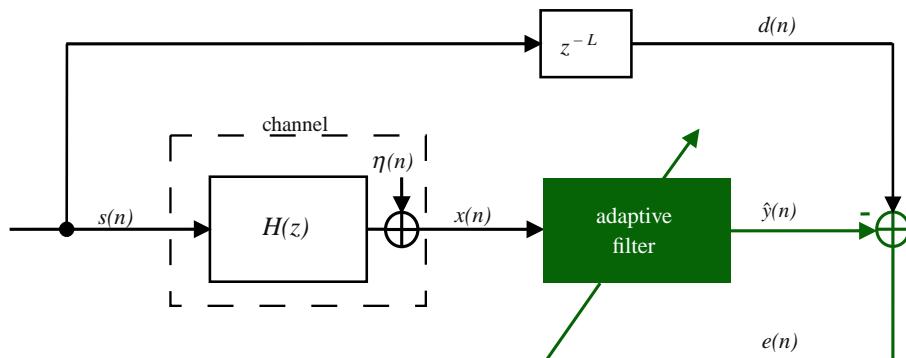

Prediction finds application in many fields. We can mention, for example, linear predictive coding (LPC) and adaptive differential pulse code modulation (ADPCM) used in speech coding, adaptive line enhancement, autoregressive spectral analysis, etc.

For example, adaptive line enhancement (ALE) seeks the solution for a classical detection problem, whose objective is to separate a narrowband signal  $y(n)$  from a wideband signal  $v(n)$ . This is the case, for example, of finding a low-level sine wave (predictable narrowband signal) in noise (non-predictable wideband signal). The signal  $d(n)$  is constituted by the sum of these two signals. Using  $d(n)$  as the reference signal and a delayed replica of it, i.e.,  $d(n-L)$ , as input of the adaptive filter as in Figure 12.15, the output  $\hat{y}(n)$  provides an estimate of the (predictable) narrowband signal  $y(n)$ , while the error signal  $e(n)$  provides an estimate of the wideband signal  $v(n)$ . The delay  $L$  is also known as *decorrelation parameter* of the ALE, since its main function is to remove the correlation between the wideband signal  $v(n)$  present in the reference  $d(n)$  and in the delayed predictor input  $d(n-L)$ .

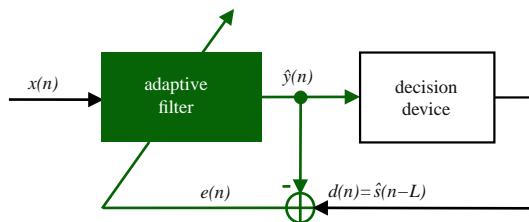

**FIGURE 12.15**

Scheme for prediction.  $x(n) = d(n-L)$  is a delayed version of  $d(n)$ .

**FIGURE 12.16**

Simplified communications system with an adaptive equalizer in the training mode.

**FIGURE 12.17**

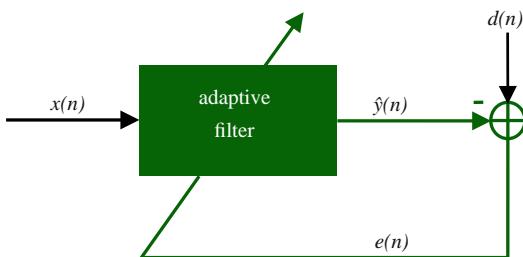

Adaptive equalizer in the decision-directed mode.

#### 1.12.1.3.4 Inverse system identification

*Inverse system identification*, also known as *deconvolution*, has been widely used in different fields as communications, acoustics, optics, image processing, control, among others. In communications, it is also known as *channel equalization* and the adaptive filter is commonly called as *equalizer*. Adaptive equalizers play an important role in digital communications systems, since they are used to mitigate the inter-symbol interference (ISI) introduced by dispersive channels. Due to its importance, we focus on the equalization application, which is explained in the sequel.

A simplified baseband communications system is depicted in Figure 12.16. The signal  $s(n)$  is transmitted through an unknown channel, whose model is constituted by an FIR filter with transfer function  $H(z) = h_0 + h_1z^{-1} + \dots + h_{K-1}z^{K-1}$  and additive noise  $\eta(n)$ . Due to the channel memory, the signal at the receiver contains contributions not only from  $s(n)$ , but also from the previous symbols  $s(n-1), s(n-2), \dots, s(n-K+1)$ , i.e.,

$$x(n) = \underbrace{\sum_{k=0}^{L-1} h_k s(n-k)}_{\text{pre-ISI}} + h_L s(n-L) + \underbrace{\sum_{k=L+1}^{K-1} h_k s(n-k)}_{\text{post-ISI}} + \eta(n). \quad (12.38)$$

**FIGURE 12.18**

Inputs and output of an adaptive filter.

Assuming that the overall channel-equalizer system imposes a delay of  $L$  samples, the adaptive filter will try to find an approximation  $\hat{y}(n)$  for  $d(n) = s(n - L)$  and for this purpose, the two summations in (12.38), which constitute the inter-symbol interference, must be mitigated. Of course, when you are transmitting information the receiver will not have access to  $d(n - L)$ . The filter will adapt during a *training* phase, in which the transmitter sends a pre-agreed signal. You can see that in this case, the role of  $x(n)$  and  $d(n)$  is the reverse of that in system identification. In this case, you would indeed like to have  $e(n) \equiv 0$ . The problem is that this is not possible, given the presence of noise in  $x(n)$ . The role of the adaptive filter is to approximately invert the effect of the channel, at the same time trying to suppress the noise (or at least, not to amplify it too much). In one sense, we are back to the problem of separating two signals, but now the mixture is in the reference signal  $x(n)$ , so what can and what cannot be done is considerably different from the other cases.

The scheme of Figure 12.16 is also called training mode, since the delayed version of the transmitted sequence  $d(n) = s(n - L)$  (training sequence) is known at the receiver. After the convergence of the filter, the signal  $d(n)$  is changed to the estimate  $\hat{s}(n - L)$  obtained at the output of a decision device, as shown in Figure 12.17. In this case, the equalizer works in the so-called decision-directed mode. The decision device depends on the signal constellation—for example, if  $s(n) = \pm 1$ , the decision device returns +1 for  $\hat{y}(n) \geq 0$ , and -1 for  $\hat{y}(n) < 0$ .

#### 1.12.1.3.5 A common formulation

In all the four groups of applications, the inputs of the adaptive filter are given by the signals  $x(n)$  and  $d(n)$  and the output by  $\hat{y}(n)$ . Note that the input  $d(n)$  appears effectively in the signal  $e(n) = d(n) - \hat{y}(n)$ , which is computed and fed back at each time instant  $n$ , as shown in Figure 12.18. In the literature, the signal  $d(n)$  is referred to as desired signal,  $x(n)$  as reference signal and  $e(n)$  as error signal. These names unfortunately are somewhat misleading, since they give the impression that our goal is to recover exactly  $d(n)$  by filtering (possibly in a nonlinear way) the reference  $x(n)$ . In almost all applications, this is far from the truth, as previously discussed. In fact, except in the case of channel equalization, exactly zeroing the error would result in very poor performance.

The only application in which  $d(n)$  is indeed a “desired signal” is channel equalization, in which  $d(n) = s(n - L)$ . Despite this particularity in channel equalization, the common feature in all adaptive filtering applications is that the filter must learn a relation between the reference  $x(n)$  and the desired

signal  $d(n)$  (we will use this name to be consistent with the literature.) In the process of building this relation, the adaptive filter is able to perform useful tasks, such as separating two mixed signals; or recovering a distorted signal. Section 1.12.2 explains this idea in more detail.

## 1.12.2 Optimum filtering

We now need to extend the ideas of Section 1.12.1.2, that applied only to periodic (deterministic) signals, to more general classes of signals. For this, we will use tools from the theory of stochastic processes. The main ideas are very similar: as before, we need to choose a structure for our filter and a means of measuring how far or how near we are to the solution. This is done by choosing a convenient cost function, whose minimum we must search iteratively, based only on measurable signals.

In the case of periodic signals, we saw that minimizing the error power (12.3), repeated below,

$$P = \sum_{k=1}^{K_0} \frac{\tilde{C}_k^2}{2} + \sum_{\ell=1}^{K_1} \frac{B_\ell^2}{2},$$

would be equivalent to zeroing the echo. However, we were not able to compute the error power exactly—we used an approximation through a time-average, as in (12.5), repeated here:

$$\hat{P}(n) = \frac{1}{N} \sum_{k=0}^{N-1} e^2(n-k),$$

where  $N$  is a convenient window length (in Section 1.12.1.2, we saw that choosing a large window length is approximately equivalent to choosing  $N = 1$  and a small step-size). Since we used an approximated estimate of the cost, our solution was also an approximation: the estimated coefficients did not converge exactly to their optimum values, but instead hovered around the optimum (Figures 12.9 and 12.10).

The minimization of the time-average  $\hat{P}(n)$  also works in the more general case in which the echo is modeled as a random signal—but what is the corresponding exact cost function? The answer is given by the property of *ergodicity* that some random signals possess. If a random signal  $s(n)$  is such that its mean  $E\{s(n)\}$  does not depend on  $n$  and its autocorrelation  $E\{s(n)s(k)\}$  depends only on  $n - k$ , it is called wide-sense stationary (WSS) [16]. If  $s(n)$  is also (mean-square) ergodic, then

$$\text{Average power of } s(n) = \lim_{N \rightarrow \infty} \frac{1}{N+1} \sum_{n=0}^N s^2(n) = E\{s^2(n)\}. \quad (12.39)$$

Note that  $E\{s^2(n)\}$  is an ensemble average, that is, the expected value is computed over all possible realizations of the random signal. Relation (12.39) means that for an ergodic signal, the time average of a single realization of the process is equal to the ensemble-average of all possible realizations of the process. This ensemble average is the exact cost function that we would like to minimize.

In the case of adaptive filters, (12.39) holds approximately for  $e(n)$  for a finite value of  $N$  if the environment does not change too fast, and if the filter adapts slowly. Therefore, for random variables we will still use the average error power as a measure of how well the adaptive filter is doing. The difference

is that in the case of periodic signals, we could understand the effect of minimizing the average error power in terms of the amplitudes of each harmonic in the signal, but now the interpretation will be in terms of ensemble averages (variances).

Although the error power is not the only possible choice for cost function, it is useful to study this choice in detail. Quadratic cost functions such as the error power have a number of properties that make them popular. For example, they are differentiable, and so it is relatively easy to find a closed-form solution for the optimum, and in the important case where all signals are Gaussian, the optimum filters are linear. Of course, quadratic cost functions are not the best option in all situations: the use of other cost functions, or even of adaptive filters not based on the minimization of a cost function, is becoming more common. We will talk about some of the most important alternatives in Sections 1.12.5.2 and 1.12.5.4.

Given the importance of quadratic cost functions, in this section we study them in detail. Our focus is on what could and what could not be done if the filter were able to measure perfectly  $E\{e^2(n)\}$  at each instant. This discussion has two main goals: the first is to learn what is feasible, so we do not expect more from a filter than it can deliver. The second is to enable us to make more knowledgeable choices when designing a filter—for example, which filter order should be used, and for system identification, which input signal would result in better performance. In Section 1.12.4.4.3 we will study the performance of adaptive filters taking into consideration their imperfect knowledge of the environment.

### 1.12.2.1 Linear least-mean squares estimation

In the examples we gave in previous sections, a generic adaptive filtering problem resumed to this: we are given two sequences,  $\{x(n)\}$  and  $\{d(n)\}$ , as depicted in Figure 12.18. It is known, from physical arguments, that  $d(n)$  has two parts, one that is in some sense related to  $x(n)$ ,  $x(n-1)$ , ..., and another that is not, and that both parts are combined additively, that is,

$$d(n) = \underbrace{\mathcal{H}(x(n), x(n-1), \dots)}_{y(n)} + v(n), \quad (12.40)$$

where  $\mathcal{H}(\cdot)$  is an unknown relation, and  $v(n)$  is the part “unrelated” to  $\{x(n)\}$ . In our examples so far,  $\mathcal{H}(\cdot)$  was linear, but we do not need to restrict ourselves to this case. Our objective is to extract  $y(n)$  and  $v(n)$  from  $d(n)$ , based only on observations of  $\{x(n)\}$  and  $\{d(n)\}$ . We saw in Section 1.12.1.2 that the average power of the difference  $e(n)$  between  $d(n)$  and our current approximation  $\hat{y}(n)$  could be used as a measure of how close we are to the solution. In general,  $\mathcal{H}(\cdot)$  is time-variant, i.e., depends directly on  $n$ . We will not write this dependence explicitly to simplify the notation.

In this section we ask in some sense the inverse problem, that is: given two sequences  $\{x(n)\}$  and  $\{d(n)\}$ , what sort of relation will be found between them if we use  $E\{e^2(n)\}$  as a standard? The difference is that we now do not assume a model such as (12.40); instead, we want to know what kind of model results from the exact minimization of  $E\{e^2(n)\}$ , where  $e(n)$  is defined as the difference between  $d(n)$  and a function of  $x(n)$ ,  $x(n-1)$ , ... .

We can answer this question in an entirely general way, without specifying beforehand the form of  $\mathcal{H}$ . This is done in Box 4. However, if we have information about the physics of a problem and know that

the relation  $\mathcal{H}(x(n), x(n-1), \dots)$  is of a certain kind, we can restrict the search for the solution  $\hat{\mathcal{H}}$  to this class. This usually reduces the complexity of the filter and increases its convergence rate (because less data is necessary to estimate a model with less unknowns, as we will see in Section 1.12.3). In this section we focus on this second option.

The first task is to describe the class  $\mathcal{F}$  of allowed functions  $\hat{\mathcal{H}}$ . This may be done by choosing a relation that depends on a few parameters, such as (recall that the adaptive filter output is  $\hat{y}(n) = \hat{\mathcal{H}}(x(n), x(n-1), \dots)$ )

$$\mathcal{F}_{\text{FIR}} \text{ (FIR filter): } \hat{y}(n) = w_0 x(n) + \dots + w_{M-1} x(n-M+1), \quad (12.41)$$

$$\mathcal{F}_{\text{IIR}} \text{ (IIR filter): } \hat{y}(n) = -a_1 \hat{y}(n-1) + b_0 x(n), \quad (12.42)$$

$$\begin{aligned} \mathcal{F}_{\text{V}} \text{ (Volterra filter): } \hat{y}(n) = & w_0 x(n) + w_1 x(n-1) + w_{0,0} x^2(n) \\ & + w_{0,1} x(n)x(n-1) + w_{1,1} x(n-1)^2, \end{aligned} \quad (12.43)$$

$$\mathcal{F}_{\text{S}} \text{ (Saturation): } \hat{y}(n) = \arctan(ax(n)). \quad (12.44)$$

In each of these cases, the relation between the input sequence  $\{x(n)\}$  and  $d(n)$  is constrained to a certain class, for example, linear length- $M$  FIR filters in (12.41), first-order IIR filters in (12.42), and second-order Volterra filters in (12.43). Each class is described by a certain number of parameters: the filter coefficients  $w_0, \dots, w_{M-1}$  in the case of FIR filters,  $a_1$  and  $b_0$  in the case of IIR filters, and so on. The task of the adaptive filter will then be to choose the values of the parameters that best fit the data.

For several practical reasons, it is convenient if we make the filter output depend linearly on the parameters, as happens in (12.41) and in (12.43). It is important to distinguish linear in the parameters from input-output linear: (12.43) is linear in the parameters, but the relation between the input sequence  $\{x(n)\}$  and the output  $\hat{y}(n)$  is nonlinear. What may come as a surprise is that the IIR filter of Eq. (12.42) is *not* linear in the parameters: in fact,  $\hat{y}(n) = -a_1 \hat{y}(n-1) + b_0 x(n) = a_1^2 \hat{y}(n-2) - a_1 b_0 x(n-1) + b_0 x(n) = \dots$  — you can see that  $\hat{y}(n)$  depends nonlinearly on  $a_1$  and  $b_0$ .

Linearly parametrized classes  $\mathcal{F}$ , such as  $\mathcal{F}_{\text{FIR}}$  (12.41) and  $\mathcal{F}_{\text{V}}$  (12.43) are popular because in general it is easier to find the optimum parameters, both theoretically and in real time. In fact, when the filter output depends linearly on the parameters and the cost function is a *convex* function of the error, it can be shown that the optimal solution is unique (see Box 5). This is a very desirable property, since it simplifies the search for the optimal solution.

In the remainder of this section we will concentrate on classes of relations that are linear in the parameters. As  $\mathcal{F}_{\text{V}}$  shows, this does not imply that we are restricting ourselves to linear models. There are, however, adaptive filtering algorithms that use classes of relations that are not linear in the parameters, such as IIR adaptive filters. On the other hand, blind equalization algorithms are based on non-convex cost functions.

Assume then that we have chosen a convenient class of relations  $\mathcal{F}$  that depends linearly on its parameters. That is, we want to solve the problem

$$\min_{\hat{\mathcal{H}} \in \mathcal{F}} E \left\{ \left[ d(n) - \hat{\mathcal{H}}(x(n), x(n-1), \dots) \right]^2 \right\}. \quad (12.45)$$

We want to know which properties the solution to this problem will have when  $\mathcal{F}$  depends linearly on a finite number of parameters. In this case,  $\mathcal{F}$  is a linear combinations of certain functions  $\phi_i$  of  $x(n), x(n - 1), \dots$

$$\hat{y}(n) = w_0\phi_0 + w_1\phi_1 + \dots + w_{M-1}\phi_{M-1} \stackrel{\Delta}{=} \mathbf{w}^T \boldsymbol{\phi}, \quad (12.46)$$

where in general  $\phi_i = \phi_i(x(n), x(n - 1), \dots), 0 \leq i \leq M - 1$ . The vector  $\boldsymbol{\phi}$  is known as *regressor*. In the case of length- $M$  FIR filters, we would have

$$\phi_0 = x(n), \phi_1 = x(n - 1), \dots, \phi_{M-1} = x(n - M + 1),$$

whereas in the case of second-order Volterra filters with memory 1, we would have

$$\phi_0 = x(n), \phi_1 = x(n - 1), \phi_2 = x^2(n), \phi_3 = x(n)x(n - 1), \phi_4 = x^2(n - 1).$$

Our problem can then be written in general terms as: find  $\mathbf{w}_o$  such that

$$\mathbf{w}_o = \arg \min_{\mathbf{w}} E\{(d - \mathbf{w}^T \boldsymbol{\phi})^2\}. \quad (12.47)$$

We omitted the dependence of the variables on  $n$  to lighten the notation. Note that, in general,  $\mathbf{w}_o$  will also depend on  $n$ .

To solve this problem, we use the facts that  $\mathbf{w}^T \boldsymbol{\phi} = \boldsymbol{\phi}^T \mathbf{w}$  to expand the expected value

$$J(\mathbf{w}) \stackrel{\Delta}{=} E\left\{\left(d - \mathbf{w}^T \boldsymbol{\phi}\right)^2\right\} = E\{d^2\} - 2\mathbf{w}^T E\{d\boldsymbol{\phi}\} + \mathbf{w}^T E\{\boldsymbol{\phi}\boldsymbol{\phi}^T\}\mathbf{w}.$$

Recall that the weight vector  $\mathbf{w}$  is *not* random, so we can take it out of the expectations.

Define the autocorrelation of  $d$ , and also the cross-correlation vector and autocorrelation matrix

$$r_d = E\{d^2\}, \quad \mathbf{r}_{d\boldsymbol{\phi}} = E\{d\boldsymbol{\phi}\}, \quad \mathbf{R}_{\boldsymbol{\phi}} = E\{\boldsymbol{\phi}\boldsymbol{\phi}^T\}. \quad (12.48)$$

The cost function then becomes

$$J(\mathbf{w}) = r_d - 2\mathbf{w}^T \mathbf{r}_{d\boldsymbol{\phi}} + \mathbf{w}^T \mathbf{R}_{\boldsymbol{\phi}} \mathbf{w}. \quad (12.49)$$

Differentiating  $J(\mathbf{w})$  with respect to  $\mathbf{w}$ , we obtain

$$\frac{\partial J}{\partial \mathbf{w}^T} = -2\mathbf{r}_{d\boldsymbol{\phi}} + 2\mathbf{R}_{\boldsymbol{\phi}} \mathbf{w},$$

and equating the result to zero, we see that the optimal solution must satisfy

$$\mathbf{R}_{\boldsymbol{\phi}} \mathbf{w}_o = \mathbf{r}_{d\boldsymbol{\phi}}. \quad (12.50)$$

These are known as the *normal*, or *Wiener-Hopf*, equations. The solution,  $\mathbf{w}_o$ , is known as the *Wiener solution*. A note of caution: the Wiener solution is not the same thing as the Wiener filter. The Wiener filter is the linear filter that minimizes the mean-square error, without restriction of filter order [17]. The difference is that the Wiener solution has the filter order pre-specified (and is not restricted to linear filters, as we saw).

When the autocorrelation matrix is non-singular (which is usually the case), the Wiener solution is

$$\mathbf{w}_o = \mathbf{R}_{\phi}^{-1} \mathbf{r}_{d\phi}. \quad (12.51)$$

Given  $\mathbf{w}_o$ , the optimum error will be

$$v_o = d - \mathbf{w}_o^T \phi. \quad (12.52)$$

Note that the expected value of  $v_o$  is not necessarily zero:

$$E\{v_o\} = E\{d\} - \mathbf{w}_o^T E\{\phi\}. \quad (12.53)$$

If, for example,  $E\{\phi\} = \mathbf{0}$  and  $E\{d\} \neq 0$ , then  $E\{v_o\} = E\{d\} \neq 0$ . In practice, it is good to keep  $E\{v_o\} = 0$ , because we usually know that  $v_o$  should approximate a zero-mean signal, such as speech or noise. We will show shortly, in Section 1.12.2.1.4, how to guarantee that  $v_o$  has zero mean.

### 1.12.2.1.1 Orthogonality condition

A key property of the Wiener solution is that the optimum error is orthogonal to the regressor  $\phi$ , that is,

$$E\{v_o \phi\} = E\{\phi(d - \underbrace{\mathbf{w}_o^T \phi}_{= \phi^T \mathbf{w}_o})\} = E\{d\phi\} - E\{\phi \phi^T\} \mathbf{w}_o = \mathbf{r}_{d\phi} - \mathbf{R}_{\phi} \mathbf{w}_o = \mathbf{0}. \quad (12.54)$$

We saw a similar condition in Section 1.12.1.2. It is very useful to remember this result, known as the *orthogonality condition*: from it, we will find when to apply the cost function (12.47) to design an adaptive filter. Note that when  $v_o$  has zero mean, (12.54) also implies that  $v_o$  and  $\phi$  are uncorrelated.

**Remark 1.** You should not confuse orthogonal with uncorrelated. Two random variables  $x$  and  $y$  are orthogonal if  $E\{xy\} = 0$ , whereas they are uncorrelated if  $E\{xy\} = E\{x\} E\{y\}$ . The two concepts coincide only if either  $x$  or  $y$  have zero mean.

**Remark 2.** The orthogonality condition is an intuitive result, if we remember that we can think of the space of random variables with finite variance as a vector space. In fact, define the cross-correlation  $r_{xy} = E\{xy\}$  between two random variables  $x$  and  $y$  as the inner product. Then the autocorrelation of a random variable  $x$ ,  $E\{x^2\}$ , would be interpreted as the square of the “length” of  $x$ . In this case, our problem (12.47) is equivalent to finding the vector in the subspace spanned by  $\phi_0, \dots, \phi_{M-1}$  that is closest to  $d$ . As we know, the solution is such that the error is orthogonal to the subspace. So, the orthogonality condition results from the vector space structure of our problem and the quadratic nature of our cost function. See Figure 12.19.

**Remark 3.** The difference between (12.54) and the corresponding result obtained in Box 4, Eq. (12.105), is that here the optimum error is orthogonal only to the functions  $\phi_i$  of  $x(n), x(n-1), \dots$  that were included in the regressor (and their linear combinations), not to any function, as in (12.105). This is not surprising: in this section the optimization was made only over the functions in class  $\mathcal{F}$ , and in Box 4 we allow any function. Both solutions, (12.106) and (12.51), will be equal if the general solution according to Box 4 is indeed in  $\mathcal{F}$ .

**Remark 4.** The optimal mean-square error is (recall that  $E\{v_o \phi\} = \mathbf{0}$ )

$$\begin{aligned} J_{\min} = r_{v,o} &= E\{v_o^2\} = E\{v_o(d - \mathbf{w}_o^T \phi)\} = E\{v_o d\} \\ &= E\{(d - \mathbf{w}_o^T \phi)d\} = E\{d^2\} - \mathbf{w}_o^T \mathbf{r}_{d\phi} = r_d - \mathbf{r}_{d\phi}^T \mathbf{R}_\phi^{-1} \mathbf{r}_{d\phi}. \end{aligned} \quad (12.55)$$

Now that we have the general solution to (12.47), we turn to the question: for which class of problems is the quadratic cost function adequate?

#### 1.12.2.1.2 Implicit vs. physical models

From (12.54), we see that the fact that we are minimizing the mean-square error between  $d$  and a linear combination of the regressor  $\phi$  induces a model

$$d = \mathbf{w}_o^T \phi + v_o, \quad (12.56)$$

in which  $v_o$  is orthogonal to  $\phi$ . This is not an assumption, as we sometimes see in the literature, but a consequence of the quadratic cost function we chose. In other words, there is always a relation such as (12.56) between any pair  $(d, \phi)$ , as long as both have finite second-order moments. This relation may make sense from a physical analysis of the problem (as we saw in the echo cancellation example), or be simply a consequence of solving (12.47) (see Section 1.12.2.1.3 for examples).

On the other hand, the orthogonality condition allows us to find out when the solution of (12.47) will be able to successfully solve a problem: assume now that we know beforehand, by physical arguments

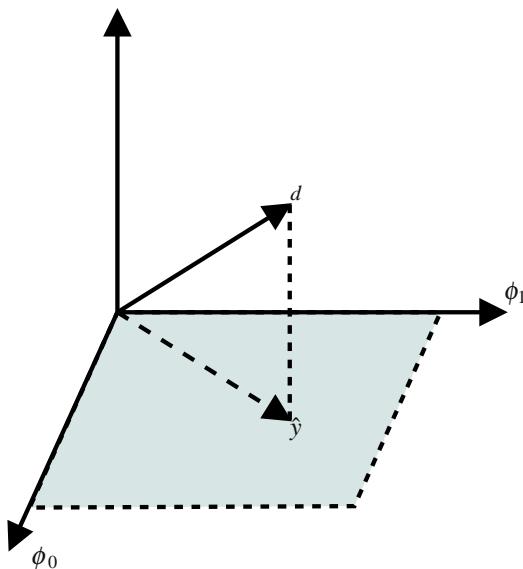

FIGURE 12.19

Orthogonality in vector spaces with inner products.

about the problem, that  $d$  and  $\phi$  must be related through

$$d = \mathbf{w}_*^T \phi + v, \quad (12.57)$$

where  $\mathbf{w}_*$  is a certain coefficient vector and  $v$  is orthogonal to  $\phi$ . Will the solution to (12.47) be such that  $\mathbf{w}_o = \mathbf{w}_*$  and  $v_o = v$ ?

To check if this is the case, we only need to evaluate the cross-correlation vector  $\mathbf{r}_{d\phi}$  assuming the model (12.57):

$$\begin{aligned} \mathbf{r}_{d\phi} &= E\{d\phi\} = E\{\phi(\underbrace{\mathbf{w}_*^T \phi}_{= \phi^T \mathbf{w}_*} + v)\} = E\{\phi\phi^T\}\mathbf{w}_* + \underbrace{E\{\phi v\}}_{= 0} = \mathbf{R}_\phi \mathbf{w}_*. \end{aligned} \quad (12.58)$$

Therefore,  $\mathbf{w}_*$  also obeys the normal equations, and we can conclude that  $\mathbf{w}_o = \mathbf{w}_*$ ,  $v_o = v$ , as long as  $\mathbf{R}_\phi$  is nonsingular.

Even if  $\mathbf{R}_\phi$  is singular, the optimal error  $v_o$  will always be equal to  $v$  (in a certain sense). In fact, if  $\mathbf{R}_\phi$  is singular, then there exists a vector  $a$  such that  $\mathbf{R}_\phi a = \mathbf{0}$  (see Fact 2 in Box 3), and thus any solution  $\mathbf{w}_o$  of the normal equations (we know from (12.58) that there is at least one,  $\mathbf{w}_*$ ) will have the form

$$\mathbf{w}_o = \mathbf{w}_* + a, \quad a \in N(\mathbf{R}_\phi), \quad (12.59)$$

where  $N(\mathbf{R}_\phi)$  is the null-space of  $\mathbf{R}_\phi$ . In addition,

$$0 = a^T \mathbf{R}_\phi a = a^T E\{\phi\phi^T\}a = E\{a^T \phi\phi^T a\} = E\{(a^T \phi)^2\}.$$

Therefore,  $a^T \phi = 0$  with probability one. Then,

$$v_o = d - \mathbf{w}_o^T \phi = d - (\mathbf{w}_* + a)^T \phi = d - \mathbf{w}_*^T \phi,$$

with probability one. Therefore, although we cannot say that  $v = v_o$  always, we can say that they are equal with probability one. In other words, when  $\mathbf{R}_\phi$  is singular we may not be able to identify  $\mathbf{w}_*$ , but (with probability one) we are still able to separate  $d$  into its two components. More about this in Section 1.12.2.1.5.

### 1.12.2.1.3 Undermodeling

We just saw that the solution to the quadratic cost function (12.47) is indeed able to separate the two components of  $d$  when the regressor that appears in physical model (12.57) is the same  $\phi$  that we used to describe our class  $\mathcal{F}$ , that is, when our choice of  $\mathcal{F}$  includes the general solution from Box 4. Let us check now what happens when this is not the case.

Assume there is a relation

$$d = \mathbf{w}_*^T \phi_e + v, \quad (12.60)$$

in which  $v$  is orthogonal to  $\phi_e$ , but our class  $\mathcal{F}$  is defined through a regressor  $\phi$  that is a subset of the “correct” one,  $\phi_e$ . This situation is called *undermodeling*: our class is not rich enough to describe the true relation between  $\{x(n)\}$  and  $\{d(n)\}$ .

Assume then that

$$\phi_e = \begin{bmatrix} \phi \\ \theta \end{bmatrix}, \quad (12.61)$$

where  $\phi \in \mathcal{R}^M$ ,  $\theta \in \mathcal{R}^{K-M}$ , with  $K > M$ . The autocorrelation of  $\phi_e$  is

$$\mathbf{R}_{\phi_e} = E\{\phi_e \phi_e^T\} = \begin{bmatrix} \mathbf{R}_\phi & \mathbf{R}_{\phi\theta} \\ \mathbf{R}_{\theta\phi}^T & \mathbf{R}_\theta \end{bmatrix},$$

where  $\mathbf{R}_{\phi\theta} = E\{\phi\theta^T\}$ . From our hypothesis that  $\phi_e$  is orthogonal to  $v$ , that is,

$$\mathbf{0} = E\{v\phi_e\} = \begin{bmatrix} E\{v\phi\} \\ E\{v\theta\} \end{bmatrix},$$

we conclude that  $\phi$  is also orthogonal to  $v$ , so

$$\mathbf{r}_{d\phi} = E\{\phi(\phi_e^T w_* + v)\} = E\{\phi\phi_e^T\}w_* + \underbrace{E\{\phi v\}}_{=0} = [\mathbf{R}_\phi \ \mathbf{R}_{\phi\theta}]w_*.$$

Assuming that  $\mathbf{R}_\phi$  is nonsingular, solving the normal Eq. (12.50) we obtain

$$\mathbf{w}_o = \mathbf{R}_\phi^{-1} [\mathbf{R}_\phi \ \mathbf{R}_{\phi\theta}] w_* = [I \ \mathbf{R}_\phi^{-1} \mathbf{R}_{\phi\theta}] w_*. \quad (12.62)$$

Now we have two interesting special cases: first, if  $\phi$  and  $\theta$  are orthogonal, i.e., if  $\mathbf{R}_{\phi\theta} = \mathbf{0}$ , then  $\mathbf{w}_o$  contains the first  $M$  elements of  $w_*$ . Let us consider a specific example: assume that

$$\phi = \begin{bmatrix} x(n) \\ x(n-1) \\ \vdots \\ x(n-M+1) \end{bmatrix}, \quad \text{but} \quad \phi_e = \begin{bmatrix} x(n) \\ x(n-1) \\ \vdots \\ x(n-K+1) \end{bmatrix}, \quad (12.63)$$

with  $M < K$ . Then  $\theta = [x(n-M) \dots x(n-K+1)]^T$ . This situation is very common in practice.

In this case,  $\mathbf{R}_{\phi\theta} = \mathbf{0}$  when  $\{x(n)\}$  is zero-mean white noise. This is one reason why white noise is the preferred input to be used in system identification: even in the (very likely in practice) case in which  $M < K$ , at least the first elements of  $w_*$  are identified without bias.

On the other hand, if  $\mathbf{R}_{\phi\theta} \neq \mathbf{0}$ , then  $\mathbf{w}_o$  is a mixture of the elements of  $w_*$ . This happens in (12.63) when the input sequence  $\{x(n)\}$  is not white. In this case, the optimum filter  $\mathbf{w}_o$  takes advantage of the correlation between the entries of  $\phi$  and  $\theta$  to estimate  $\theta$  given  $\phi$ , and uses these estimated values to obtain a better approximation for  $d$ . Sure enough, if you write down the problem of approximating  $\theta$  linearly from  $\phi$ , namely,

$$\mathbf{W}_o = \arg \min_{\mathbf{W}} E \left\{ \left\| \theta - \mathbf{W}^T \phi \right\|^2 \right\},$$

you will see that the solution is exactly  $\mathbf{W}_o = \mathbf{R}_\phi^{-1} \mathbf{R}_{\phi\theta}$ .

What is important to notice is that in both cases the optimum error  $v_o$  is not equal to  $v$ :

$$v_o = d - \mathbf{w}_o^T \boldsymbol{\phi} = \mathbf{w}_*^T \boldsymbol{\phi}_e + v - \mathbf{w}_o^T \boldsymbol{\phi}.$$

Partitioning  $\mathbf{w}_* = [\mathbf{w}_{*,1}^T \mathbf{w}_{*,2}^T]^T$ , with  $\mathbf{w}_{*,1} \in \mathcal{R}^M$ ,  $\mathbf{w}_{*,2} \in \mathcal{R}^{K-M}$ , we have

$$\begin{aligned} v_o &= (\mathbf{w}_{*,1} - \mathbf{w}_o)^T \boldsymbol{\phi} + \mathbf{w}_{*,2}^T \boldsymbol{\theta} + v = \mathbf{w}_{*,2}^T \mathbf{R}_{\boldsymbol{\phi}\boldsymbol{\theta}}^T \mathbf{R}_{\boldsymbol{\phi}}^{-1} \boldsymbol{\phi} + \mathbf{w}_{*,2}^T \boldsymbol{\theta} + v \\ &= \mathbf{w}_{*,2}^T (\boldsymbol{\theta} - \mathbf{R}_{\boldsymbol{\phi}\boldsymbol{\theta}}^T \mathbf{R}_{\boldsymbol{\phi}}^{-1} \boldsymbol{\phi}) + v. \end{aligned}$$

Although  $v_o \neq v$ , you may check that indeed  $E\{v_o \boldsymbol{\phi}\} = \mathbf{0}$ .

As another example, assume that we have two variables such that  $d = ax + bx^3 + v$ , in which  $v$  has zero mean and is independent of  $x$ , and  $a$  and  $b$  are constants. Assume that we choose as regressor simply  $\boldsymbol{\phi} = x$ , so we try to solve

$$w_o = \arg \min_w E \left\{ (d - wx)^2 \right\}.$$

In this case we have

$$R_{\boldsymbol{\phi}} = E\{x^2\}, \quad r_{d\boldsymbol{\phi}} = E\{xd\} = E\{ax^2 + bx^4\},$$

since  $E\{x^k v\} = E\{x^k\}E\{v\} = 0$ . The optimum solution is thus

$$w_o = \frac{aE\{x^2\} + bE\{x^4\}}{E\{x^2\}},$$

and the optimum error is

$$v_o = d - w_o x = ax + bx^3 + v - \frac{aE\{x^2\} + bE\{x^4\}}{E\{x^2\}} x = v + b \left( x^2 - \frac{E\{x^4\}}{E\{x^2\}} \right) x \neq v.$$

However,  $v_o$  is again orthogonal to  $x$  (but not to  $x^3$ , which we did not include in the regressor).

What happens in the opposite situation, when we include more entries in  $\boldsymbol{\phi}$  than necessary? As one would expect, in this case the parameters related to these unnecessary entries will be zeroed in the optimum solution  $\mathbf{w}_o$ . This does not mean, however, that we should hasten to increase  $\boldsymbol{\phi}$  to make  $\mathcal{F}$  as large as possible, and leave to the filter the task of zeroing whatever was not necessary. This is because increasing the number of parameters to be estimated has a cost. The first and more obvious cost is in terms of memory and number of computations. However, we saw in Section 1.12.1.2 that an actual adaptive filter usually does not converge to the exact optimum solution, but rather hovers around it. Because of this, increasing the number of parameters may in fact decrease the quality of the solution. We explain this in more detail in Section 1.12.4.

#### 1.12.2.1.4 Zero and non-zero mean variables

Up to now we did not assume anything about the means of  $d$  and  $\boldsymbol{\phi}$ . If both  $d$  and  $\boldsymbol{\phi}$  have zero mean, we can interpret all autocorrelations as variances or covariance matrices, according to the case. To see this, assume that

$$E\{d\} = 0, \quad E\{\boldsymbol{\phi}\} = \mathbf{0}. \tag{12.64}$$

Then  $E\{\hat{y}\} = E\{\mathbf{w}_o^T \boldsymbol{\phi}\} = 0$ , and thus

$$E\{v_o\} = E\{d\} - \mathbf{w}_o^T E\{\boldsymbol{\phi}\} = 0 + \mathbf{w}_o^T \mathbf{0} = 0,$$

so the optimum error has zero mean. In this case,  $r_d = E\{d^2\} = \sigma_d^2$  is the variance of  $d$ , and  $E\{v_o^2\} = \sigma_{v,o}^2$  is the variance of  $v_o$ , so (12.55) becomes

$$J_{\min} = \sigma_{v,o}^2 = E\{v_o^2\} = \sigma_d^2 - \mathbf{r}_{d\boldsymbol{\phi}}^T \mathbf{R}_{\boldsymbol{\phi}}^{-1} \mathbf{r}_{d\boldsymbol{\phi}}. \quad (12.65)$$

Since  $\mathbf{R}_{\boldsymbol{\phi}}$  is positive-definite, we conclude that the uncertainty in  $v_o$  (its variance) is never larger than the uncertainty in  $d$  (Box 3).

However,  $v_o$  may have a nonzero mean if either  $d$  or  $\boldsymbol{\phi}$  has nonzero mean. This is verified as follows. Define

$$\bar{d} = E\{d\}, \quad \bar{\boldsymbol{\phi}} = E\{\boldsymbol{\phi}\}, \quad (12.66)$$

then

$$E\{v_o\} = E\{d - \mathbf{r}_{d\boldsymbol{\phi}}^T \mathbf{R}_{\boldsymbol{\phi}}^{-1} \boldsymbol{\phi}\} = \bar{d} - \mathbf{r}_{d\boldsymbol{\phi}}^T \mathbf{R}_{\boldsymbol{\phi}}^{-1} \bar{\boldsymbol{\phi}} \neq 0$$

in general (for example, if  $\bar{\boldsymbol{\phi}} = \mathbf{0}$ , but  $\bar{d} \neq 0$ ).

In many applications,  $v_o$  should approximate some signal that is constrained to have zero mean, such as speech or noise, or because  $v_o$  will be passed through a system with a high DC gain (such as an integrator), so it may be useful to guarantee that  $v_o$  has zero mean. How can this be done if the means of  $d$  and  $\boldsymbol{\phi}$  are not zero? This problem is quite common, particularly when  $\boldsymbol{\phi}$  includes nonlinear functions of  $x(n)$ . Fortunately, there are two easy solutions: First, if one knew the means of  $d$  and  $\boldsymbol{\phi}$ , one could define zero-mean variables

$$d_c = d - E\{d\}, \quad \boldsymbol{\phi}_c = \boldsymbol{\phi} - E\{\boldsymbol{\phi}\}, \quad (12.67)$$

and use them instead of the original variables in (12.47). This is the simplest solution, but we often do not know the means  $\bar{d}$  and  $\bar{\boldsymbol{\phi}}$ .

The second solution is used when the means are not known: simply add an extra term to  $\boldsymbol{\phi}$ , defining an extended regressor (not to be confused with the extended regressor from Section 1.12.2.1.3)

$$\boldsymbol{\phi}_e = \begin{bmatrix} 1 \\ \boldsymbol{\phi} \end{bmatrix}, \quad (12.68)$$

and an extended weight vector  $\mathbf{w}_e \in \mathcal{R}^{M+1}$ . The first coefficient of  $\mathbf{w}_e$  will take care of the means, as we show next. The extended cross-correlation vector and autocorrelation matrix are

$$\mathbf{r}_{d\boldsymbol{\phi}_e} = \begin{bmatrix} \bar{d} \\ \mathbf{r}_{d\boldsymbol{\phi}} \end{bmatrix}, \quad \mathbf{R}_{\boldsymbol{\phi}_e} = \begin{bmatrix} 1 & \bar{\boldsymbol{\phi}}^T \\ \bar{\boldsymbol{\phi}} & \mathbf{R}_{\boldsymbol{\phi}} \end{bmatrix}.$$

Assuming that  $\mathbf{R}_{\phi_e}$  and  $\mathbf{R}_\phi$  are nonsingular, we can compute  $\mathbf{w}_{o,e}$  if we evaluate the inverse of  $\mathbf{R}_{\phi_e}$  using Schur complements (See Fact 3 in Box 3), as follows

$$\begin{aligned}\mathbf{w}_{o,e} &= \mathbf{R}_{\phi_e}^{-1} \mathbf{r}_{d\phi_e} \\ &= \begin{bmatrix} 1 & \mathbf{0}^T \\ -\mathbf{R}_\phi^{-1} \bar{\phi} & \mathbf{I} \end{bmatrix} \begin{bmatrix} (1 - \bar{\phi}^T \mathbf{R}_\phi^{-1} \bar{\phi})^{-1} & \mathbf{0}^T \\ \mathbf{0} & \mathbf{R}_\phi^{-1} \end{bmatrix} \begin{bmatrix} 1 - \bar{\phi}^T \mathbf{R}_\phi^{-1} \\ \mathbf{0} & \mathbf{I} \end{bmatrix} \begin{bmatrix} \bar{d} \\ \mathbf{r}_{d\phi} \end{bmatrix} \\ &= \begin{bmatrix} 1 & \mathbf{0}^T \\ -\mathbf{R}_\phi^{-1} \bar{\phi} & \mathbf{I} \end{bmatrix} \begin{bmatrix} (1 - \bar{\phi}^T \mathbf{R}_\phi^{-1} \bar{\phi})^{-1} & \mathbf{0}^T \\ \mathbf{0} & \mathbf{R}_\phi^{-1} \end{bmatrix} \begin{bmatrix} \bar{d} - \bar{\phi}^T \mathbf{R}_\phi^{-1} \mathbf{r}_{d\phi} \\ \mathbf{r}_{d\phi} \end{bmatrix} \\ &= \begin{bmatrix} 1 & \mathbf{0}^T \\ -\mathbf{R}_\phi^{-1} \bar{\phi} & \mathbf{I} \end{bmatrix} \begin{bmatrix} \frac{\bar{d} - \bar{\phi}^T \mathbf{R}_\phi^{-1} \mathbf{r}_{d\phi}}{1 - \bar{\phi}^T \mathbf{R}_\phi^{-1} \bar{\phi}} \\ \mathbf{R}_\phi^{-1} \mathbf{r}_{d\phi} \end{bmatrix} = \begin{bmatrix} \frac{\bar{d} - \bar{\phi}^T \mathbf{R}_\phi^{-1} \mathbf{r}_{d\phi}}{1 - \bar{\phi}^T \mathbf{R}_\phi^{-1} \bar{\phi}} \\ \mathbf{R}_\phi^{-1} \mathbf{r}_{d\phi} - \frac{\bar{d} - \bar{\phi}^T \mathbf{R}_\phi^{-1} \mathbf{r}_{d\phi}}{1 - \bar{\phi}^T \mathbf{R}_\phi^{-1} \bar{\phi}} \mathbf{R}_\phi^{-1} \bar{\phi} \end{bmatrix}.\end{aligned}$$

Using this result, we can evaluate now  $E\{v_{o,e}\} = E\{d\} - \mathbf{w}_{o,e}^T E\{\phi_e\}$  as follows (we used the fact that the inverse of a symmetric matrix is also symmetric from Box 3):

$$\begin{aligned}E\{v_{o,e}\} &= \bar{d} - \frac{\bar{d} - \bar{\phi}^T \mathbf{R}_\phi^{-1} \mathbf{r}_{d\phi}}{1 - \bar{\phi}^T \mathbf{R}_\phi^{-1} \bar{\phi}} - \mathbf{r}_{d\phi}^T \mathbf{R}_\phi^{-1} \bar{\phi} + \frac{\bar{d} - \bar{\phi}^T \mathbf{R}_\phi^{-1} \mathbf{r}_{d\phi}}{1 - \bar{\phi}^T \mathbf{R}_\phi^{-1} \bar{\phi}} \bar{\phi}^T \mathbf{R}_\phi^{-1} \bar{\phi} \\ &= \bar{d} - \mathbf{r}_{d\phi}^T \mathbf{R}_\phi^{-1} \bar{\phi} - \frac{\bar{d} - \bar{\phi}^T \mathbf{R}_\phi^{-1} \mathbf{r}_{d\phi}}{1 - \bar{\phi}^T \mathbf{R}_\phi^{-1} \bar{\phi}} (1 - \bar{\phi}^T \mathbf{R}_\phi^{-1} \bar{\phi}) = 0.\end{aligned}$$

### 1.12.2.1.5 Sufficiently rich signals

We saw in Section 1.12.2.1.2 that even when  $\mathbf{R}_\phi$  is singular, we can recover the optimum  $v_o$  (with probability one), but not the optimum  $\mathbf{w}_*$ . Let us study this problem in more detail, since it is important for system identification. So, what does it mean in practice to have a singular autocorrelation function  $\mathbf{R}_\phi$ ? The answer to this question can be quite complicated when the input signals are nonstationary (i.e., when  $\mathbf{R}_\phi$  is not constant), so in this case we refer the interested reader to texts in adaptive control (such as [18]), which treat this problem in detail (although usually from a deterministic point of view). We consider here only the case in which the signals  $\{d(n), x(n)\}$  are jointly wide-sense stationary.

In this case,  $\mathbf{R}_\phi$  may be singular because some entries of  $\phi$  are linear combinations of the others. For example, if we choose  $\phi_0 = x(n)$  and  $\phi_1 = 2x(n)$ , then

$$\mathbf{R}_\phi = E\{x^2(n)\} \begin{bmatrix} 1 & 2 \\ 2 & 4 \end{bmatrix},$$

which is singular.

However, there are more subtle ways in which  $\mathbf{R}_\phi$  may become singular. Assume for example that our input sequence is given by

$$x(n) = \cos(\omega_0 n + \varphi), \quad (12.69)$$

where  $0 < \omega_0 \leq \pi$  is the frequency, and  $\varphi$  is a random phase, uniformly distributed in the interval  $[0, 2\pi)$ . This kind of model (sinusoidal signals with random phases), by the way, is the bridge between the periodic signals from Section 1.12.1.2 and the stochastic models discussed in this section. In this case, consider a vector  $\phi$  formed from a delay line with  $x(n)$  as input,

$$\phi = [x(n) \ x(n-1) \ \dots \ x(n-M+1)]^T.$$

If  $M = 2$ , we have

$$\mathbf{R}_\phi = \begin{bmatrix} E\{x^2(n)\} & E\{x(n)x(n-1)\} \\ E\{x(n)x(n-1)\} & E\{x^2(n-1)\} \end{bmatrix} = \frac{1}{2} \begin{bmatrix} 1 & \cos(\omega_0) \\ \cos(\omega_0) & 1 \end{bmatrix}.$$

The determinant of  $\mathbf{R}_\phi$  is  $1 - \cos^2(\omega_0) = \sin^2(\omega_0) \neq 0$  if  $\omega_0 \neq 0$  and  $\omega_0 \neq \pi$ .

However, for any  $M \geq 3$ , the resulting  $\mathbf{R}_\phi$  will be singular: we can write

$$\phi = \frac{1}{2} e^{j(\omega_0 n + \varphi)} \begin{bmatrix} 1 \\ e^{-j\omega_0} \\ \vdots \\ e^{-j(M-1)\omega_0} \end{bmatrix} + \frac{1}{2} e^{-j(\omega_0 n + \varphi)} \begin{bmatrix} 1 \\ e^{j\omega_0} \\ \vdots \\ e^{j(M-1)\omega_0} \end{bmatrix},$$

and since  $E\{(e^{j\omega_0 n + j\varphi})^2\} = E\{e^{j2(\omega_0 n + \varphi)}\} = 0$ ,  $E\{e^{j(\omega_0 n + \varphi)}e^{-j(\omega_0 n + \varphi)}\} = 1$ , we have

$$\begin{aligned} \mathbf{R}_\phi &= \frac{1}{4} \begin{bmatrix} 1 \\ e^{-j\omega_0} \\ \vdots \\ e^{-j(M-1)\omega_0} \end{bmatrix} \begin{bmatrix} 1 & e^{j\omega_0} & \dots & e^{j(M-1)\omega_0} \end{bmatrix} \\ &\quad + \frac{1}{4} \begin{bmatrix} 1 \\ e^{j\omega_0} \\ \vdots \\ e^{j(M-1)\omega_0} \end{bmatrix} \begin{bmatrix} 1 & e^{-j\omega_0} & \dots & e^{-j(M-1)\omega_0} \end{bmatrix}. \end{aligned}$$

Since  $\mathbf{R}_\phi$  is the sum of two rank-one matrices, its rank is at most two. It will be two when  $0 < \omega_0 < \pi$ , since in this case the vectors are linearly independent. We conclude that when the input signal is a sinusoid as in (12.69), the optimum solution to (12.47) will never be able to identify more than two coefficients. This argument can be generalized: if  $x(n)$  is composed of  $K$  sinusoids of different frequencies, then  $\mathbf{R}_\phi$  will be nonsingular if and only if  $M \leq 2K$ .

The general conclusion is that  $\mathbf{R}_\phi$  will be singular or not, depending on which functions are chosen as inputs, and on the input signal. We say that the input is *sufficiently rich* for a given problem if it is such that  $\mathbf{R}_\phi$  is nonsingular. We show a few examples next.

### 1.12.2.1.6 Examples

The concepts we saw in Sections 1.12.2.1.2–1.12.2.1.5 can be understood intuitively if we return to our example in Section 1.12.1.2. In that example, the true echo was obtained by filtering the input  $x(n)$  by

an unknown  $H(z)$ , so we had

$$d(n) = \sum_{k=0}^K h_k x(n-k) + v(n),$$

where  $K$  is the true order of the echo path,  $v(n) = B \cos(\omega_1 n + \theta)$  and  $x(n) = A \cos(\omega_0 n + \varphi)$ . We considered only one harmonic for simplicity.

We are trying to cancel the echo, by constructing an approximated transfer function  $\hat{H}(z)$ , which is modeled as an FIR filter with  $M$  coefficients. As we saw in Section 1.12.1.2, if  $x(n)$  is a simple sinusoid, the echo will be completely canceled if we satisfy (12.8), reproduced below

$$\operatorname{Re}\{\hat{H}(e^{j\omega_0})\} = \operatorname{Re}\{H(e^{j\omega_0})\}, \quad \operatorname{Im}\{\hat{H}(e^{j\omega_0})\} = \operatorname{Im}\{H(e^{j\omega_0})\}.$$

If  $K = M = 1$ , so  $H(z) = h_0 + h_1 z^{-1}$  and  $\hat{H}(z) = w_0 + w_1 z^{-1}$ , this condition becomes

$$\begin{aligned} w_0 + w_1 \cos(-\omega_0) &= h_0 + h_1 \cos(-\omega_0), \\ w_1 \sin(-\omega_0) &= h_1 \sin(-\omega_0), \end{aligned}$$

with a single solution  $w_0 = h_0$ ,  $w_1 = h_1$ .

On the other hand, if the input were as before (a single sinusoid), but  $K = 2$ , so  $H(z) = h_0 + h_1 z^{-1} + h_2 z^{-2}$ , the equations would be

$$\begin{aligned} w_0 + w_1 \cos(-\omega_0) &= h_0 + h_1 \cos(-\omega_0) + h_2 \cos(-2\omega_0), \\ w_1 \sin(-\omega_0) &= h_1 \sin(-\omega_0) + h_2 \sin(-2\omega_0), \end{aligned}$$

and the solution would be unique (since  $\mathbf{R}_\phi$  is nonsingular), but would not approximate  $h_0$  and  $h_1$  in general.

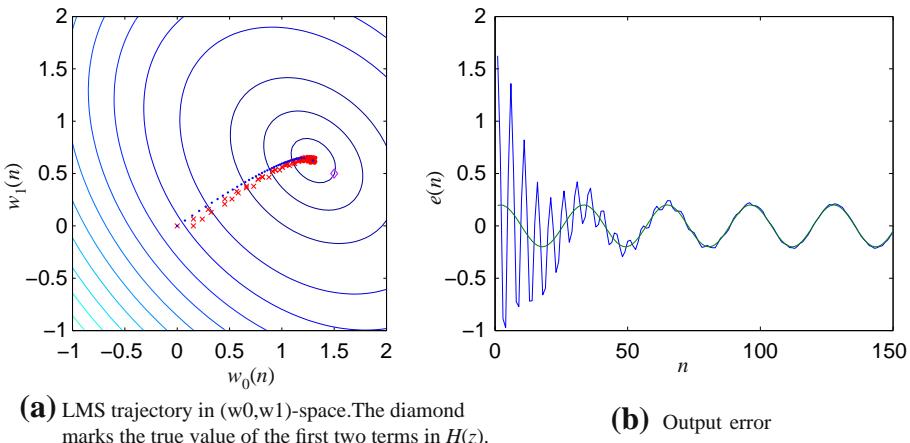

This is an example of an undermodeled system, as we saw in Section 1.12.2.1.3. Figure 12.20 shows the LMS algorithm derived in Section 1.12.1.2 applied to this problem. Note that, even though  $w_0(n)$ ,  $w_1(n)$  do not converge to  $h_0$ ,  $h_1$ , in this example the error  $e(n)$  does approximate well  $v(n)$ . This happens because in this case  $x(n)$  is periodic, and the term  $x(n-2)$  can be obtained exactly as a linear combination of  $x(n)$  and  $x(n-1)$  (Check that using the expressions for  $v_0$  from Section 1.12.2.1.3, we obtain  $v_0 = v$  in this case.)

If we tried to identify  $H(z)$  by adding an extra coefficient to  $\hat{H}(z)$ , the equations would be

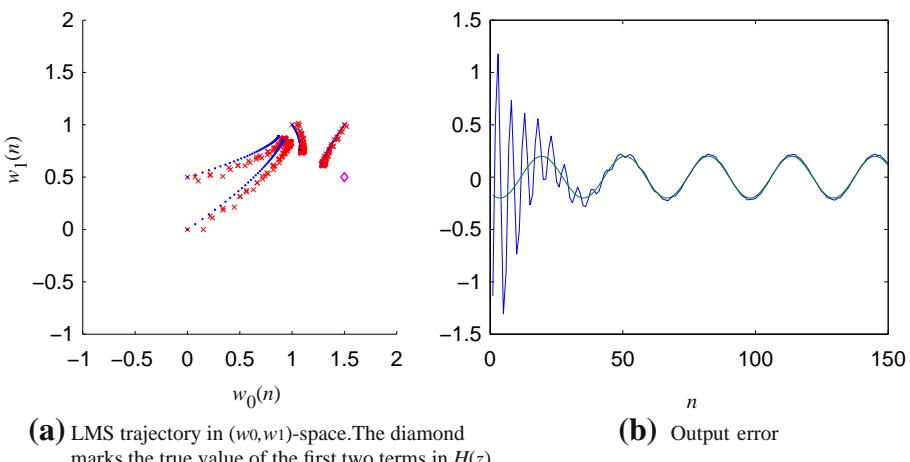

$$\begin{aligned} w_0 + w_1 \cos(-\omega_0) + w_2 \cos(-2\omega_0) &= h_0 + h_1 \cos(-\omega_0) + h_2 \cos(-2\omega_0), \\ w_1 \sin(-\omega_0) + w_2 \sin(-2\omega_0) &= h_1 \sin(-\omega_0) + h_2 \sin(-2\omega_0). \end{aligned} \tag{12.70}$$

Now  $w_0 = h_0$ ,  $w_1 = h_1$ , and  $w_2 = h_2$  is a solution, but not the only one. Depending on the initial condition, the filter would converge to a different solution, as can be seen in Figure 12.21 (the level sets are not shown, because they are not closed curves in this case). The input is not rich enough (in harmonics) to excite the unknown system  $H(z)$  so that the adaptive filter might identify it, as we saw in Section 1.12.2.1.5. However, for all solutions the error converges to  $v(n)$ .

If the input had a second harmonic ( $K_0 = 2$ ), we would add two more equations to (12.70), corresponding to  $\hat{H}(e^{2j\omega_0}) = H(e^{2j\omega_0})$ , and the filter would be able to identify systems with up to four coefficients.

**FIGURE 12.20**

LMS in undermodeled case.

**FIGURE 12.21**

LMS under non-sufficiently rich input.

The important message is that the adaptive filter only “sees” the error  $d(n) - \hat{y}(n)$ . If a mismatch between the true echo path  $H(z)$  and the estimated one  $\hat{H}(z)$  is not observable through looking only at the error signal, the filter will not converge to  $H(z)$ . Whether a mismatch is observable or not through the error depends on both  $H(z)$  and the input signal being used: the input must excite a large enough

number of frequencies so that  $H(z)$  can be estimated correctly. For this reason, in system identification a good input would be white noise.

### 1.12.2.2 Complex variables and multi-channel filtering

Adaptive filters used in important applications such as communications and radar have complex variables as input signals. In this section, we extend the results of Section 1.12.2.1 to consider complex signals. We start with the general solution, then restrict the result to the more usual case of circular signals.

We first show that the general solution for complex signals is equivalent to an adaptive filter with two inputs and two outputs: Indeed, if all input variables are complex, then the error  $e(n) = d(n) - \hat{y}(n)$  will also be complex, that is,  $e(n) = e_r(n) + j e_i(n)$ , where  $e_r(n), e_i(n) \in \mathcal{R}$  are the real and imaginary parts of  $e(n)$ . We must then minimize  $E\{|e(n)|^2\} = E\{e_r^2(n)\} + E\{e_i^2(n)\}$ , the total power of the complex signal  $e(n)$ . The quadratic cost function (12.45) must be changed to

$$J(\mathbf{w}) = E\{|e(n)|^2\} = E\{e(n)e^*(n)\} = E\{e_r^2(n)\} + E\{e_i^2(n)\},$$

where  $e^*(n)$  is the complex conjugate of  $e(n)$ . Now, we need to be careful about what exactly is the coefficient vector  $\mathbf{w}$  in this case: If the regressor is  $\phi = \phi_r + j\phi_i$  and  $d = d_r + j d_i$ , in principle  $\hat{y} = \hat{y}_r + j\hat{y}_i$  should be such that both its real and imaginary parts depend on both the real and imaginary parts of  $\phi$ , that is,

$$\begin{aligned}\hat{y}_r &= \mathbf{w}_{rr}^T \phi_r + \mathbf{w}_{ri}^T \phi_i, \\ \hat{y}_i &= \mathbf{w}_{ir}^T \phi_r + \mathbf{w}_{ii}^T \phi_i.\end{aligned}\quad (12.71)$$

Note that there is no *a priori* reason for us to imagine that there should be a special relation between the pairs  $(\mathbf{w}_{rr}, \mathbf{w}_{ri})$  and  $(\mathbf{w}_{ir}, \mathbf{w}_{ii})$ . That is, we are dealing with two different coefficient vectors and one extended regressor:

$$\mathbf{w}_r = \begin{bmatrix} \mathbf{w}_{rr} \\ \mathbf{w}_{ri} \end{bmatrix}, \quad \mathbf{w}_i = \begin{bmatrix} \mathbf{w}_{ir} \\ \mathbf{w}_{ii} \end{bmatrix}, \quad \boldsymbol{\theta} = \begin{bmatrix} \phi_r \\ \phi_i \end{bmatrix}. \quad (12.72)$$

Let us proceed for the time being separating the real and imaginary channels of our filter. Later, in Section 1.12.2.2.1, we return to complex algebra. With these definitions, we can write

$$\hat{y}_r = \mathbf{w}_r^T \boldsymbol{\theta}, \quad \hat{y}_i = \mathbf{w}_i^T \boldsymbol{\theta}. \quad (12.73)$$

The cost function then becomes

$$\begin{aligned}J(\mathbf{w}_r, \mathbf{w}_i) &= E\{(d_r - \mathbf{w}_r^T \boldsymbol{\theta})^2\} + E\{(d_i - \mathbf{w}_i^T \boldsymbol{\theta})^2\} \\ &= E\{d_r^2 - 2\mathbf{w}_r^T \boldsymbol{\theta} d_r + \mathbf{w}_r^T \boldsymbol{\theta} \boldsymbol{\theta}^T \mathbf{w}_r\} + E\{d_i^2 - 2\mathbf{w}_i^T \boldsymbol{\theta} d_i + \mathbf{w}_i^T \boldsymbol{\theta} \boldsymbol{\theta}^T \mathbf{w}_i\} \\ &= r_{d_r} - 2\mathbf{w}_r^T \mathbf{r}_{d_r \boldsymbol{\theta}} + \mathbf{w}_r^T \mathbf{R}_{\boldsymbol{\theta}} \mathbf{w}_r + r_{d_i} - 2\mathbf{w}_i^T \mathbf{r}_{d_i \boldsymbol{\theta}} + \mathbf{w}_i^T \mathbf{R}_{\boldsymbol{\theta}} \mathbf{w}_i,\end{aligned}\quad (12.74)$$

where the autocorrelation matrix and cross-correlation vectors are given by

$$\mathbf{R}_{\boldsymbol{\theta}} = \begin{bmatrix} \mathbf{R}_r & \mathbf{R}_{ri} \\ \mathbf{R}_{ir} & \mathbf{R}_i \end{bmatrix}, \quad \mathbf{r}_{d_r \boldsymbol{\theta}} = \begin{bmatrix} \mathbf{r}_{rr} \\ \mathbf{r}_{ri} \end{bmatrix}, \quad \mathbf{r}_{d_i \boldsymbol{\theta}} = \begin{bmatrix} \mathbf{r}_{ir} \\ \mathbf{r}_{ii} \end{bmatrix}, \quad (12.75)$$

where we simplified the notation, writing  $\mathbf{R}_r$  instead of  $\mathbf{R}_{\phi_r}$ ,  $\mathbf{R}_{ri}$  instead of  $\mathbf{R}_{\phi_r \phi_i}$ ,  $\mathbf{r}_{rr}$  instead of  $\mathbf{r}_{d_r \phi_r}$ , and so on.

Differentiating (12.74) to find the minimum, we obtain

$$\frac{\partial J}{\partial \mathbf{w}_r^T} = -2\mathbf{r}_{d_r \theta} + 2\mathbf{R}_\theta \mathbf{w}_r, \quad \frac{\partial J}{\partial \mathbf{w}_i^T} = -2\mathbf{r}_{d_i \theta} + 2\mathbf{R}_\theta \mathbf{w}_i. \quad (12.76)$$

Therefore, the optimum filters satisfy

$$\begin{bmatrix} \mathbf{R}_r & \mathbf{R}_{ri} \\ \mathbf{R}_{ir} & \mathbf{R}_i \end{bmatrix} \begin{bmatrix} \mathbf{w}_{rr,o} \\ \mathbf{w}_{ri,o} \end{bmatrix} = \begin{bmatrix} \mathbf{r}_{rr} \\ \mathbf{r}_{ri} \end{bmatrix}, \quad \begin{bmatrix} \mathbf{R}_r & \mathbf{R}_{ri} \\ \mathbf{R}_{ir} & \mathbf{R}_i \end{bmatrix} \begin{bmatrix} \mathbf{w}_{ir,o} \\ \mathbf{w}_{ii,o} \end{bmatrix} = \begin{bmatrix} \mathbf{r}_{ir} \\ \mathbf{r}_{ii} \end{bmatrix}. \quad (12.77)$$

The optimum error is then

$$v_{r,o} = d_r - [\mathbf{w}_{rr,o}^T \mathbf{w}_{ri,o}^T] \boldsymbol{\theta}, \quad v_{i,o} = d_i - [\mathbf{w}_{ir,o}^T \mathbf{w}_{ii,o}^T] \boldsymbol{\theta}. \quad (12.78)$$

There is also an orthogonality condition for this case: using (12.77), we obtain

$$\mathbb{E}\{v_{r,o} \boldsymbol{\theta}\} = \mathbb{E}\{d_r \boldsymbol{\theta}\} - \mathbb{E}\{\boldsymbol{\theta} \boldsymbol{\theta}^T\} \begin{bmatrix} \mathbf{w}_{rr,o} \\ \mathbf{w}_{ri,o} \end{bmatrix} = \mathbf{0}, \quad (12.79a)$$

$$\mathbb{E}\{v_{i,o} \boldsymbol{\theta}\} = \mathbb{E}\{d_i \boldsymbol{\theta}\} - \mathbb{E}\{\boldsymbol{\theta} \boldsymbol{\theta}^T\} \begin{bmatrix} \mathbf{w}_{ir,o} \\ \mathbf{w}_{ii,o} \end{bmatrix} = \mathbf{0}. \quad (12.79b)$$

The value of the cost function at the minimum can be obtained using this result. As in the case of real variables,

$$\begin{aligned} \mathbb{E}\{v_{r,o}^2\} &= \mathbb{E}\{v_{r,o} (d_r - [\mathbf{w}_{rr,o}^T \mathbf{w}_{ri,o}^T] \boldsymbol{\theta})\} \\ &= \mathbb{E}\{v_{r,o} d_r\} = \mathbb{E}\{d_r^2\} - [\mathbf{w}_{rr,o}^T \mathbf{w}_{ri,o}^T] \mathbb{E}\{d_r \boldsymbol{\theta}\}, \end{aligned}$$

where we used (12.79a) in the second equality. Doing similarly for  $v_{i,o}$ , we obtain

$$r_{v_{r,o}} = \mathbb{E}\{v_{r,o}^2\} = r_{d_r} - [\mathbf{w}_{rr,o}^T \mathbf{w}_{ri,o}^T] \mathbf{r}_{d_r \theta}, \quad (12.80a)$$

$$r_{v_{i,o}} = \mathbb{E}\{v_{i,o}^2\} = r_{d_i} - [\mathbf{w}_{ir,o}^T \mathbf{w}_{ii,o}^T] \mathbf{r}_{d_i \theta}, \quad (12.80b)$$

$$J_{\min} = r_{v_{r,o}} + r_{v_{i,o}}. \quad (12.80c)$$

What we have just described is a two-input/two-output optimal filter. In the next section, we re-derive it using complex algebra. Note that multi-channel filters have applications that are unrelated to complex variables, particularly in control [18], stereo echo cancellation [19, 20], and active noise control [21–24].

### 1.12.2.2.1 Widely-linear complex least-mean squares

This general solution can be obtained in a more straightforward way if we use the complex gradients described in Box 6. Keeping the regressor  $\boldsymbol{\theta}$  as in (12.72) and defining the extended complex weight vector as  $\boldsymbol{\omega} = \mathbf{w}_r + j\mathbf{w}_i$ , we can write the cost function as

$$J(\boldsymbol{\omega}) = \mathbb{E}\{(d - \boldsymbol{\omega}^H \boldsymbol{\theta})(d - \boldsymbol{\omega}^H \boldsymbol{\theta})^*\} = r_d - \boldsymbol{\omega}^H \mathbf{r}_{d\theta} - \mathbf{r}_{d\theta}^H \boldsymbol{\omega} + \boldsymbol{\omega}^H \mathbf{R}_\theta \boldsymbol{\omega},$$

where we defined  $r_d = E\{|d|^2\}$  and  $\mathbf{r}_{d\theta} = E\{d^*\boldsymbol{\theta}\}$ . Note that  $(\cdot)^H$  represents the Hermitian transpose, that is, transpose followed by conjugation. Differentiating  $J(\boldsymbol{\omega})$  with respect to  $\boldsymbol{\omega}^H$ , as described in Box 6, we obtain

$$\frac{\partial J}{\partial \boldsymbol{\omega}^H} = -\mathbf{r}_{d\theta} + \mathbf{R}_\theta \boldsymbol{\omega}. \quad (12.81)$$

The normal equations then become

$$\mathbf{R}_\theta \boldsymbol{\omega}_0 = \mathbf{r}_{d\theta}. \quad (12.82)$$

Expanding the real and imaginary parts of (12.82), we recover (12.77). Similarly, the optimum error and the minimum value of the cost are

$$v_0 = d - \boldsymbol{\omega}_0^H \boldsymbol{\theta}, \quad J_{\min} = E\{|v_0|^2\} = E\{|d|^2\} - \boldsymbol{\omega}_0^H \mathbf{r}_{d\theta}. \quad (12.83)$$

Comparing with (12.80), we see that  $v_0 = v_{r,o} + j v_{i,o}$ , and the value of  $J_{\min}$  is the same as before. However, as you noticed, using a complex weight vector  $\boldsymbol{\omega}$  and the complex derivatives of Box 6, all expressions are much simpler to derive.

The filter using a complex weight vector  $\boldsymbol{\omega}$  and the real regressor  $\boldsymbol{\theta}$  constitutes a version of what is known as *widely-linear* complex filter. This version was recently proposed in [25] as a reduced-complexity alternative to the widely-linear complex filter originally proposed in [26, 27], which uses as regressor the extended vector

$$\boldsymbol{\phi}_e = \begin{bmatrix} \boldsymbol{\phi} \\ \boldsymbol{\phi}^* \end{bmatrix}, \quad (12.84)$$

composed of the original regressor  $\boldsymbol{\phi}$  and its complex conjugate  $\boldsymbol{\phi}^*$  (computational complexity is reduced because the number of operations required to compute  $\boldsymbol{\omega}^H \boldsymbol{\theta}$  is about half of what is necessary to evaluate  $\boldsymbol{\omega}^H \boldsymbol{\phi}_e$ ). Widely-linear estimation has been receiving much attention lately, due to new applications that have appeared [28–31].

But why the name *widely linear*? The reason for this name is that the complex regressor  $\boldsymbol{\phi}$  does not appear linearly in the expressions, but only by separating its real and imaginary parts (as in  $\boldsymbol{\theta}$ ) or by including its complex conjugate (as in  $\boldsymbol{\phi}_e$ ). Both these expressions, from the point of view of a complex variable, are nonlinear.

What would be a *linear* complex filter, then? This is the subject of the next section.

### 1.12.2.2 Linear complex least-mean squares

There are many applications in which the data and regressor are such that their real and imaginary parts are similarly distributed, so that

$$\mathbf{R}_r = \mathbf{R}_i, \quad r_{dr} = r_{di}, \quad \mathbf{R}_{ri} = -\mathbf{R}_{ir}, \quad \mathbf{r}_{rr} = \mathbf{r}_{ii}, \quad \mathbf{r}_{ri} = -\mathbf{r}_{ir}. \quad (12.85)$$

Under these conditions, we say that the pair  $(d, \boldsymbol{\phi})$  is *complex circular*, or simply *circular*.

In this case, we can rewrite (12.77) as

$$\begin{bmatrix} \mathbf{R}_r & \mathbf{R}_{ri} \\ -\mathbf{R}_{ri} & \mathbf{R}_r \end{bmatrix} \begin{bmatrix} \mathbf{w}_{rr} \\ \mathbf{w}_{ri} \end{bmatrix} = \begin{bmatrix} \mathbf{r}_{rr} \\ \mathbf{r}_{ri} \end{bmatrix}, \quad \begin{bmatrix} \mathbf{R}_r & \mathbf{R}_{ri} \\ -\mathbf{R}_{ri} & \mathbf{R}_r \end{bmatrix} \begin{bmatrix} \mathbf{w}_{ir} \\ \mathbf{w}_{ii} \end{bmatrix} = \begin{bmatrix} -\mathbf{r}_{ri} \\ \mathbf{r}_{rr} \end{bmatrix}.$$

Expand these equations as follows (notice the change in order in (12.86b))

$$\mathbf{R}_r \mathbf{w}_{rr} + \mathbf{R}_{ri} \mathbf{w}_{ri} = \mathbf{r}_{rr}, \quad -\mathbf{R}_{ri} \mathbf{w}_{rr} + \mathbf{R}_r \mathbf{w}_{ri} = \mathbf{r}_{ri}, \quad (12.86a)$$

$$\mathbf{R}_r \mathbf{w}_{ii} - \mathbf{R}_{ri} \mathbf{w}_{ir} = \mathbf{r}_{rr}, \quad \mathbf{R}_{ri} \mathbf{w}_{ii} + \mathbf{R}_r \mathbf{w}_{ir} = -\mathbf{r}_{ri}. \quad (12.86b)$$

Now we can see that, if  $(\mathbf{w}_{rr}, \mathbf{w}_{ri})$  is a solution to (12.86a), then

$$(\mathbf{w}_{ii} = \mathbf{w}_{rr}, \mathbf{w}_{ir} = -\mathbf{w}_{ri}) \quad (12.87)$$

is a solution to (12.86b). Therefore, when the input signals are circular, the number of degrees of freedom in the problem is actually smaller. In this case, there is a very nice way of recovering the solutions, working only with complex algebra. Indeed, defining  $\mathbf{w} = \mathbf{w}_{rr} + j\mathbf{w}_{ri}$ , we have

$$\begin{aligned} \mathbf{w}^H \boldsymbol{\phi} &= (\mathbf{w}_{rr} - j\mathbf{w}_{ri})^T (\boldsymbol{\phi}_r + j\boldsymbol{\phi}_i) \\ &= \left( \mathbf{w}_{rr}^T \boldsymbol{\phi}_r + \mathbf{w}_{ri}^T \boldsymbol{\phi}_i \right) + j \left( \mathbf{w}_{rr}^T \boldsymbol{\phi}_i - \mathbf{w}_{ri}^T \boldsymbol{\phi}_r \right), \end{aligned} \quad (12.88)$$

which is equivalent to (12.71) with the identities (12.87). Using this definition, it is possible to obtain the optimum solution (12.86a), (12.86b), and (12.87) using only complex algebra, following exactly the same steps as our derivation for the real case in the previous section.

This path is very useful, we can derive almost all results for real or complex circular adaptive filters using the same arguments. Let us see how it goes. First, define  $\hat{y} = \mathbf{w}^H \boldsymbol{\phi}$ , so our problem becomes

$$\min_{\mathbf{w} \in \mathcal{C}^M} E \left\{ |d - \mathbf{w}^H \boldsymbol{\phi}|^2 \right\}. \quad (12.89)$$

Expanding the cost, recalling that now  $|d - \mathbf{w}^H \boldsymbol{\phi}|^2 = (d - \mathbf{w}^H \boldsymbol{\phi})(d - \mathbf{w}^H \boldsymbol{\phi})^* = (d - \mathbf{w}^H \boldsymbol{\phi})(d^* - \boldsymbol{\phi}^H \mathbf{w})$ , we obtain

$$\begin{aligned} J(\mathbf{w}) &= E \left\{ |d|^2 - \mathbf{w}^H \boldsymbol{\phi} d^* - d \boldsymbol{\phi}^H \mathbf{w} + \mathbf{w}^H \boldsymbol{\phi} \boldsymbol{\phi}^H \mathbf{w} \right\} \\ &= r_d - \mathbf{w}^H \mathbf{r}_{d\boldsymbol{\phi}} - \mathbf{r}_{d\boldsymbol{\phi}}^H \mathbf{w} + \mathbf{w}^H \mathbf{R}_{\boldsymbol{\phi}} \mathbf{w}, \end{aligned} \quad (12.90)$$

where we defined  $r_d = E\{|d|^2\}$ ,  $\mathbf{r}_{d\boldsymbol{\phi}} = E\{d^* \boldsymbol{\phi}\}$ ,  $\mathbf{R}_{\boldsymbol{\phi}} = E\{\boldsymbol{\phi} \boldsymbol{\phi}^H\}$ .

We need to find the minimum of this cost. One easy solution is to use the rules for differentiation of real functions of complex variables, as described in Box 6. These rules are very useful, and surprisingly easy to use: basically, we can treat  $\mathbf{w}$  and its conjugate  $\mathbf{w}^H$  as if they were independent variables, that is

$$\frac{\partial J}{\partial \mathbf{w}^H} = -\mathbf{r}_{d\boldsymbol{\phi}} + \mathbf{R}_{\boldsymbol{\phi}} \mathbf{w}. \quad (12.91)$$

Equating the gradient to zero, the solution is (assuming that  $\mathbf{R}_{\boldsymbol{\phi}}$  is nonsingular)

$$\mathbf{w}_o = \mathbf{R}_{\boldsymbol{\phi}}^{-1} \mathbf{r}_{d\boldsymbol{\phi}}, \quad (12.92)$$

which is exactly equal to (12.51). This is the advantage of this approach: the expressions for complex and real problems are *almost* equal. The important differences are the conjugates that appear in the

definitions of  $\mathbf{R}_\phi$  and  $\mathbf{r}_{d\phi}$ , and the absence of a factor of 2 in the gradient (12.91). This follows from the definition of complex derivative we used (see Box 6). Here this difference is canceled out in the solution (12.92), but further on we will find situations in which there will be a different factor for the case of real and for the case of complex variables.

Let us check that (12.92) is really equivalent to (12.86a). Expanding  $\mathbf{R}_\phi$  and  $\mathbf{r}_{d\phi}$  and using the circularity conditions (12.85), we obtain

$$\mathbf{R}_\phi = \mathbb{E}\{\boldsymbol{\phi}\boldsymbol{\phi}^H\} = \mathbb{E}\{(\boldsymbol{\phi}_r + j\boldsymbol{\phi}_i)(\boldsymbol{\phi}_r - j\boldsymbol{\phi}_i)^T\} = \mathbf{R}_r + \mathbf{R}_i + j(\mathbf{R}_{ir} - \mathbf{R}_{ri}), \quad (12.93a)$$

$$= 2\mathbf{R}_r - 2j\mathbf{R}_{ri}, \quad (12.93b)$$

and

$$\begin{aligned} \mathbf{r}_{d\phi} &= \mathbb{E}\{d^*\boldsymbol{\phi}\} = \mathbb{E}\{(d_r - jd_i)(\boldsymbol{\phi}_r + j\boldsymbol{\phi}_i)\} = \mathbf{r}_{rr} + \mathbf{r}_{ii} + j(\mathbf{r}_{ri} - \mathbf{r}_{ir}) \\ &= 2\mathbf{r}_{rr} + 2jr_{ri}, \end{aligned} \quad (12.94)$$

so, equating the gradient (12.91) to zero,  $\mathbf{w}_o = \mathbf{w}_{r,o} + j\mathbf{w}_{i,o}$  must satisfy

$$\begin{aligned} 2(\mathbf{R}_r - j\mathbf{R}_{ri})(\mathbf{w}_{r,o} + j\mathbf{w}_{i,o}) &= 2(\mathbf{r}_{rr} + jr_{ri}), \\ \mathbf{R}_r\mathbf{w}_{r,o} + \mathbf{R}_{ri}\mathbf{w}_{i,o} + j(\mathbf{R}_r\mathbf{w}_{i,o} - \mathbf{R}_{ri}\mathbf{w}_{r,o}) &= \mathbf{r}_{rr} + jr_{ri}. \end{aligned} \quad (12.95)$$

Comparing the real and imaginary parts of (12.95) with (12.86a), we see that they indeed correspond to the same set of equations.

A few important remarks:

**Remark 5.** The orthogonality condition still holds in the complex circular case, but with a small difference: defining the optimum error as before,

$$v_o = d - \mathbf{w}_o^H \boldsymbol{\phi},$$

we obtain, noting that  $(\mathbf{w}_o^H \boldsymbol{\phi})^* = \boldsymbol{\phi}^H \mathbf{w}_o$ ,

$$\mathbb{E}\{v_o^* \boldsymbol{\phi}\} = \mathbb{E}\{d^* \boldsymbol{\phi} - \boldsymbol{\phi} \boldsymbol{\phi}^H \mathbf{w}_o\} = \mathbf{r}_{d\phi} - \mathbf{R}_\phi \mathbf{w}_o = \mathbf{0}. \quad (12.96)$$

**Remark 6.** The complex gradient (12.91) seems strange because it does not include the factors of 2 that would appear in the real case. This difference will appear in many expressions in the following sections, whenever we need to differentiate between the real and complex cases. However, the difference is illusory: if you go back to (12.93b) and (12.94), you will see that the factor of two is actually there, just hidden by the definition of autocorrelation and cross-correlation under the circularity conditions.

**Remark 7.** The optimum error power can be obtained as in the real case, and is equal to

$$\mathbb{E}\{|v_o|^2\} = r_d - \mathbf{w}_o^H \mathbf{r}_{d\phi} = r_d - \mathbf{r}_{d\phi}^H \mathbf{R}_\phi^{-1} \mathbf{r}_{d\phi}. \quad (12.97)$$

---

**Box 4: Least mean-squares estimation**

---

Here we consider the general problem of finding the optimum relation  $\hat{\mathcal{H}}_o$  between  $d(n)$  and  $x(n)$ , such that

$$\hat{\mathcal{H}}_o = \arg \min_{\hat{\mathcal{H}}} E \left\{ d(n) - \hat{\mathcal{H}}(x(n), x(n-1), \dots) \right\}, \quad (12.98)$$

without restricting  $\mathcal{H}$  to a particular class.

In order to understand well this problem, let us consider first the simpler case where the relation between  $x(n)$  and  $d(n)$  is memoryless, that is, our function depends only on the current value of  $x(n)$ . Dropping the time index to simplify the notation, our problem then becomes how to find a function  $\hat{\mathcal{H}}$  that, applied to a certain random variable  $x$ , approximates a certain random variable  $d$  so that the mean-square error is minimized, that is, we want to solve

$$\min_{\hat{\mathcal{H}}} E \{ [d - \hat{\mathcal{H}}(x)]^2 \}. \quad (12.99)$$

Assume that the joint probability density function  $p_{dx}(d, x)$  of  $d$  and  $x$  is known (we are assuming that  $d$  and  $x$  are continuous random variables, but the final result in (12.100) also holds if they are discrete). Then,

$$\begin{aligned} E \{ [d - \hat{\mathcal{H}}(x)]^2 \} &= \int \int [d - \hat{\mathcal{H}}(x)]^2 p_{dx}(d, x) d d dx \\ &= \int \underbrace{\left\{ \int [d - \hat{\mathcal{H}}(x)]^2 p_{d|x}(d|x) d d \right\}}_{E_d \{ [d - \hat{\mathcal{H}}(x)]^2 | x \}} p_x(x) dx \\ &= E_x \left\{ E_d \left\{ [d - \hat{\mathcal{H}}(x)]^2 | x \right\} \right\}, \end{aligned} \quad (12.100)$$

where we use the subscripts  $E_d$  and  $E_x$  to highlight that the expectations are taken with respect to  $d$  or  $x$  only.

Note that the inner integrand  $E_d \{ [d - \hat{\mathcal{H}}(x)]^2 | x \}$  in (12.100) is nonnegative. Therefore, if we minimize it for each value of  $x$ , we will obtain the minimum of the full expression. That is, the optimum  $\hat{\mathcal{H}}_o$  is the function defined by

$$\hat{\mathcal{H}}_o(x) = \arg \min_{\hat{\mathcal{H}}(x)} E_d \left\{ [d - \hat{\mathcal{H}}(x)]^2 | x \right\}. \quad (12.101)$$

It is important to remember that, fixed  $x$ ,  $\hat{\mathcal{H}}(x)$  is simply a number. This can be seen more easily expanding the expectations in (12.101)

$$\begin{aligned} E_d \left\{ [d - \hat{\mathcal{H}}(x)]^2 | x \right\} &= \int (d^2 - 2d\hat{\mathcal{H}}(x) + \hat{\mathcal{H}}^2(x)) p_{d|x}(d|x) dd \\ &= \int d^2 p_{d|x}(d|x) dd - 2\hat{\mathcal{H}}(x) \int dp_{d|x}(d|x) dd + \hat{\mathcal{H}}^2(x) \int p_{d|x}(d|x) dd \\ &= E_d \{ d^2 | x \} - 2E \{ d | x \} \hat{\mathcal{H}}(x) + \hat{\mathcal{H}}^2(x). \end{aligned}$$

Differentiating with respect to  $\hat{\mathcal{H}}(x)$  and equating to zero, we obtain the solution

$$\hat{\mathcal{H}}_o(x) = E_d\{d|x\} \stackrel{\Delta}{=} \hat{y}(n), \quad (12.102)$$

which is indeed a function of  $x$ , as desired.

Let us study the properties of this solution. First, define

$$v_o = d - \hat{\mathcal{H}}_o(x).$$

Note that  $v_o$  and  $\hat{\mathcal{H}}_o$  are not necessarily equal to  $v$  and  $\mathcal{H}$  from (12.40). Evaluating the average of  $\hat{\mathcal{H}}_o(x)$ , we obtain

$$E_x\{\hat{\mathcal{H}}_o(x)\} = E_x\{E_d\{d|x\}\} = E\{d\},$$

by an argument similar to that used to obtain (12.100). We conclude that  $v_o$  has zero mean. In addition, for any function  $f(x)$  of  $x$  for which the expected values exist, we have

$$E\{v_o f(x)\} = E_x\{E_d\{df(x)\}\} - E\{E_d\{d|x\}f(x)\} = 0 = E\{v_o\}E\{f(x)\}, \quad (12.103)$$

since  $E_d\{df(x)|x\} = f(x)E_d\{d|x\}$ . This result means that the error  $v_o$  is uncorrelated to any function of the reference data  $x$ , which is a very strong condition. It basically means that we have extracted all second-order information available in  $x$  about  $d$ .

We remark that (12.103) does not imply that  $x$  and  $v_o$  are independent. A simple counter-example is the following: consider two discrete-valued random variables  $r$  and  $s$  with joint probabilities given by Table 12.1. Then  $E\{sf(r)\} = 1/4 \cdot (-1) \cdot f(+1) + 1/4 \cdot (+1) \cdot f(+1) + 1/2 \cdot 0 \cdot f(-1) = 0, \forall f(\cdot)$ , but  $r$  and  $s$  are not independent.

In the more general case in which  $\hat{\mathcal{H}}$  is allowed to depend on previous samples of  $x(n)$ , the arguments and the final conclusion are similar:

$$\arg \min_{\hat{\mathcal{H}}} E \left\{ \left[ d - \hat{\mathcal{H}}(x(n), x(n-1), \dots) \right]^2 \right\} = E\{d | x(n), x(n-1), \dots\}, \quad (12.104)$$

and defining

$$v_o(n) = d(n) - E\{d | x(n), x(n-1), \dots\},$$

**Table 12.1** Counter-Example: (12.103) does not Imply Independence

$r \setminus s$	-1	0	1
-1	0	1/2	0
1	1/4	0	1/4

it holds that  $v_o(n)$  has zero mean and is uncorrelated with any function of  $x(n), x(n-1), \dots$ :

$$\mathbb{E}\{v_o(n)\} = 0, \quad \mathbb{E}\{v_o(n)f(x(n), x(n-1), \dots)\} = 0. \quad (12.105)$$

Note that, in general, the optimal solution of (12.104) depends on  $n$ , so we should write

$$\hat{\mathcal{H}}_{o,n}(x(n), x(n-1), \dots) = \mathbb{E}\{d|x(n), x(n-1), \dots\}, \quad (12.106)$$

to make the time dependence explicit.

We can now return to the question at the start of this section: From our results thus far, we see that minimizing  $\mathbb{E}\{e^2(n)\}$  leads to a model which relates  $d(n)$  and the sequence  $\{x(n)\}$  such that

$$d(n) = \hat{\mathcal{H}}_{o,n}(x(n), x(n-1), \dots) + v_o(n),$$

in which  $v_o(n)$  is uncorrelated with any function  $f(\cdot)$  of  $x(n), x(n-1), \dots$ . In other words, the solution of (12.104) imposes such a model on our data, even if this model makes no physical sense at all. This is an important point: such a model will always result from the minimization of the mean-square error, at least as long as the statistics of  $d(n)$  and  $\{x(n)\}$  are such that the expected values in (12.104) are finite.

Now, what if we knew beforehand, by physical arguments about the data, that a model such as (12.40) holds between  $d(n)$  and  $\{x(n)\}$ , such that  $v(n)$  has zero mean and is uncorrelated to any function of  $x(n), x(n-1), \dots$ ? Will it result that the solution of (12.104) will be such that

$$\hat{\mathcal{H}}_o(x(n), x(n-1), \dots) = \mathcal{H}(x(n), x(n-1), \dots), \quad v_o(n) = v(n)?$$

To answer this question, let us go back to (12.99), and use (12.40) to find the solution. We thus have (we omit the arguments of  $d(n), v(n)$  and  $\mathcal{H}(\cdot)$  for simplicity)

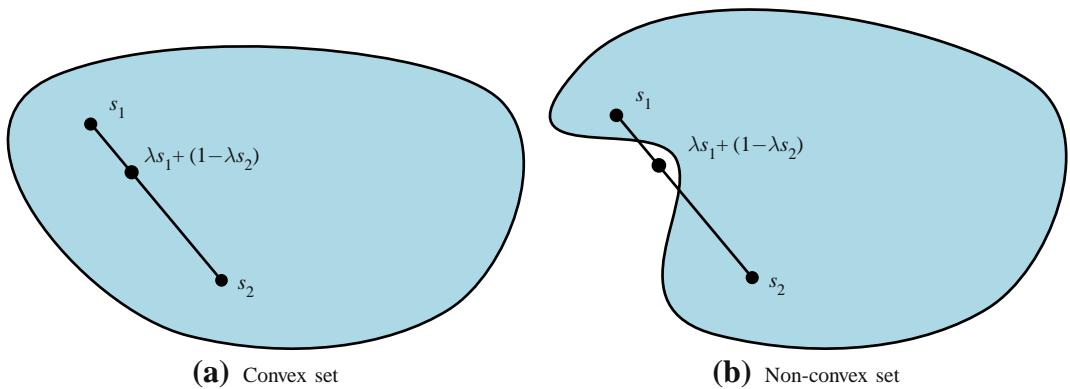

$$\min_{\hat{\mathcal{H}}} \mathbb{E}\{[d - \hat{\mathcal{H}}(x)]^2\} = \min_{\hat{\mathcal{H}}} \mathbb{E}\left\{[\mathcal{H}_n + v - \hat{\mathcal{H}}]^2\right\}.$$

Since  $v$  is orthogonal to any function of  $x(n), x(n-1), \dots$  by assumption, it will be orthogonal to  $\mathcal{H}_n$  and  $\hat{\mathcal{H}}$  in particular. Therefore, we can simplify the cost as

$$\min_{\hat{\mathcal{H}}} \mathbb{E}\{[d - \hat{\mathcal{H}}(x)]^2\} = \min_{\hat{\mathcal{H}}} \left[ \mathbb{E}\left\{(\mathcal{H} - \hat{\mathcal{H}})^2\right\} + \mathbb{E}\{v^2\} \right]. \quad (12.107)$$

Both terms in (12.107) are positive, and only the first depends on  $\hat{\mathcal{H}}$ . Therefore, the solution is indeed  $\hat{\mathcal{H}} = \mathcal{H}$  and  $v_o = v$ , as one would wish (to be precise,  $\mathcal{H}$  and  $\hat{\mathcal{H}}$  could differ on a set of probability zero).

We conclude that we can use (12.102) as a criterion for separating the two parts  $y(n)$  and  $v(n)$  of our model for  $d(n)$  if and only if  $v(n)$  satisfies (12.105). This holds, for example, if  $v(n)$  has zero mean and is independent of  $x(n-k)$  for all  $k \geq 0$ .

**FIGURE 12.22**

Convexity.

Note that since  $\hat{y}(n) = \hat{\mathcal{H}}_{o,n}(x(n), x(n-1), \dots)$  is itself a function of  $x(n), x(n-1), \dots$ , (12.105) implies that

$$\mathbb{E}\{v_o(n)\hat{y}(n)\} = 0,$$

and we have

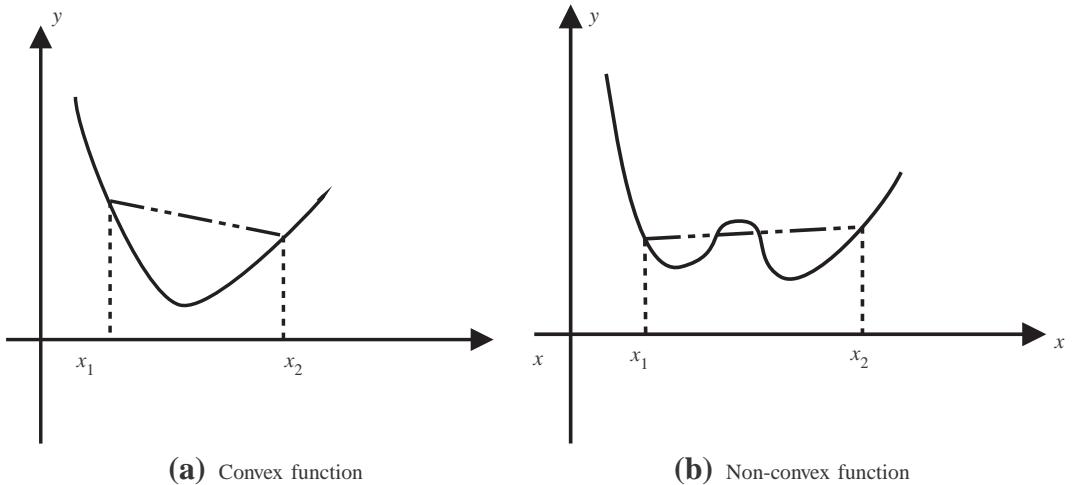

$$\begin{aligned} \mathbb{E}\{v_o^2(n)\} &= \mathbb{E}\{v_o[d(n) - \hat{y}(n)]\} = \mathbb{E}\{v_o d(n)\} \\ &= \mathbb{E}\{[d(n) - \hat{y}(n)]d(n)\} \\ &= \mathbb{E}\{d^2(n)\} - \mathbb{E}\{d(n)\hat{y}(n)\} \\ &= \mathbb{E}\{d^2(n)\} - \mathbb{E}\{[\hat{y}(n) + v_o(n)]\hat{y}(n)\} \\ &= \mathbb{E}\{d^2(n)\} - \mathbb{E}\{\hat{y}^2(n)\}. \end{aligned}$$

Recalling that  $\mathbb{E}\{\hat{y}(n)\} = \mathbb{E}\{d(n)\}$ , if we add and subtract  $\mathbb{E}^2\{d(n)\}$  to the last result, we conclude that

$$\mathbb{E}\{v_o^2(n)\} = \sigma_d^2 - \sigma_{\hat{y}}^2 \leq \sigma_d^2, \quad (12.108)$$

where  $\sigma_d^2$  and  $\sigma_{\hat{y}}^2$  are the variances of  $d(n)$  and of  $\hat{y}(n)$ .

The solution we just found is very general (it assumes little about  $\mathcal{H}$ ), and there are ways of computing it adaptively from the data, using for example algorithms known as particle filters [32]. The solution requires, however, that one builds approximations for the joint probability distribution of  $d(n)$  and  $x(n), x(n-1), \dots$ , which in general requires a large amount of data, resulting in relatively high complexity and relatively slow convergence. If you know more about the relation between  $\{x(n)\}$  and  $d(n)$ , this information might be used to constrain the search to a smaller class of problems, potentially leading to simpler algorithms with faster convergence. That is the goal of adaptive filters, and the reason why we restricted ourselves to this case in the main text.

**FIGURE 12.23**

## Convex functions.

## Box 5: Convex functions

Convex sets are such that lines between any two points in the set always stay entirely in the set (see Figure 12.22). More formally, a set  $\mathcal{S} \in \mathbb{R}^n$  is convex if

$$s_1, s_2 \in \mathcal{S} \Rightarrow \lambda s_1 + (1 - \lambda) s_2 \in \mathcal{S}, \quad \text{for all } \lambda \in [0, 1].$$

Convex functions, on the other hand, are functions  $f(\mathbf{x}) : \mathcal{R}^n \rightarrow \mathcal{R}$  such that for all  $\mathbf{x}_1, \mathbf{x}_2 \in \mathcal{R}^n$  and  $0 < \lambda < 1$ ,

$$f(\lambda \mathbf{x}_1 + (1 - \lambda) \mathbf{x}_2) \leq \lambda f(\mathbf{x}_1) + (1 - \lambda) f(\mathbf{x}_2).$$

The function is called *strictly convex* if the inequality is strict ( $<$  instead of  $\leq$ ). For example,  $f(x) = x^2$  is strictly convex. Figure 12.23 shows examples of convex and non-convex functions. An important property of strictly convex functions is that they always have a unique minimum, that is, they never have sub-optimal local minima.

### **Box 6: Wirtinger derivatives and minima of functions of a complex variable**

Suppose you want to minimize a function

$$f : \mathcal{C} \rightarrow \mathcal{R}, \\ w \in \mathcal{C} \mapsto f(w) \in \mathcal{R}, \quad (12.109)$$

that is, a function that takes a complex argument to a real value. The minimization problem is well defined, since the image of  $f$  is real. However, we cannot use standard arguments about derivatives and stationary points to find the minimum, because a function like this is never analytic, that is, the standard derivative used in complex analysis does not exist.

To see why, we need to think about  $f$  as a function of two variables,  $x$  and  $y$ , the real and imaginary parts of  $w$ . Take  $f(w) = |w|^2 = ww^*$  for example. We can write it as a function of  $x$  and  $y$  as

$$\hat{f}(x, y) = f(x + jy) = x^2 + y^2. \quad (12.110)$$

Since it is a function of two variables, the derivatives in principle depend on the direction we are moving along. Consider the derivative at a point  $w$  along the  $x$  axis, that is, keeping  $y$  constant:

$$\lim_{\epsilon \rightarrow 0} \frac{(x + \epsilon)^2 + y^2 - (x^2 + y^2)}{\epsilon} = 2x.$$

On the other hand, along the  $y$  axis, we have

$$\lim_{\epsilon \rightarrow 0} \frac{x^2 + (y + \epsilon)^2 - (x^2 + y^2)}{\epsilon} = 2y,$$

that is, the derivative at point  $w$  is different according to the direction we are moving. This is essentially what is meant by saying that the function is not analytic at  $w$ .

For contrast, consider now the analytic function  $g = w^2$ . Its derivative is the same, no matter which direction we take:

$$\begin{aligned} & \lim_{\epsilon \rightarrow 0} \frac{(x + \epsilon + jy)^2 - (x + jy)^2}{\epsilon} \\ &= \lim_{\epsilon \rightarrow 0} \frac{(x + \epsilon)^2 - y^2 + 2j(xy + \epsilon y) - (x^2 - y^2 + 2jxy)}{\epsilon} = 2w. \end{aligned}$$

Similarly, differentiating along the  $y$  axis we obtain again the same result

$$\lim_{\epsilon \rightarrow 0} \frac{(x + j(y + \epsilon))^2 - (x + jy)^2}{\epsilon} = 2w.$$

When the derivative at a certain point  $w_0$  is the same along every direction, we can define derivatives of complex functions writing simply

$$\frac{dg(w_0)}{dw} = \lim_{\Delta w \rightarrow 0} \frac{g(w_0 + \Delta w) - g(w_0)}{\Delta w}, \quad (12.111)$$

since we know the limit does not depend on the direction along which  $\Delta w$  goes to zero.

It can be shown that a function is analytic at a given point only if the *Cauchy-Riemann conditions* hold at that point. Separating a generic complex function  $g$  into its real and imaginary parts  $g(w) = u(x, y) + jv(x, y)$ , the Cauchy-Riemann conditions are [33]

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y}, \quad \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x}.$$

In the case of a *real* function of a complex variable, such as  $f$  defined as in (12.109),  $v \equiv 0$ , and of course the conditions could hold only for points in which the real part has zero partial derivatives.

This means that we cannot search for the stationary points of a function such as (12.109) using the derivative defined as in (12.111). We could of course always go back and interpret the function as a function of two variables, as we did in (12.110). In order to find the minimum of  $f(w)$ , we would need to find the stationary points of  $\hat{f}(x, y)$

$$\frac{\partial \hat{f}}{\partial x} = 0, \quad \frac{\partial \hat{f}}{\partial y} = 0.$$

This works just fine, of course, but there is a nice trick, which allows us to keep working with complex variables in a simple way. The idea is to define derivatives differently, such that optimization problems become easy to solve, using what is known as *Wirtinger calculus*.

Real functions of complex variables are usually defined in terms of variables and its conjugates, since  $w + w^*$  and  $ww^*$  are both real. The idea is to define derivatives such that  $w$  and  $w^*$  can be treated as if they were independent variables, as follows. Despite the motivation, the new derivatives are defined for general functions  $g : \mathcal{C} \rightarrow \mathcal{C}$ .

Define partial derivatives of a function  $g : \mathcal{C} \rightarrow \mathcal{C}$  with respect to  $w$  and  $w^*$  as

$$\frac{\partial g}{\partial w} = \frac{1}{2} \left\{ \frac{\partial g}{\partial x} - j \frac{\partial g}{\partial y} \right\}, \quad \frac{\partial g}{\partial w^*} = \frac{1}{2} \left\{ \frac{\partial g}{\partial x} + j \frac{\partial g}{\partial y} \right\}. \quad (12.112)$$

You can check that if  $g$  is analytic at a given point (so  $g$  satisfies the Cauchy-Riemann conditions at that point), then  $\partial g / \partial w^* = 0$  at that point.

Consider, for example,  $g(w) = w^m (w^*)^n = (x + jy)^m (x - jy)^n$ . Then,

$$\begin{aligned} \frac{\partial g}{\partial w} &= \frac{1}{2} \left\{ m(x + jy)^{m-1} (x - jy)^n + n(x + jy)^m (x - jy)^{n-1} \right. \\ &\quad \left. - j(m(x + jy)^{m-1} (x - jy)^n - n(x + jy)^m (x - jy)^{n-1}) \right\} \\ &= \frac{1}{2} \left\{ mw^{m-1} (w^*)^n + nw^m (w^*)^{n-1} + mw^{m-1} (w^*)^n - nw^m (w^*)^{n-1} \right\} \\ &= mw^{m-1} (w^*)^n. \end{aligned}$$

As advertised, the final result is what we would obtain if we had treated  $w$  and  $w^*$  as two independent variables. Similarly, you can check that

$$\frac{\partial g}{\partial w^*} = nw^m (w^*)^{n-1}.$$

An important special case is the quadratic function  $f(w) = d - w^*r - r^*w + w^*wR$ , which assumes only real values if  $d$  and  $R$  are real. Using the previous result, we see that

$$\frac{\partial f}{\partial w} = -r^* + w^*R, \quad \frac{\partial f}{\partial w^*} = -r + wR.$$

Note that there is no factor of 2 in this case. This difference between Wirtinger derivatives and standard real derivatives will propagate to many expressions in this text.

Now, the definitions (12.112) are useful for minimizing real functions of complex variables as in (12.109), since from (12.112)

$$\frac{\partial f}{\partial w^*} = 0 \Leftrightarrow \frac{\partial \hat{f}}{\partial x} = 0 \quad \text{and} \quad \frac{\partial \hat{f}}{\partial y} = 0.$$

Applying this idea to our quadratic function, we see that

$$\frac{\partial f}{\partial w^*} = 0 \Rightarrow R w_0 = r \Rightarrow w_0 = r/R,$$

if  $R \neq 0$ . In addition,

$$\frac{\partial^2 f}{\partial w \partial w^*} = R,$$

and we can conclude that  $w_0$  is a minimum as long as  $R > 0$ .

The same conclusions could easily be obtained working directly with  $\hat{f}$ . The Wirtinger derivatives are merely a shortcut, that makes working with complex variables very similar to working with real variables. A good detailed description of Wirtinger derivatives can be found in [34].

In the vector case, the definitions and results are very similar. Given a function

$$g : \mathcal{C}^M \rightarrow \mathcal{R},$$

$$\mathbf{w} = \begin{bmatrix} w_0 \\ w_1 \\ \vdots \\ w_{M-1} \end{bmatrix} \in \mathcal{C}^M \mapsto g(\mathbf{w}),$$

with  $w_i = x_i + j y_i$ ,  $i = 0, \dots, M-1$ , we define

$$\frac{\partial g}{\partial \mathbf{w}} = \left[ \frac{\partial g}{\partial w_0} \cdots \frac{\partial g}{\partial w_{M-1}} \right] = \frac{1}{2} \left[ \frac{\partial g}{\partial x_0} - j \frac{\partial g}{\partial y_0} \cdots \frac{\partial g}{\partial x_{M-1}} - j \frac{\partial g}{\partial y_{M-1}} \right],$$

$$\frac{\partial g}{\partial \mathbf{w}^H} = \begin{bmatrix} \frac{\partial g}{\partial w_0^*} \\ \vdots \\ \frac{\partial g}{\partial w_{M-1}^*} \end{bmatrix} = \frac{1}{2} \begin{bmatrix} \frac{\partial g}{\partial x_0} - j \frac{\partial g}{\partial y_0} \\ \vdots \\ \frac{\partial g}{\partial x_{M-1}} - j \frac{\partial g}{\partial y_{M-1}} \end{bmatrix}.$$

Using our definition of gradients, the second derivative of  $f$  (its *Hessian*) is

$$\frac{\partial^2 f}{\partial \mathbf{w} \partial \mathbf{w}^H} = \begin{bmatrix} \frac{\partial}{\partial \mathbf{w}} \left\{ \frac{\partial f}{\partial w_0^*} \right\} \\ \vdots \\ \frac{\partial}{\partial \mathbf{w}} \left\{ \frac{\partial f}{\partial w_{M-1}^*} \right\} \end{bmatrix} = \begin{bmatrix} \frac{\partial^2 f}{\partial w_0 \partial w_0^*} & \cdots & \frac{\partial^2 f}{\partial w_{M-1} \partial w_0^*} \\ \vdots & \ddots & \vdots \\ \frac{\partial^2 f}{\partial w_0 \partial w_{M-1}^*} & \cdots & \frac{\partial^2 f}{\partial w_{M-1} \partial w_{M-1}^*} \end{bmatrix}.$$

The most important example is the quadratic function

$$f(\mathbf{w}) = r_d - \mathbf{w}^H \mathbf{r}_{d\phi} - \mathbf{r}_{d\phi}^H \mathbf{w} + \mathbf{w}^H \mathbf{R}_\phi \mathbf{w},$$

where  $r_d$  is a real variable, and  $\mathbf{R}_\phi$  is Hermitian symmetric. Then, we have

$$\frac{\partial f}{\partial \mathbf{w}^H} = -\mathbf{r}_{d\phi} + \mathbf{R}_\phi \mathbf{w}.$$

We see that a stationary point of  $f$  is such that  $\mathbf{R}_\phi \mathbf{w}_o = \mathbf{r}_{d\phi}$ . In addition,

$$\frac{\partial^2 f}{\partial \mathbf{w} \partial \mathbf{w}^H} = \mathbf{R}_\phi,$$

and we conclude that  $\mathbf{w}_o$  is the single point of minimum of  $f$  if and only if  $\mathbf{R}_\phi$  is positive-definite.

Note that in the complex case, the gradient and the Hessian do not have the factors of 2 that we saw in the real case (see Box 1).

---

### 1.12.3 Stochastic algorithms

In this section, we focus on three of the most important adaptive algorithms: the least-mean squares (LMS) algorithm, the normalized least-mean squares (NLMS) algorithm, and the recursive least-squares (RLS) algorithm, which are the basis of many other algorithms. These three stochastic algorithms are derived in detail and analyzed using different methods. We present different approaches for analyzing an adaptive filter, because the variety and complexity of their behavior makes it difficult for a single technique to be able to handle all situations. The analyses provided here allow us to predict the behavior of the algorithms in transient and steady-state, and choose values of parameters (such as the step-size) for which the filters operate adequately. In particular, we study conditions under which the filters will remain stable.

We assume linearly parametrized classes, such as FIR ( $\mathcal{F}_{\text{FIR}}$ ) and Volterra ( $\mathcal{F}_V$ ) filters (see Section 1.12.2.1). In these classes, each element of the input regressor vector is given by a certain function  $\phi_i$   $i = 0, 1, \dots, M-1$  of  $x(n), x(n-1), \dots, x(n-N)$ . In the case of length- $M$  FIR filters, we have

$$\begin{aligned} \boldsymbol{\phi}(n) &= [\phi_0(n) \phi_1(n) \cdots \phi_{M-1}(n)]^T \\ &= [x(n) x(n-1) \cdots x(n-M+1)]^T, \end{aligned} \quad (12.113)$$

whereas in the case of second-order Volterra filters with memory  $N = 1$  and real-valued signals, we have

$$\begin{aligned} \boldsymbol{\phi}(n) &= [\phi_0(n) \phi_1(n) \phi_2(n) \phi_3(n) \phi_4(n)]^T \\ &= [x(n) x(n-1) x^2(n) x(n)x(n-1) x^2(n-1)]^T. \end{aligned} \quad (12.114)$$

As much as possible, our presentation in this section is independent of the choices of  $\mathcal{F}$  and  $\phi(\cdot)$ . However, some algorithms are designed for a specific class  $\mathcal{F}$  (the most common case are fast algorithms designed for FIR filters (12.113)). In these cases, we will alert the reader of the restriction.

Using the results of Box 6, the derivation of algorithms for real or circular complex inputs is very similar, the only differences being the need of conjugating a few variables in some expressions, and the appearance of a factor  $\beta = 2$  in the expressions of gradients of functions of real variables, and  $\beta = 1$  in the complex case.

In general, the output of a length- $M$  adaptive filter is given by

$$\hat{y}(n) = \mathbf{w}^H(n)\boldsymbol{\phi}(n) = w_0^*(n)\phi_0(n) + w_1^*(n)\phi_1(n) + \cdots + w_{M-1}^*(n)\phi_{M-1}(n). \quad (12.115)$$

In the case of Volterra filters, it is common to use the notation  $w_{k,\ell}$  for the weight related to the input  $x(n-k)x(n-\ell)$  (see Eq. (12.43)). However, to obtain a common formulation independent of the class  $\mathcal{F}$ , we denote the weight vector as

$$\mathbf{w}(n) = [w_0(n) \ w_1(n) \ w_2(n) \ \cdots \ w_{M-1}(n)]^T. \quad (12.116)$$

The task of the adaptive filter will be to choose in a recursive form the values of the parameters  $w_0, w_1, \dots, w_{M-1}$  that best fit the data at each time instant  $n$ .

Figure 12.24 shows the scheme of a length- $M$  adaptive filter for linearly parametrized classes, where  $\Phi$  denotes the set of functions  $\phi_i(\cdot), i = 0, 1, \dots, M-1$  of  $x(n), x(n-1), \dots, x(n-N)$  that generate the elements  $\phi_0(n), \phi_1(n), \dots, \phi_{M-1}(n)$  of the input regressor vector  $\boldsymbol{\phi}(n)$ . The number of samples of the signal  $x(n)$  depends on the class  $\mathcal{F}$  and is given by  $N+1$ . An FIR filter with length  $M$  requires  $N+1 = M$  samples. On the other hand, a Volterra filter with memory  $N$ , requires  $N+1$  samples, but the length of the corresponding adaptive filter depends on the order of the Volterra series expansion. At each time instant, the output of the adaptive filter  $\hat{y}(n)$  is compared with the desired signal  $d(n)$  to compute the error  $e(n) = d(n) - \hat{y}(n)$ . In order to minimize a cost function of this error, a stochastic algorithm uses  $e(n)$  to adjust the filter weights.

### 1.12.3.1 LMS algorithm

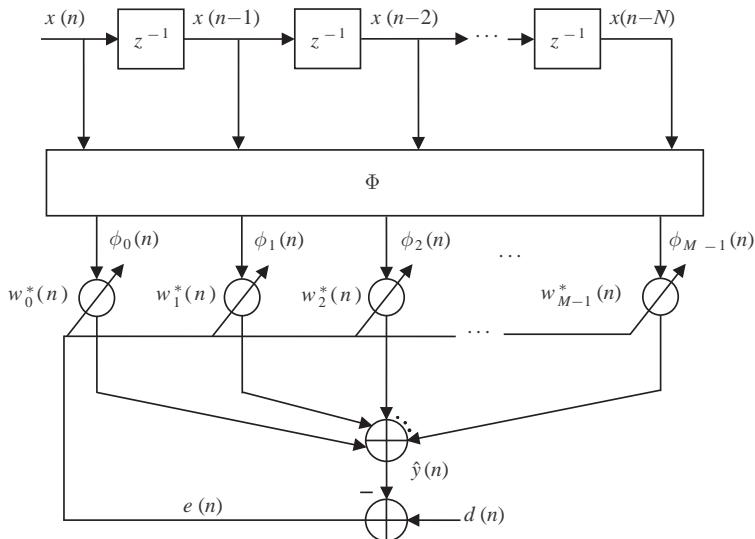

The update equation of the steepest-descent algorithm is given by

$$\mathbf{w}(n+1) = \mathbf{w}(n) - \frac{\mu}{\beta} \nabla_{\mathbf{w}} J(n), \quad (12.117)$$

where  $\mu$  is a step-size and  $\beta = 1$  (resp.,  $\beta = 2$ ) for complex (resp., real) data (see Box 6). This algorithm requires exact measurements of the gradient vector. For the case of minimization of the mean-square error, that is, if  $J(n) = E\{|e(n)|^2\}$ ,

$$\nabla_{\mathbf{w}} J(n) = -\beta \mathbf{r}_{d\phi} + \beta \mathbf{R}_{\phi} \mathbf{w}(n) \quad (12.118)$$

at each iteration  $n$  (see Box 1 for an introduction to gradient algorithms). Note that the exact gradient requires a prior knowledge of the correlation matrix  $\mathbf{R}_{\phi}$  and the cross-correlation vector  $\mathbf{r}_{d\phi}$ , which is not feasible in real-time applications. For example, in the hands-free telephone application described in Section 1.12.1.1, the input signal of the adaptive filter is the far-end speech (see Figures 12.3 and 12.4). A speech signal is nonstationary and therefore, it is not possible to obtain exact estimates for  $\mathbf{R}_{\phi}$  and  $\mathbf{r}_{d\phi}$  at each time instant. Furthermore, good estimates would demand much processing time, which

**FIGURE 12.24**

Scheme for a length- $M$  adaptive filter assuming linearly parametrized classes.

could insert an inadmissible delay in the system, making this approach not feasible, except in off-line applications. Similar restrictions appear in virtually all adaptive filtering applications.

To circumvent this problem, a stochastic version of the steepest descent algorithm was proposed, the least-mean squares (LMS) algorithm. Instead of minimizing the exact mean-square error, the LMS algorithm minimizes a straightforward approximation to it:  $|e(n)|^2$ . The idea, as we saw in Section 1.12.1.2.4, is that the algorithm will approximately average the cost-function if adaptation is slow (small step-size). The estimation error is

$$e(n) = d(n) - \mathbf{w}^H(n)\boldsymbol{\phi}(n), \quad (12.119)$$

so the gradient of the instantaneous cost function is

$$\hat{\nabla}_{\mathbf{w}} J(n) = -\beta\boldsymbol{\phi}(n)d^*(n) + \beta\boldsymbol{\phi}(n)\boldsymbol{\phi}^H(n)\mathbf{w}(n) = -\beta\boldsymbol{\phi}(n)e^*(n). \quad (12.120)$$

Since  $e(n)$  depends on the old estimate of the weight vector, it is called an *a priori* estimation error, by opposition to the *a posteriori* error that will be introduced in (12.129). Instead of minimizing the instantaneous cost function, the stochastic gradient defined in (12.120) can be obtained by replacing the instantaneous estimates

$$\hat{\mathbf{R}}_{\boldsymbol{\phi}}(n) = \boldsymbol{\phi}(n)\boldsymbol{\phi}^H(n) \quad (12.121)$$

and

$$\hat{\mathbf{r}}_{d\boldsymbol{\phi}}(n) = \boldsymbol{\phi}(n)d^*(n) \quad (12.122)$$

in (12.118).

**Table 12.2** Summary of the LMS Algorithm

Initialization:  
Set  $\mathbf{w}(0) = \mathbf{0}$   
For  $n = 0, 1, 2, \dots$ , compute  
 $\hat{y}(n) = \mathbf{w}^H(n)\phi(n)$   
 $e(n) = d(n) - \hat{y}(n)$   
 $\mathbf{w}(n+1) = \mathbf{w}(n) + \mu e^*(n)\phi(n)$

**Table 12.3** Computational Cost of the LMS Algorithm for Complex and Real-Valued Signals in Terms of Real Multiplications and Real Additions Per Iteration

Term	Real Signals		Complex Signals	
	x	+	x	+
$\hat{y}^*(n) = \phi^H(n)[\mathbf{w}(n)]$	M	$M - 1$	$4M$	$4M - 2$
$e^*(n) = d^*(n) - [\hat{y}^*(n)]$		1		2
$\mu[e^*(n)]$	1		2	
$[\mu e^*(n)]\phi(n)$	M		$4M$	$2M$
$\mathbf{w}(n+1) = [\mathbf{w}(n)] + [\mu e^*(n)\phi(n)]$		M		$2M$
TOTAL per iteration	$2M + 1$	$2M$	$8M + 2$	$8M$

Replacing (12.120) in (12.117), we arrive at the update equation for LMS, i.e.,

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \mu \phi(n) e^*(n). \quad (12.123)$$

As explained in Section 1.12.1.2.4 and illustrated in the animations of Figure 12.9, although there is no explicit average being taken in the LMS algorithm, it in fact computes an implicit approximate average if the step-size is small.

The LMS algorithm is summarized in Table 12.2. Its computational cost increases linearly with the length of the filter, i.e., the computational cost is  $\mathcal{O}(M)$ . Table 12.3 shows the number of real multiplications and real additions per iteration for real and complex-valued signals. The quantities inside brackets were computed in previous steps. We assume that a complex multiplication requires 4 real multiplications and 2 real additions (it is possible to use less multiplications and more additions), and a complex addition requires 2 real additions. Different ways of carrying out the calculations may result in a different computational cost. For example, if we first computed  $\mu \times \phi(n)$  followed by  $[\mu \phi(n)] \times e^*(n)$ , LMS would require  $M - 1$  more real multiplications per iteration than the ordering of Table 12.3, considering real-valued signals. For complex-valued signals, the cost would be even higher, since LMS would require  $4M - 2$  and  $2M$  more real multiplications and real additions, respectively.

### 1.12.3.1.1 A deterministic approach for the stability of LMS

Finding the range of step-sizes such that the recursion (12.123) converges is a complicated task. There are two main approaches to finding the maximum step-size: an average approach and a deterministic (worst-case) approach. The average approach will be treated in Section 1.12.4.3. Since the deterministic approach is easy to explain intuitively, we address it in the sequel (although a precise proof is not so simple, see [35,36] for a full analysis).

For simplicity, assume that our filter is such that  $d(n) \equiv 0$ . Although this is not a very likely situation to encounter in practice, it allows us to avoid technical details that would complicate considerably the discussion, and still arrive at the important conclusions.

Let us rewrite the LMS recursion, expanding the error with  $d(n) = 0$  as  $e^*(n) = -(\mathbf{w}^H(n)\boldsymbol{\phi}(n))^* = -\boldsymbol{\phi}^H(n)\mathbf{w}(n)$  to obtain

$$\mathbf{w}(n+1) = [\mathbf{I} - \mu\boldsymbol{\phi}(n)\boldsymbol{\phi}^H(n)]\mathbf{w}(n). \quad (12.124)$$

This is a linear system, but not a time-invariant one. It will be stable if the eigenvalues  $\lambda_i(n)$  of the matrix  $\mathbf{A}(n) = \mathbf{I} - \mu\boldsymbol{\phi}(n)\boldsymbol{\phi}^H(n)$  satisfy

$$\max_i |\lambda_i(n)| \leq 1, \quad \text{for all } n \geq 0. \quad (12.125)$$

Be careful, if  $d(n)$  were not identically zero, condition (12.125) would have to be slightly modified to guarantee stability (see, e.g., [36,37]).

The eigenvalues of  $\mathbf{A}(n)$  are easy to find, if we note that  $\boldsymbol{\phi}(n)$  is an eigenvector of  $\mathbf{A}(n)$  (the case  $\boldsymbol{\phi}(n) = \mathbf{0}$  is trivial):

$$\mathbf{A}(n)\boldsymbol{\phi}(n) = \boldsymbol{\phi}(n) - \mu\boldsymbol{\phi}(n)\boldsymbol{\phi}^H(n)\boldsymbol{\phi}(n) = (1 - \mu\|\boldsymbol{\phi}(n)\|^2)\boldsymbol{\phi}(n),$$

where  $\|\boldsymbol{\phi}(n)\|^2 = \boldsymbol{\phi}^H(n)\boldsymbol{\phi}(n)$  is the square of the Euclidean norm. The corresponding eigenvalue is  $\lambda_1 = 1 - \mu\|\boldsymbol{\phi}(n)\|^2$ . All other eigenvalues are equal to one (the eigenvectors are all vectors orthogonal to  $\boldsymbol{\phi}(n)$ .) Therefore, the LMS algorithm (12.124) will be stable whenever

$$-1 \leq 1 - \mu\|\boldsymbol{\phi}(n)\|^2 \leq 1 \iff 0 \leq \mu \leq \frac{2}{\sup_{n \geq 0} \|\boldsymbol{\phi}(n)\|^2}. \quad (12.126)$$

The *supremum* (sup) of a sequence is an extension to the maximum, defined to avoid a technicality. Consider the sequence  $f(n) = \{1 - 0.5^n\}$ ,  $n \geq 0$ . Strictly speaking, it has no maximum, since there is no  $n_0$  for which  $f(n_0) \geq f(n)$  for all  $n \geq 0$ . The supremum is defined so we can avoid this problem:  $\sup_{n \geq 0} f(n) = 1$ . Therefore, the supremum is equal to the maximum whenever the later exists, but is also defined for some sequences that do not have a maximum. The *infimum* (inf) has a similar relation to the minimum.

This condition is sufficient for stability, but is too conservative, since  $\|\boldsymbol{\phi}(n)\|^2$  is not at its highest value at all instants. A popular solution is to use *normalization*. The idea is simple: adopt a time-variant step-size  $\mu(n)$  such that

$$\mu(n) = \frac{\tilde{\mu}}{\varepsilon + \|\boldsymbol{\phi}(n)\|^2}, \quad (12.127)$$

with  $0 < \tilde{\mu} < 2$  and where  $\varepsilon > 0$  is used to avoid division by zero. The resulting algorithm is known as *normalized LMS* (NLMS). We will talk more about it in the next section.

### 1.12.3.2 Normalized LMS algorithm

One problem with the LMS algorithm is how to choose the step-size. How large should it be to enable a high convergence rate, provide an acceptable misadjustment, and even ensure the stability of LMS? More importantly, how can this choice be made so that the filter will work correctly even for very different input signals? One answer to this problem is the normalized LMS algorithm which we describe now. It uses a time varying step-size, which is particularly useful when the statistics of the input signals change quickly.

Thus, replacing the fixed step-size  $\mu$  by a time varying step-size  $\mu(n)$  in (12.123), we obtain

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \mu(n)\phi(n)e^*(n). \quad (12.128)$$

In order to increase the convergence speed, we could try to find  $\mu(n)$  such that the *a posteriori* estimation error,

$$\xi(n) = d(n) - \mathbf{w}^H(n+1)\phi(n), \quad (12.129)$$

is zeroed. Note that, in contrast to the *a priori* estimation error defined in (12.119),  $\xi(n)$  depends on the updated estimate of the weight vector, hence the name *a posteriori* estimation error. Replacing (12.128) in (12.129), we obtain

$$\begin{aligned} \xi(n) &= \underbrace{d(n) - \mathbf{w}^H(n)\phi(n)}_{e(n)} - \mu(n)\phi^H(n)\phi(n)e(n) \\ &= [1 - \mu(n)\phi^H(n)\phi(n)]e(n). \end{aligned} \quad (12.130)$$

In order to enforce  $\xi(n) = 0$  at each time instant  $n$ , we must select

$$\mu(n) = \frac{1}{\phi^H(n)\phi(n)} = \frac{1}{\|\phi(n)\|^2}. \quad (12.131)$$

Replacing (12.131) in (12.128), we obtain the update equation of the normalized least-squares algorithm, i.e.,

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \frac{1}{\|\phi(n)\|^2}\phi(n)e^*(n). \quad (12.132)$$

Note that the time varying step-size  $\mu(n)$  depends inversely on the instantaneous power of the input vector  $\phi(n)$ . Indeed, we will show in Section 1.12.4.3 that the maximum value of the fixed step-size  $\mu$  to ensure the convergence and mean-square stability of LMS depends inversely on the power of the input signal.

In order to make (12.132) more reliable for practical implementations, it is common to introduce two positive constants: a fixed step-size  $\tilde{\mu}$  to control the rate of convergence (and the misadjustment) and the regularization factor  $\varepsilon$  to prevent division by a small value when  $\|\phi(n)\|^2$  is small. With these constants, the NLMS update equation reduces to

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \frac{\tilde{\mu}}{\varepsilon + \|\phi(n)\|^2}\phi(n)e^*(n). \quad (12.133)$$

Some authors refer to (12.132) as NLMS and to (12.133) as  $\varepsilon$ -NLMS. However, for simplicity we will refer to both as NLMS. The name “normalized” is due to a most useful property of NLMS: the range of values of  $\tilde{\mu}$  for which the algorithm remains stable is independent of the statistics of  $x(n)$ , i.e.,  $0 < \tilde{\mu} < 2$ , as can be observed in Section 1.12.3.1.1.

As pointed out in [3], the NLMS algorithm can also be interpreted as a quasi-Newton algorithm. As briefly explained in Box 1, a quasi-Newton algorithm updates the weights using approximations for the Hessian matrix and gradient vector, i.e.,

$$\mathbf{w}(n+1) = \mathbf{w}(n) - \frac{\mu}{\beta} \left[ \widehat{\nabla}_{\mathbf{w}}^2 J(n) \right]^{-1} \widehat{\nabla}_{\mathbf{w}} J(n). \quad (12.134)$$

Assuming the following instantaneous approximations

$$\widehat{\nabla}_{\mathbf{w}} J(n) = -\beta \boldsymbol{\phi}(n) d^*(n) + \beta \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \mathbf{w}(n) = -\beta \boldsymbol{\phi}(n) e^*(n) \quad (12.135)$$

and

$$\widehat{\nabla}_{\mathbf{w}}^2 J(n) = \varepsilon \mathbf{I} + \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n), \quad (12.136)$$

and replacing them in (12.134), we arrive at the stochastic recursion

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \mu \left[ \varepsilon \mathbf{I} + \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \right]^{-1} \boldsymbol{\phi}(n) e^*(n). \quad (12.137)$$

The term  $\varepsilon \mathbf{I}$  guarantees that (12.136) is invertible (a rank-one matrix such as  $\boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n)$  is never invertible).

To compute  $[\varepsilon \mathbf{I} + \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n)]^{-1}$ , we can use the *matrix inversion lemma* (Box 3), which gives us an expression for the inverse of an  $M \times M$  matrix of the form

$$\mathbf{A} = \mathbf{B} + \mathbf{C} \mathbf{D} \mathbf{C}^H, \quad (12.138)$$

where  $\mathbf{B}$  and  $\mathbf{D}$  are two square matrices with dimensions  $M$  and  $N$ , respectively, and  $\mathbf{C}$  is an  $M \times N$  matrix. According to the matrix inversion lemma, the inverse of  $\mathbf{A}$  is given by

$$\mathbf{A}^{-1} = \mathbf{B}^{-1} - \mathbf{B}^{-1} \mathbf{C} (\mathbf{D}^{-1} + \mathbf{C}^H \mathbf{B}^{-1} \mathbf{C})^{-1} \mathbf{C}^H \mathbf{B}^{-1}. \quad (12.139)$$

Thus, identifying

$$\mathbf{A} = \varepsilon \mathbf{I} + \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n), \quad \mathbf{B} = \varepsilon \mathbf{I}, \quad \mathbf{C} = \boldsymbol{\phi}(n), \quad \text{and} \quad \mathbf{D} = 1,$$

we obtain

$$[\varepsilon \mathbf{I} + \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n)]^{-1} = \varepsilon^{-1} \mathbf{I} - \frac{\varepsilon^{-2}}{1 + \varepsilon^{-1} \boldsymbol{\phi}^H(n) \boldsymbol{\phi}(n)} \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n). \quad (12.140)$$

Multiplying (12.140) from the right by  $\boldsymbol{\phi}(n)$ , after some algebraic manipulations, we get

$$[\varepsilon \mathbf{I} + \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n)]^{-1} \boldsymbol{\phi}(n) = \frac{\boldsymbol{\phi}(n)}{\varepsilon + \boldsymbol{\phi}^H(n) \boldsymbol{\phi}(n)} = \frac{\boldsymbol{\phi}(n)}{\varepsilon + \|\boldsymbol{\phi}(n)\|^2}. \quad (12.141)$$

**Table 12.4** Summary of the NLMS Algorithm

Initialization:

Set  $\mathbf{w}(0) = \mathbf{0}$  and  $0 < \tilde{\mu} < 2$

For  $n = 0, 1, 2, \dots$ , compute

$$\hat{y}(n) = \mathbf{w}^H(n)\phi(n)$$

$$e(n) = d(n) - \hat{y}(n)$$

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \frac{\tilde{\mu}}{\varepsilon + \|\phi(n)\|^2} e^*(n)\phi(n)$$

Replacing (12.141) in (12.137), we arrive at (12.133). Since Newton-based algorithms converge faster than gradient-based algorithms, it is expected that NLMS exhibits a higher convergence rate than that of LMS, which is indeed the case in general.

The NLMS algorithm is summarized in Table 12.4. To obtain its computational cost, we can use the same procedure considered in the computation of the number of operations of LMS (see Table 12.3). For complex-valued signals, NLMS requires  $10M + 2$  real multiplications,  $10M$  real additions and one real division per iteration. For real-valued signals, it requires  $3M + 1$  real multiplications and  $3M$  real additions per iteration. Note that for input vectors with a shift structure such as the FIR filters of Eq. (12.113), its computational cost can be reduced if  $\|\phi(n)\|^2$  is computed by the following recursion

$$\|\phi(n)\|^2 = \|\phi(n-1)\|^2 - |x(n-M)|^2 + |x(n)|^2 \quad (12.142)$$

with initialization  $\|\phi(-1)\| = 0$ .

### 1.12.3.3 RLS algorithm

The convergence rate of LMS-type algorithms varies considerably with the input signal  $x(n)$ , since they are based on steepest-descent optimization algorithms. If  $x(n)$  is a white noise, the convergence rate is high. On the other hand, if the correlation between successive samples of  $x(n)$  is high, LMS-type algorithms converge slowly. The RLS algorithm does not have this drawback. However, this advantage has a price: a considerable increase in the computational cost. Furthermore, numerical errors play a more important role in RLS and may even lead to divergence of the weight estimates. Different versions of RLS were proposed to circumvent this problem. In the sequel, we obtain the equations of the conventional RLS algorithm.

The RLS can be derived in different ways (much as NLMS). Each form of arriving at the algorithm highlights a different set of its properties: one that leads to many new algorithms and insights is the connection between RLS and Kalman filters described in [38].

We present here shorter routes, starting with a derivation based on deterministic arguments. In fact, RLS solves a deterministic least-squares problem, which is based on the weighted least-squares cost function

$$J_{\text{LS}}(n) = \sum_{\ell=0}^n \lambda^{n-\ell} |\xi(\ell)|^2, \quad (12.143)$$

where  $0 \ll \lambda < 1$  is a constant known as *forgetting factor*,

$$\xi(\ell) = d(\ell) - \mathbf{w}^H \boldsymbol{\phi}(\ell), \quad (12.144)$$

are *a posteriori* errors and

$$\mathbf{w}(n+1) = \arg \min_{\mathbf{w}} J_{\text{LS}}(n). \quad (12.145)$$

The factor  $\lambda^{n-\ell}$  emphasizes the most recent errors, forgetting the errors from the remote past. This is important, otherwise the algorithm would give too much weight to the remote past and would not be able to track variations in the input signals. Note that  $\mathbf{w}(n+1)$  minimizes  $J_{\text{LS}}(n)$  at each time instant. Thus, RLS provides an exact solution for the least-squares problem at each time instant. As the NLMS algorithm, RLS seeks to minimize the *a posteriori* error  $|\xi(n)|^2$ , searching for an exact solution to an optimization problem. The difference is that RLS searches for a weight vector  $\mathbf{w}(n+1)$  that takes into consideration the whole past history of inputs, minimizing  $\lambda^n |\xi(0)|^2 + \lambda^{n-1} |\xi(1)|^2 + \dots + \lambda |\xi(n-1)|^2 + |\xi(n)|^2$  at each time instant  $n$ , not only the current value  $|\xi(n)|^2$  as in NLMS.

The error sequence  $\xi(\ell)$  weighted by  $\lambda^{(n-\ell)/2}$  in the interval  $0 \leq \ell \leq n$  can be written in a vectorial form, i.e.,

$$\xi(n) = \mathbf{d}(n) - \Phi(n)\mathbf{w}^*, \quad (12.146)$$

where

$$\xi(n) = [\xi(n) \ \lambda^{1/2}\xi(n-1) \ \dots \ \lambda^{n/2}\xi(0)]^T, \quad (12.147)$$

$$\mathbf{d}(n) = [d(n) \ \lambda^{1/2}d(n-1) \ \dots \ \lambda^{n/2}d(0)]^T \quad (12.148)$$

and

$$\Phi(n) = \begin{bmatrix} \phi_0(n) & \phi_1(n) & \dots & \phi_{M-1}(n) \\ \lambda^{1/2}\phi_0(n-1) & \lambda^{1/2}\phi_1(n-1) & \dots & \lambda^{1/2}\phi_{M-1}(n-1) \\ \lambda\phi_0(n-2) & \lambda\phi_1(n-2) & \dots & \lambda\phi_{M-1}(n-2) \\ \vdots & \ddots & \ddots & \vdots \\ \lambda^{n/2}\phi_0(0) & \lambda^{n/2}\phi_1(0) & \dots & \lambda^{n/2}\phi_{M-1}(0) \end{bmatrix}. \quad (12.149)$$

Note that the weighted least-squares cost function can be rewritten in terms of the vector  $\xi(n)$ , i.e.,

$$J_{\text{LS}}(n) = \xi^H(n)\xi(n) = \|\xi(n)\|^2 = \sum_{\ell=0}^n \lambda^{n-\ell} |\xi(\ell)|^2. \quad (12.150)$$

Now, we have to find the weight vector  $\mathbf{w}(n+1)$  that minimizes (12.150). The gradient of  $J_{\text{LS}}(n)$  with relation to  $\mathbf{w}^H$  is given by

$$\nabla_{\mathbf{w}} J_{\text{LS}}(n) = -\beta \Phi^T(n) \mathbf{d}^*(n) + \beta \Phi^T(n) \Phi^*(n) \mathbf{w}, \quad (12.151)$$

where as usual,  $\beta = 1$  (resp.,  $\beta = 2$ ) for complex (resp., real) data. Defining

$$\widehat{\mathbf{R}}_{\boldsymbol{\phi}}(n) = \Phi^T(n) \Phi^*(n) = \sum_{\ell=0}^n \lambda^{n-\ell} \boldsymbol{\phi}(\ell) \boldsymbol{\phi}^H(\ell) \quad (12.152)$$

and

$$\hat{\mathbf{r}}_{d\phi}(n) = \Phi^T(n)\mathbf{d}^*(n) = \sum_{\ell=0}^n \lambda^{n-\ell} d^*(\ell) \boldsymbol{\phi}(\ell), \quad (12.153)$$

in which  $\boldsymbol{\phi}(n)$  is defined as before, (12.151) can be rewritten as

$$\nabla_{\mathbf{w}} J_{LS}(n) = -\beta \hat{\mathbf{r}}_{d\phi}(n) + \beta \hat{\mathbf{R}}_{\phi}(n) \mathbf{w}. \quad (12.154)$$

Equating  $\nabla_{\mathbf{w}} J_{LS}(n)$  to the null vector, we get the normal equations

$$\hat{\mathbf{R}}_{\phi}(n) \mathbf{w}(n+1) = \hat{\mathbf{r}}_{d\phi}(n). \quad (12.155)$$

Note that these are a deterministic version of the normal equations we saw in Section 1.12.2.1. Therefore, to minimize  $J_{LS}(n)$ , the weight vector  $\mathbf{w}(n+1)$  must satisfy

$$\mathbf{w}(n+1) = \hat{\mathbf{R}}_{\phi}^{-1}(n) \hat{\mathbf{r}}_{d\phi}(n), \quad (12.156)$$

which requires the computation of the inverse correlation matrix  $\hat{\mathbf{R}}_{\phi}^{-1}(n)$  at each time instant. Note that this is only valid if  $\hat{\mathbf{R}}_{\phi}^{-1}(n)$  is nonsingular. In particular, the inverse does not exist if  $n < M$  (Box 3). Assuming  $\lambda = 1$  and that the signals  $x(n)$  and  $d(n)$  are jointly stationary and ergodic, we obtain the following steady-state relations

$$\lim_{n \rightarrow \infty} \frac{1}{n+1} \hat{\mathbf{R}}_{\phi}(n)|_{\lambda=1} = \mathbf{R}_{\phi} \quad \text{and} \quad \lim_{n \rightarrow \infty} \frac{1}{n+1} \hat{\mathbf{r}}_{d\phi}(n)|_{\lambda=1} = \mathbf{r}_{d\phi}.$$

Therefore, the deterministic normal equations converge to the stochastic normal equations when  $\lambda = 1$ , and the weight vector obtained from (12.156) converges to the Wiener solution, i.e.,

$$\lim_{n \rightarrow \infty} \mathbf{w}(n+1)|_{\lambda=1} = \mathbf{R}_{\phi}^{-1} \mathbf{r}_{d\phi} = \mathbf{w}_o. \quad (12.157)$$

We should mention that with  $\lambda = 1$  the convergence rate of RLS goes to zero, i.e., it loses the ability to follow the statistical variations of the observed data. An equivalent result is obtained for LMS or NLMS when the fixed step-size  $\mu$  or  $\tilde{\mu}$  is replaced by  $1/n$  [39].

The computational cost of (12.156) is high due to the computation of the inverse matrix. In order to solve the normal equations in real-time and with less cost, we should rewrite (12.152) and (12.153) as recursions, i.e.,

$$\hat{\mathbf{R}}_{\phi}(n) = \lambda \hat{\mathbf{R}}_{\phi}(n-1) + \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n), \quad (12.158)$$

and

$$\hat{\mathbf{r}}_{d\phi}(n) = \lambda \hat{\mathbf{r}}_{d\phi}(n-1) + d^*(n) \boldsymbol{\phi}(n), \quad (12.159)$$

with initializations  $\hat{\mathbf{R}}_{\phi}(-1) = \delta \mathbf{I}$  and  $\hat{\mathbf{r}}_{d\phi}(-1) = \mathbf{0}$ , where  $\delta$  is a small positive constant. Note that (12.159) is identical to (12.153), but (12.158) leads to the estimate

$$\hat{\mathbf{R}}_{\phi}(n) = \lambda^{n+1} \delta \mathbf{I} + \sum_{\ell=0}^n \lambda^{n-\ell} \boldsymbol{\phi}(\ell) \boldsymbol{\phi}^H(\ell), \quad (12.160)$$

and therefore the initialization guarantees the existence of the inverse at all instants. For  $0 \ll \lambda < 1$ , the initialization  $\widehat{\mathbf{R}}_{\phi}(-1) = \delta \mathbf{I}$  is forgotten and (12.158) becomes close to (12.152) as  $n$  increases. Furthermore, if you want the algorithm to forget quickly the initialization, besides using  $0 \ll \lambda < 1$ , you should choose  $\delta$  small ( $\delta^{-1}$  large). Note however that a certain amount of regularization may be useful in practice, to avoid problems when the input signal has long stretches with low power.

In order to obtain a recursion for the inverse matrix  $\widehat{\mathbf{R}}_{\phi}^{-1}(n)$ , we can use the matrix inversion lemma (Box 3) by comparing (12.138) with (12.158) and identifying

$$\mathbf{A} = \widehat{\mathbf{R}}_{\phi}(n), \quad \mathbf{B} = \lambda \widehat{\mathbf{R}}_{\phi}(n-1), \quad \mathbf{C} = \boldsymbol{\phi}(n), \quad \text{and} \quad \mathbf{D} = 1.$$

Thus, using (12.139), we obtain

$$\widehat{\mathbf{R}}_{\phi}^{-1}(n) = \lambda^{-1} \widehat{\mathbf{R}}_{\phi}^{-1}(n-1) - \frac{\lambda^{-2} \widehat{\mathbf{R}}_{\phi}^{-1}(n-1) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \widehat{\mathbf{R}}_{\phi}^{-1}(n-1)}{1 + \lambda^{-1} \boldsymbol{\phi}^H(n) \widehat{\mathbf{R}}_{\phi}^{-1}(n-1) \boldsymbol{\phi}(n)}. \quad (12.161)$$

Defining  $\mathbf{P}(n) \triangleq \widehat{\mathbf{R}}_{\phi}^{-1}(n)$ , with some algebraic manipulations in (12.161), we arrive at

$$\mathbf{P}(n) = \frac{1}{\lambda} \left[ \mathbf{P}(n-1) - \frac{\mathbf{P}(n-1) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \mathbf{P}(n-1)}{\lambda + \boldsymbol{\phi}^H(n) \mathbf{P}(n-1) \boldsymbol{\phi}(n)} \right] \quad (12.162)$$

with initialization  $\mathbf{P}(-1) = \delta^{-1} \mathbf{I}$ . This equation allow us to compute the inverse correlation matrix in a recurrent form, avoiding the explicit computation of a matrix inverse. However, the implementation of (12.162) in finite precision arithmetic requires some care to avoid numerical problems, as explained in Section 1.12.3.3.1.

To simplify the following equations, it is convenient to define the column vector

$$\mathbf{k}(n) = \frac{\mathbf{P}(n-1) \boldsymbol{\phi}(n)}{\lambda + \boldsymbol{\phi}^H(n) \mathbf{P}(n-1) \boldsymbol{\phi}(n)}, \quad (12.163)$$

which is the so-called Kalman gain. Thus, (12.162) can be rewritten as

$$\mathbf{P}(n) = \lambda^{-1} \left[ \mathbf{I} - \mathbf{k}(n) \boldsymbol{\phi}^H(n) \right] \mathbf{P}(n-1). \quad (12.164)$$

Using (12.164) and some algebraic manipulations in (12.163), we arrive at

$$\begin{aligned} \mathbf{k}(n) &= \lambda^{-1} \mathbf{P}(n-1) \boldsymbol{\phi}(n) - \lambda^{-1} \mathbf{k}(n) \boldsymbol{\phi}^H(n) \mathbf{P}(n-1) \boldsymbol{\phi}(n) \\ &= \lambda^{-1} \left[ \mathbf{I} - \mathbf{k}(n) \boldsymbol{\phi}^H(n) \right] \mathbf{P}(n-1) \boldsymbol{\phi}(n) \\ &= \mathbf{P}(n) \boldsymbol{\phi}(n). \end{aligned} \quad (12.165)$$

Thus, using (12.159) and (12.165) in (12.156), the weight vector  $\mathbf{w}(n+1)$  can also be computed recursively, i.e.,

$$\begin{aligned} \mathbf{w}(n+1) &= \mathbf{P}(n) \hat{\mathbf{r}}_{d\phi}(n) \\ &= \lambda \mathbf{P}(n) \hat{\mathbf{r}}_{d\phi}(n-1) + \mathbf{P}(n) \boldsymbol{\phi}(n) d^*(n) \\ &= \lambda \mathbf{P}(n) \hat{\mathbf{r}}_{d\phi}(n-1) + \mathbf{k}(n) d^*(n). \end{aligned} \quad (12.166)$$

**Table 12.5** Summary of the Conventional RLS Algorithm

Initialization:

Set  $\mathbf{P}(-1) = \delta^{-1} \mathbf{I}$ ;  $\delta = \text{small positive constant}$

$\mathbf{w}(0) = \mathbf{0}$  and  $0 \ll \lambda < 1$

For  $n = 0, 1, 2, \dots$ , compute

$$\mathbf{k}(n) = \frac{\mathbf{P}(n-1)\phi(n)}{\lambda + \phi^H(n)\mathbf{P}(n-1)\phi(n)}$$

$$\hat{y}(n) = \mathbf{w}^H(n)\phi(n)$$

$$e(n) = d(n) - \hat{y}(n)$$

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \mathbf{k}(n)e^*(n)$$

$$\mathbf{P}(n) = \lambda^{-1} [\mathbf{I} - \mathbf{k}(n)\phi^H(n)]\mathbf{P}(n-1)$$

Replacing (12.164) in (12.166), we arrive at

$$\begin{aligned} \mathbf{w}(n+1) &= \mathbf{P}(n-1)\hat{r}_{d\phi}(n-1) - \mathbf{k}(n)\phi^H(n)\mathbf{P}(n-1)\hat{r}_{d\phi}(n-1) + \mathbf{k}(n)d^*(n) \\ &= \mathbf{w}(n) - \mathbf{k}(n)\phi^H(n)\mathbf{w}(n) + \mathbf{k}(n)d^*(n) \\ &= \mathbf{w}(n) + \mathbf{k}(n)\underbrace{[d(n) - \mathbf{w}^H(n)\phi(n)]^*}_{e(n)}. \end{aligned} \quad (12.167)$$

The RLS algorithm was derived here as an exact solution for the least-squares problem. However, it also can be interpreted as a *quasi-Newton* algorithm assuming the instantaneous approximation for the gradient vector as in (12.135) and considering  $\mathbf{P}(n)$  as an approximation for the inverse Hessian matrix. Replacing these approximations in (12.134), we arrive at the same stochastic recursion (12.167).

The RLS algorithm is summarized in Table 12.5. Its computational cost increases with  $M^2$ , much faster than those of LMS and NLMS. Different ways of carrying out the calculations may result in a slightly different computational cost, but all with the same order of magnitude, i.e.,  $\mathcal{O}(M^2)$ . Performing the calculations in the following order [3]:

$$\begin{aligned} &\phi^H(n) \times [\mathbf{w}(n)] \\ &d^*(n) - [\phi^H(n)\mathbf{w}(n)] \\ &\lambda^{-1}\phi(n) \\ &\mathbf{P}(n-1) \times [\lambda^{-1}\phi(n)] \\ &\phi^H(n) \times [\lambda^{-1}\mathbf{P}(n-1)\phi(n)] \\ &1 + [\lambda^{-1}\phi^H(n)\mathbf{P}(n-1)\phi(n)] \\ &1/[1 + \lambda^{-1}\phi^H(n)\mathbf{P}(n-1)\phi(n)] \\ &[\lambda^{-1}\phi^H(n)\mathbf{P}(n-1)\phi(n)] \times \left[ \frac{1}{1 + \lambda^{-1}\phi^H(n)\mathbf{P}(n-1)\phi(n)} \right] \end{aligned}$$

$$\begin{aligned}
& [\lambda^{-1} \mathbf{P}(n-1) \boldsymbol{\phi}(n)] \times \left[ \frac{\lambda^{-1} \boldsymbol{\phi}^H(n) \mathbf{P}(n-1) \boldsymbol{\phi}(n)}{1 + \lambda^{-1} \boldsymbol{\phi}^H(n) \mathbf{P}(n-1) \boldsymbol{\phi}(n)} \right] \\
& \mathbf{P}(n) \boldsymbol{\phi}(n) = [\lambda^{-1} \mathbf{P}(n-1) \boldsymbol{\phi}(n)] - \left[ \frac{\lambda^{-2} \mathbf{P}(n-1) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \mathbf{P}(n-1) \boldsymbol{\phi}(n)}{1 + \lambda^{-1} \boldsymbol{\phi}^H(n) \mathbf{P}(n-1) \boldsymbol{\phi}(n)} \right] \\
& [\mathbf{P}(n) \boldsymbol{\phi}(n)] \times [d^*(n) - \boldsymbol{\phi}^H(n) \mathbf{w}(n)] \\
& \mathbf{w}(n+1) = [\mathbf{w}(n)] + [\mathbf{P}(n) \boldsymbol{\phi}(n) (d^*(n) - \boldsymbol{\phi}^H(n) \mathbf{w}(n))],
\end{aligned}$$

the conventional RLS requires  $4M^2 + 16M + 1$  real multiplications,  $4M^2 + 12M - 1$  real additions, and one real division per iteration for complex-valued signals. For real-valued data, it requires  $M^2 + 5M + 1$  real multiplications,  $M^2 + 3M$  real additions, and one real division per iteration. Note that the quantities inside brackets were computed in previous steps.

#### 1.12.3.3.1 Practical implementation of RLS

The RLS algorithm must be implemented carefully, because it is sensitive to numerical errors, which may accumulate and make the algorithm unstable. The problem can be understood intuitively as follows. In the conventional RLS algorithm, the inverse of the autocorrelation matrix is computed recursively by (expanding (12.161))

$$\mathbf{P}(n) = \lambda^{-1} \mathbf{P}(n-1) - \frac{\lambda^{-2} \mathbf{P}(n-1) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \mathbf{P}(n-1)}{1 + \lambda^{-1} \boldsymbol{\phi}^H(n) \mathbf{P}(n-1) \boldsymbol{\phi}(n)},$$

i.e., as the difference between two positive (semi-) definite matrices. Note that, since  $\lambda \leq 1$ , the factor multiplying the current  $\mathbf{P}(n-1)$  is  $\lambda^{-1} \geq 1$ . In infinite precision arithmetic, any growth due to this factor will be compensated by the second term. However, in finite precision arithmetic this compensation may not take place, and the factor  $\lambda^{-1}$  may make the recursion numerically unstable—usually, what happens is that  $\mathbf{P}(n)$  loses its positive character, so the matrix will have a negative eigenvalue, which in its turn leads to the divergence of the coefficients. Thus, to avoid problems one would need to guarantee that  $\mathbf{P}(n)$  stays symmetric and positive-definite for all time instants  $n$  (these properties are known as *backward consistency* of RLS [40, 41]). Symmetry can be guaranteed by computing only the upper or lower triangular part of  $\mathbf{P}(n)$ , and copying the result to obtain the rest of elements. However, it is also necessary to guarantee positive-definiteness. Reference [42] describes how this can be achieved.

Due to the fast convergence rate of RLS, a large literature is devoted to finding numerically stable and low-cost (i.e.,  $\mathcal{O}(M)$ ) versions of RLS. This is not an easy problem, that required the work of numerous researchers to be solved. Nowadays the user has a very large number of different versions of RLS to choose from. There are versions with formal proofs of stability, versions that work well in practice, but without formal proofs, versions with  $\mathcal{O}(M^2)$  complexity, and versions with  $\mathcal{O}(M)$  complexity. The interested reader can find more references in Section 1.12.5.1.2.

One approach to ensure the consistency of  $\mathbf{P}(n)$  uses a property of symmetric and positive-definite matrices (see Box 3): Cholesky factorizations. A symmetric and positive-definite matrix  $\mathbf{P}(n)$  may

always be factored as

$$\mathbf{P}(n) = \mathcal{P}(n)\mathcal{P}^H(n), \quad (12.168)$$

where  $\mathcal{P}(n)$  is a lower triangular  $M \times M$  matrix, called Cholesky factor of  $\mathbf{P}(n)$ . Thus, an algorithm that computes  $\mathcal{P}(n)$  instead of  $\mathbf{P}(n)$  can avoid the numerical instability of the conventional RLS algorithm. There are many algorithms based on this main idea; for some of them a precise stability proof is available [40]. A recent and very complete survey of QR-RLS algorithms is available in [43].

Another approach is available when the regressor sequence  $\{\phi(n)\}$  has shift structure. In this case, it is possible to derive *lattice*-based RLS filters that are in practice stable, although no formal proof is available at this time, as described, for example, in [5].

A more practical solution for the implementation of the RLS algorithm was proposed recently in [44]. This approach avoids propagation of the inverse covariance matrix, using an iterative method to solve (12.155) at each step. The computational complexity is kept low by using the previous solution as initialization, and by restricting the majority of the multiplications to multiplications by powers of two (which can be implemented as simple shifts). See Section 1.12.5.1.3.

### 1.12.3.4 Comparing convergence rates

To compare the convergence of LMS, NLMS, and RLS, we show next two examples. In Example 1, we consider a system identification application and in Example 2, we use these algorithms to update the weights of an equalizer.

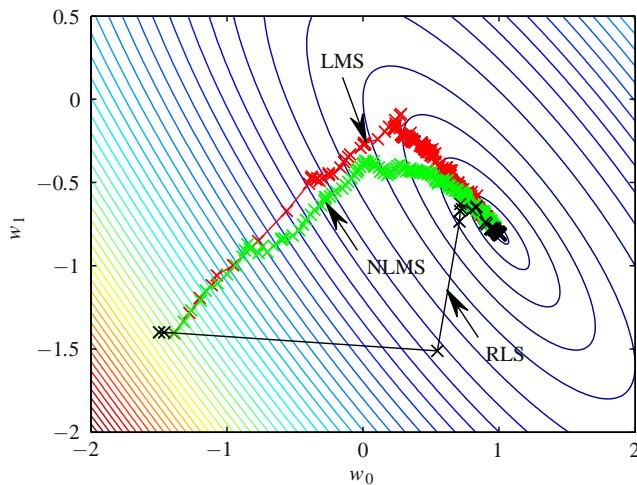

As we will see in more detail in Section 1.12.4, adaptive filters are compared based on how well they handle different classes of signals. For example, we could be interested in seeing how two filters handle white noise, or how they handle a certain level of correlation at the input. Given the stochastic nature of the inputs, the performance measures are defined in terms of averaged cost functions, most commonly the mean-square error (MSE), that is, the average of  $|e(n)|^2$  over all possible inputs in a given class. These averages can be computed theoretically, as we show in Section 1.12.4, or via simulations.

For example, the MSE as a function of time, that is, the curve  $E\{|e(n)|^2\} \times n$ , is called a filter's *learning curve*. A comparison of learning curves obtained theoretically and from simulations can be seen in Figure 12.30 further ahead. When simulations are used, one runs a filter  $L$  times for an interval of  $N$  samples, starting always from the same conditions. For each run  $\ell$ , the error  $e^{(\ell)}(n)$  is computed for  $1 \leq n \leq N$ , and one obtains the so-called *ensemble-average learning curve*

$$\widehat{E}(n) \triangleq \frac{1}{L} \sum_{\ell=1}^L |e^{(\ell)}(n)|^2.$$

Usually the ensemble-average learning curve will be a reasonable approximation of the true learning curve for a reasonably small value of  $L$  (say, from 50 to 1000), but in some situations this may not be true—see [45, 46] for examples and a detailed explanation.

**Example 1.** The aim of this example is to identify the system  $\mathbf{w}_o = [1 - 0.8]^T$ , assuming that the regressor  $\phi(n)$  is obtained from a process  $x(n)$  generated with a first-order autoregressive model, whose transfer function is  $1/(1 - 0.8z^{-1})$ . This model is fed with an i.i.d. Gaussian random process with unitary variance. Moreover, additive i.i.d. noise  $v(n)$  with variance  $\sigma_v^2 = 0.01$  is added to form the desired signal.

**FIGURE 12.25**

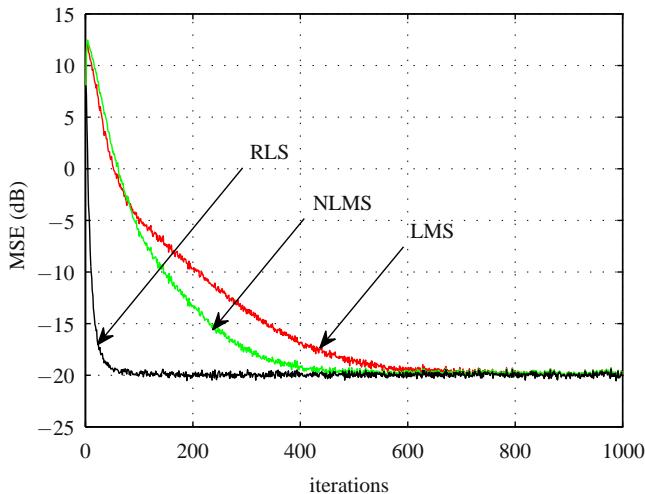

LMS ( $\mu = 0.01$ ), NLMS ( $\tilde{\mu} = 0.05$ ,  $\varepsilon = 0.5$ ) and RLS ( $\lambda = 0.99$ ,  $\delta = 1$ ) initialized at  $\mathbf{w}(0) = [-1.5 \ -1.4]^T$ ,  $\sigma_v^2 = 0.01$ . [Click](#) the animation video file.

Considering an adaptive filter with  $M = 2$  coefficients, we can obtain a contour plot of the mean-square error cost as a function of  $w_0$  and  $w_1$  as shown in Figure 12.25. The animations in Figure 12.25 illustrate the behavior of LMS ( $\mu = 0.01$ ), NLMS ( $\tilde{\mu} = 0.05$ ,  $\varepsilon = 0.5$ ), and RLS ( $\lambda = 0.99$ ,  $\delta = 1$ ) initialized at  $\mathbf{w}(0) = [-1.5 \ -1.4]^T$ . The correspondent curves of MSE along the iterations, estimated from the ensemble-average of 1000 independent runs, are shown in Figure 12.26. As expected for a colored input signal, RLS converges much faster than NLMS and LMS. NLMS converges faster than LMS and achieves the solution through a different path. To obtain a good behavior of NLMS in this example, we had to choose a relatively large regularization factor  $\varepsilon$ . This is always necessary when NLMS is used with few coefficients since in this case,  $\|\phi(n)\|^2$  has a high probability of becoming too close to zero and de-stabilizing the algorithm. This is shown in the analysis of Section 1.12.4.

**Example 2.** Now, we assume the transmission of a QPSK (quadrature phase shift-keying) signal, whose symbols belong to the alphabet  $\{\pm 1 \pm j1\}$ . This signal suffers the effect of the channel (taken from [47])

$$\begin{aligned} H(z) = & (-0.2 + j0.3) + (-0.5 + j0.4)z^{-1} + (0.7 - j0.6)z^{-2} \\ & +(0.4 + j0.3)z^{-3} + (0.2 + j0.1)z^{-4} \end{aligned} \quad (12.169)$$

and of additive white Gaussian noise (AWGN) under a signal-to-noise ratio (SNR) of 30 dB. The equalizer is an adaptive filter with  $M = 15$  coefficients initialized with zero and the desired signal is the transmitted sequence delayed by  $L = 9$  samples (go back to Figure 12.16 to see the equalization scheme). The adaptation parameters ( $\mu$ ,  $\tilde{\mu}$ ,  $\varepsilon$ ,  $\lambda$ ) were chosen in order to obtain the same steady-state performance of LMS, NLMS, and RLS (note that with a longer filter, the regularization parameter  $\varepsilon$  can be much

**FIGURE 12.26**

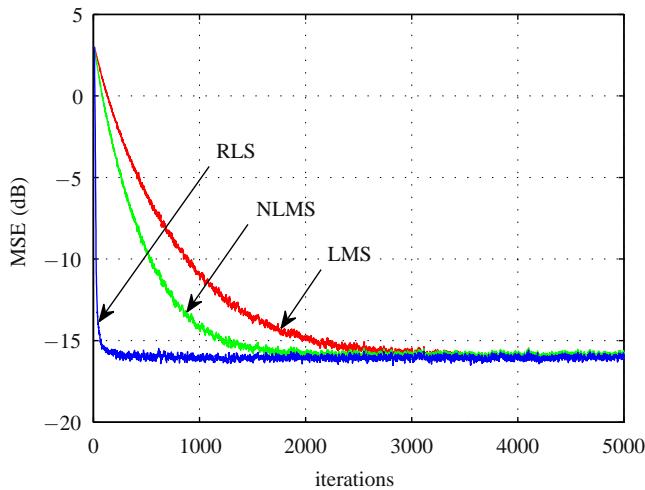

MSE along the iterations for LMS ( $\mu = 0.01$ ), NLMS ( $\hat{\mu} = 0.05$ ,  $\varepsilon = 0.5$ ) and RLS ( $\lambda = 0.99$ ,  $\delta = 1$ ) initialized at  $\mathbf{w}(0) = [-1.5 \ -1.4]^T$ ,  $\sigma_v^2 = 0.01$ , and ensemble-average of 1000 independent runs.

smaller than in the previous example). Figure 12.27 shows the MSE along the iterations, estimated from the ensemble-average of 1000 independent runs. Again, RLS presents the fastest convergence rate, followed by NLMS and LMS. These algorithms achieve the same steady-state MSE and therefore, present the same performance after convergence, which can be observed in Figure 12.28 where the equalizer output signal constellations are shown. The Matlab file used in this simulation is available at <http://www.lps.usp.br>.

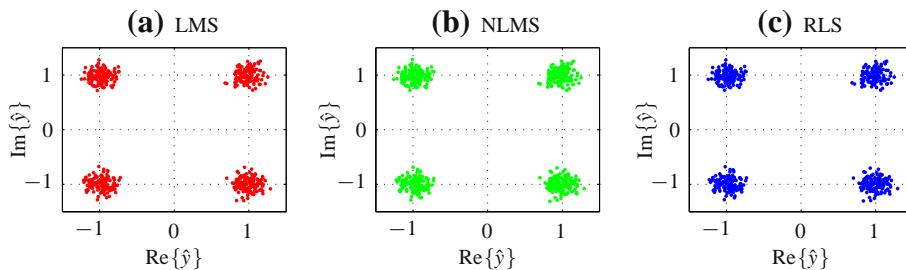

## 1.12.4 Statistical analysis

Closed-form expressions for the mean-square performance of adaptive filters facilitate comparisons between different algorithms and provide information about stability, convergence rate, mean-square error, and tracking capability. Since adaptive algorithms are obtained from stochastic approximations of the cost-functions, gradients and Hessians, their performance will degrade in comparison with the performance of the exact algorithms. Thus, stochastic analyses are also important to measure the performance degradation in relation to the exact algorithms.

The analysis of an adaptive algorithm constitutes a very hard problem, since adaptive filters are time-variant, stochastic, and nonlinear systems. Therefore, it is common to introduce simplifying approximations. They consist in most cases of disregarding the dependence between variables, for example, approximating the expected value of the product of two random variables, say,  $E\{xy\}$ , by the product of the expected values,  $E\{x\}E\{y\}$ . For historical reasons, these approximations are usually referred to as *assumptions* in the literature.

**FIGURE 12.27**

MSE along the iterations for LMS ( $\mu = 10^{-3}$ ), NLMS ( $\tilde{\mu} = 0.08$ ,  $\varepsilon = 10^{-5}$ ), and RLS ( $\lambda = 0.997$ ,  $\delta = 1$ ) initialized at  $\mathbf{w}(0) = \mathbf{0}$ ; QPSK,  $L = 9$ ,  $M = 15$ , and ensemble-average of 1000 independent runs; equalization of the channel (12.169).

**FIGURE 12.28**

Equalizer output signal constellations after convergence for (a) LMS ( $\mu = 10^{-3}$ ), (b) NLMS ( $\tilde{\mu} = 0.08$ ,  $\varepsilon = 10^{-5}$ ), and (c) RLS ( $\lambda = 0.997$ ,  $\delta = 1$ ); initialized at  $\mathbf{w}(0) = \mathbf{0}$ ; QPSK,  $L = 9$ ,  $M = 15$ ; equalization of the channel (12.169).

In some situations, in particular for LMS and some of its variants, the approximations are proved to converge to the exact solution in the limiting case of slow adaptation ( $\mu \rightarrow 0$  in the case of LMS), and their predictions tend to be reasonable for the range of step-sizes used in practice. We will not reproduce these proofs here, since they are in general very technical, but they can be found in [48–53] for the case of LMS, and [39] for more general filters.

The literature contains a few exact analytical results, but only for LMS, under very particular conditions [54–56]. In addition, the complexity of these exact models grows very quickly with the number of coefficients, so they are only useful for short filters (up to about five coefficients.).

The performance of an adaptive filter is usually described by evaluating the mean and the mean square (variance) of the weight error vector and of the error signal  $e(n)$ . This usually works very well for slow adaptation (i.e., small step-size). However, for fast adaptation, the behavior of an adaptive filter is considerably more complicated than can be seen by looking only at means and variances. Some of the phenomena that appear in LMS with large step-sizes are described in [46, 57]. References [45, 58–60] study algorithms with strong nonlinearities, for which the usual approximations are not always valid.

The analysis of NLMS was considered in [61–68]. Many works consider only tapped-delay line regressors, the case of Volterra filters is considered for example in [69–73]. For RLS filters, important models for infinite-precision arithmetic can be found in [74, 75]. The case of finite-precision arithmetic is discussed in Section 1.12.5.1.2.

The real importance of the approximations used in the adaptive filtering literature is that they lead to reasonably simple models that capture well the overall behavior of an adaptive filter. Simple models provide intuition about how a filter will behave if a given parameter is changed, which is important for a designer to make good decisions. Some approximations are made because without them the mathematical analysis would not be feasible, but others are used mainly because they lead to simpler models. Of course, there are situations in which it is important to study a filter in more detail, reducing the number of assumptions used in the analysis, as in the references just cited.

In this section we analyze three of the most common adaptive filters—LMS, NLMS, and RLS, starting with LMS in Section 1.12.4.3, and then showing how to extend these results to the other algorithms in Section 1.12.4.4. To start, we need to define some useful performance measures. The *mean-square error* (MSE) is simply the expected value of  $|e(n)|^2$ :

$$J(n) \triangleq E\{|e(n)|^2\}. \quad (12.170)$$

The most widely measure of performance used in the literature of adaptive filtering is the *excess mean-square error* (EMSE), which is defined as

$$\xi(n) \triangleq E\{|e_a(n)|^2\}, \quad (12.171)$$

where the *excess a priori error* is given by

$$e_a(n) = \tilde{\mathbf{w}}^H(n)\phi(n), \quad (12.172)$$

and the weight error vector by

$$\tilde{\mathbf{w}}(n) = \mathbf{w}_o(n) - \mathbf{w}(n). \quad (12.173)$$

Note that the optimal solution  $\mathbf{w}_o(n)$  is now allowed to be time-variant. Note also the difference between  $e_a(n)$  and  $e(n)$ , defined in (12.119). Both are *a priori* errors, but  $e_a(n)$  is computed with  $\tilde{\mathbf{w}}(n)$ , whereas  $e(n)$  is computed with  $\mathbf{w}(n)$ . The EMSE measures how much  $J(n)$  exceeds its minimum value  $J_{\min}(n)$  due to adaptation: if you were able to find the optimum filter coefficients  $\mathbf{w}_o(n)$  at each time, the EMSE would be zero. Since the actual filter coefficients are never exactly equal to the optimum values, the

EMSE measures the effect of this difference on the error variance. Closely related to the EMSE, the *misadjustment* is defined as

$$\mathcal{M}(n) \triangleq \zeta(n)/\sigma_v^2. \quad (12.174)$$

The *excess a posteriori error*  $e_p(n)$  is mostly used in the analysis and derivations of algorithms. It is the error obtained *after* using the current data  $\phi(n)$  to update the coefficient vector (thus the names *a priori* and *a posteriori*), i.e.,

$$e_p(n) = \tilde{\mathbf{w}}^H(n+1)\phi(n). \quad (12.175)$$

Again, note the difference with respect to  $\xi(n)$ , defined in (12.129).

Another common performance measure is the *mean-square deviation* (MSD). It measures how far  $\mathbf{w}(n)$  is from  $\mathbf{w}_o(n)$  in average:

$$\chi(n) \triangleq E\{\|\tilde{\mathbf{w}}(n)\|^2\}. \quad (12.176)$$

The EMSE is the most frequently performance measure used for comparisons between adaptive filters; however in some applications, particularly for system identification, the MSD is more adequate.

We now will discuss a general model for the input signals, considering a set of approximations that leads to reasonable, yet simple models.

#### 1.12.4.1 Data model

From the orthogonality principle (recall Section 1.12.2), the optimal solution  $\mathbf{w}_o(n)$  satisfies the property

$$E\{\phi(n)[d(n) - \mathbf{w}_o^H(n)\phi(n)]\} = \mathbf{0}, \quad (12.177)$$

i.e., the input regressor vector  $\phi(n)$  is uncorrelated with the optimal estimation error

$$v_o(n) \triangleq d(n) - \mathbf{w}_o^H(n)\phi(n), \quad (12.178)$$

whose mean is zero and whose variance  $\sigma_v^2(n) = E\{|v_o(n)|^2\}$  is equal to the minimum cost  $J_{\min}(n)$ . Thus, a linear regression model for  $d(n)$  holds, i.e.,

$$d(n) = \mathbf{w}_o^H(n)\phi(n) + v_o(n). \quad (12.179)$$

It then follows that

$$e(n) = d(n) - \mathbf{w}^H(n)\phi(n) = \tilde{\mathbf{w}}^H(n)\phi(n) + v_o(n) = e_a(n) + v_o(n), \quad (12.180)$$

and the MSE is given by

$$\begin{aligned} J(n) &= E\{|e(n)|^2\} = E\{|e_a(n)|^2\} + 2E\{e_a(n)v_o(n)\} + E\{|v_o(n)|^2\} = \\ &= \zeta(n) + 2E\{e_a(n)v_o(n)\} + \sigma_v^2(n). \end{aligned}$$

The first approximation (or assumption) used in adaptive filtering analysis is to disregard the cross-term  $E\{e_a(n)v_o(n)\}$ . Since  $v_o(n)$  and  $\phi(n)$  are uncorrelated, but not necessarily independent, the cross-term does not vanish in general. From observations, however, one notes that the cross-term is usually negligible, compared to the other terms. In order to obtain a simple model for the adaptive filter, we will assume that  $\phi(n)$  and  $v_o(n)$  are independent of each other, and of previous samples  $\phi(n-k)$ ,  $v(n-k)$  for  $k > 0$ :

**Assumption 1.** The sequences  $\{\phi(n)\}$  and  $\{v_o(n)\}$  are independent and identically distributed (iid), and independent of each other (not only orthogonal). In addition, the sequence  $\{\phi(n)\}$  is assumed stationary and  $\{v_o(n)\}$  is zero-mean.

The last two assumptions are not in fact necessary, but they simplify the analysis. In general the sequence  $\{\phi(n)\}$  is not iid: for example if  $\phi(n)$  is formed from a tap-delay line or from a Volterra series expansion (see Eqs. (12.113) and (12.114))  $\phi(n)$  and  $\phi(n - 1)$  will have terms in common. However, assuming that the sequences are iid leads to simple models that in general are good approximations for the range of step-sizes usually found in practice, in particular for small step-sizes. The analysis based on Assumption 1 is known in the literature as *independence theory*.

Going back to the adaptive filter recursions (see Tables 12.2–12.5, and also Eq. (12.221) further ahead) we see that the current weight error  $\tilde{w}(n)$  is a function of past inputs  $\phi(n - 1), \phi(n - 2), \dots$  and noise samples  $v(n - 1), v(n - 2), \dots$ , but *not* of the current samples  $\phi(n)$  and  $v_o(n)$ . Therefore, under Assumption 1,  $\tilde{w}(n)$  is independent of  $v_o(n)$  and  $\phi(n)$ , so that

$$\text{E}\{e_a(n)v_o(n)\} = \text{E}\{\tilde{w}^H(n)\}\text{E}\{\phi(n)\}\text{E}\{v_o(n)\} = 0.$$

We conclude that under Assumption 1, the MSE  $J(n) = \text{E}\{|e(n)|^2\}$  is related to the EMSE via

$$J(n) = \zeta(n) + J_{\min}(n) = \zeta(n) + \sigma_v^2, \quad (12.181)$$

since Assumption 1 implies that  $J_{\min}(n)$  is a constant.

We also need a model for the variation of the optimal solution. Again, our choice is a model that captures the main consequences of a non-constant  $w_o(n)$ , without unnecessarily complicating the analysis.

**Assumption 2 (Random-walk model).** In a nonstationary environment,  $w_o$  varies as

$$w_o(n + 1) = w_o(n) + q(n), \quad (12.182)$$

where  $q(n)$  is zero-mean i.i.d vector with positive-definite autocorrelation matrix  $Q = \text{E}\{q(n)q^H(n)\}$ , independent of the initial condition  $w(0)$ , and of  $\{\phi(\ell), v(\ell)\}$  for all  $\ell$ .

The covariance matrix of  $w_o$ , according to (12.182), grows slowly to infinity. A more general model for the variation of  $w_o$  uses the recursion

$$\begin{cases} w_o(n + 1) = w_o(n) + \theta(n), \\ \theta(n) = \alpha\theta(n - 1) + q(n), \quad 0 \leq |\alpha| < 1, \end{cases}$$

whose covariance matrix remains bounded, but the analysis becomes more complicated [3]. Therefore, it is common in the literature to adopt the model (12.182). Note that both models assume that  $\{x(n)\}$  is a stationary random sequence, although  $w_o(n)$  is allowed to vary with  $n$ .

#### 1.12.4.2 Relating the covariance matrix of the weight-error vector to the EMSE and the MSD

The covariance matrix of the weight-error vector is defined as

$$S(n) \triangleq \text{E}\left\{\tilde{w}(n)\tilde{w}^H(n)\right\}. \quad (12.183)$$

This matrix is important in the statistical analysis of adaptive filters since it is related to the MSD and the EMSE as we show next.

Recall that the MSD is given by

$$\chi(n) = \mathbb{E} \left\{ \|\tilde{\mathbf{w}}(n)\|^2 \right\} = \sum_{i=0}^{M-1} \mathbb{E} \left\{ \tilde{w}_i^2(n) \right\}.$$

Now, the terms  $\mathbb{E}\{\tilde{w}_i^2(n)\}$  are exactly the terms that appear in the diagonal of  $\mathbf{S}(n)$ , therefore, recalling that the *trace* of a square matrix is the sum of its main-diagonal elements (see Box 3), we obtain

$$\chi(n) = \sum_{i=0}^{M-1} \mathbb{E}\{\tilde{w}_i^2(n)\} = \sum_{m=0}^{M-1} s_{mm}(n) = \text{Tr}(\mathbf{S}(n)). \quad (12.184)$$

Under Assumption 1,  $\phi(n)$  and  $\tilde{\mathbf{w}}(n)$  are independent, as we just saw. Therefore,

$$\begin{aligned} \xi(n) &= \mathbb{E}\{|\tilde{\mathbf{w}}^H(n)\phi(n)|^2\} = \mathbb{E}\{\tilde{\mathbf{w}}^H(n)\phi(n)(\tilde{\mathbf{w}}^H(n)\phi(n))^*\} \\ &= \mathbb{E}\{\tilde{\mathbf{w}}^H(n)\phi(n)\phi^H(n)\tilde{\mathbf{w}}(n)\} = \mathbb{E} \left\{ \mathbb{E}\{\tilde{\mathbf{w}}^H(n)\phi(n)\phi^H(n)\tilde{\mathbf{w}}(n)|\tilde{\mathbf{w}}(n)\} \right\} \\ &= \mathbb{E} \left\{ \tilde{\mathbf{w}}^H(n) \mathbb{E}\{\phi(n)\phi^H(n)|\tilde{\mathbf{w}}(n)\} \tilde{\mathbf{w}}(n) \right\} = \mathbb{E}\{\tilde{\mathbf{w}}^H(n)\mathbf{R}_\phi\tilde{\mathbf{w}}(n)\}, \end{aligned}$$

where we used Assumption 1 to write  $\mathbb{E}\{\phi(n)\phi^H(n)\} = \mathbf{R}_\phi$  (constant), and two properties of expected values. The first is that, for any two random variables  $a, b$ ,

$$\mathbb{E}\{ab\} = \mathbb{E}\{\mathbb{E}\{ab|b\}\} = \mathbb{E}\{\mathbb{E}\{a|b\}b\},$$

where the inner expected value is taken with respect to  $a$ , and the second with respect to  $b$ . The second property is that, if  $a$  and  $b$  are independent, then  $\mathbb{E}\{a|b\}$  does not depend on  $b$ , i.e.,  $\mathbb{E}\{a|b\} = \mathbb{E}\{a\}$ .

To proceed, we apply a useful trick from matrix theory. You can check by direct computation that, if  $\mathbf{A} \in \mathcal{C}^{K \times L}$  and  $\mathbf{B} \in \mathcal{C}^{L \times K}$ , then  $\text{Tr}(\mathbf{AB}) = \text{Tr}(\mathbf{BA})$ . Applying this property with  $\mathbf{A} \leftarrow \tilde{\mathbf{w}}^H(n)$  and  $\mathbf{B} \leftarrow \mathbf{R}_\phi\tilde{\mathbf{w}}(n)$ , we obtain

$$\xi(n) = \text{Tr} \left( \mathbf{R}_\phi \mathbb{E}\{\tilde{\mathbf{w}}(n)\tilde{\mathbf{w}}^H(n)\} \right) = \text{Tr} \left( \mathbf{R}_\phi \mathbf{S}(n) \right). \quad (12.185)$$

Since  $\mathbf{R}_\phi$  is symmetric, there always exists an orthogonal matrix  $\mathbf{U}$  (i.e.,  $\mathbf{U}^{-1} = \mathbf{U}^H$ ) that diagonalizes  $\mathbf{R}_\phi$ , that is,

$$\mathbf{U}^H \mathbf{R}_\phi \mathbf{U} = \begin{bmatrix} \lambda_1 & 0 & \cdots & 0 \\ 0 & \lambda_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \lambda_M \end{bmatrix} \triangleq \boldsymbol{\Lambda}, \quad (12.186)$$

where  $\lambda_1, \lambda_2, \dots, \lambda_M$  are the eigenvalues of  $\mathbf{R}_\phi$  (see Box 3). Defining the rotated matrix

$$\mathbf{S}'(n) \triangleq \mathbf{U}^H \mathbf{S}(n) \mathbf{U}$$

and recalling that  $\mathbf{U}\mathbf{U}^H = \mathbf{I}$ , (12.184) and (12.185) can be rewritten respectively as

$$\chi(n) = \text{Tr}(\mathbf{U} \underbrace{\mathbf{U}^H \mathbf{S}(n) \mathbf{U}}_{\mathbf{S}'(n)} \mathbf{U}^H) = \text{Tr}(\mathbf{U} \mathbf{S}'(n) \mathbf{U}^H) \quad (12.187)$$

and

$$\zeta(n) = \text{Tr}(\mathbf{U} \underbrace{\mathbf{U}^H \mathbf{R}_\phi \mathbf{U}}_{\Lambda} \underbrace{\mathbf{U}^H \mathbf{S}(n) \mathbf{U}}_{\mathbf{S}'(n)} \mathbf{U}^H) = \text{Tr}(\mathbf{U} \Lambda \mathbf{S}'(n) \mathbf{U}^H). \quad (12.188)$$

Using again the fact that  $\text{Tr}(\mathbf{AB}) = \text{Tr}(\mathbf{BA})$ , with  $\mathbf{A} \leftarrow \mathbf{U}$ , we obtain

$$\chi(n) = \text{Tr}(\mathbf{S}'(n)) \quad (12.189)$$

and

$$\zeta(n) = \text{Tr}(\Lambda \mathbf{S}'(n)). \quad (12.190)$$

Note that both the MSD (12.189) and the EMSE (12.190) depend only on the diagonal entries of  $\mathbf{S}'(n)$ . We can work therefore only with these diagonal entries, defining the vectors

$$\mathbf{s}'(n) = \text{diag}(\mathbf{S}'(n)) = [s'_0(n) s'_1(n) \cdots s'_{M-1}(n)]^T, \quad (12.191)$$

and

$$\mathbf{l} = [\lambda_0, \dots, \lambda_{M-1}]^T, \quad (12.192)$$

where  $\text{diag}(\mathbf{A})$  represents a column vector with the diagonal elements of  $\mathbf{A}$ , and evaluating the MSD and EMSE respectively as

$$\chi(n) = \sum_{k=0}^{M-1} s'_k(n) \quad (12.193)$$

and

$$\zeta(n) = \mathbf{l}^T \mathbf{s}'(n) = \sum_{k=0}^{M-1} \lambda_k s'_k(n). \quad (12.194)$$

Again, the MSD and EMSE depend only on the elements of the diagonal of the rotated matrix  $\mathbf{S}'(n)$ . In the case of EMSE, these elements are weighed by the eigenvalues of the autocorrelation matrix  $\mathbf{R}_\phi$ . As we shall see in Section 1.12.4.3, the stability of LMS can be studied through a recursion for the vector  $\mathbf{s}'(n)$ .

Thus, according to the previous results, in order to obtain closed-form expressions for the MSD and the EMSE of an adaptive algorithm, one path is to find a recursion for the covariance matrix  $\mathbf{S}(n)$  or for the vector  $\mathbf{s}'(n)$ . However, this is not the only method to analyze adaptive algorithms, as we shall see in Section 1.12.4.4.

### 1.12.4.3 Statistical analysis of the LMS algorithm

In this section, we present a statistical analysis for the LMS algorithm, assuming that the optimal solution  $\mathbf{w}_o$  remains constant ( $\mathbf{q}(n) \equiv \mathbf{0}$ , for all  $n$ ). This analysis predicts the behavior of LMS in steady-state and in transient, and provides a range of the step-size  $\mu$  for which LMS operates adequately. If you are familiar with the LMS analysis, go to Section 1.12.4.4, where we present a unified analysis for LMS, NLMS, and RLS algorithms in a nonstationary environment.

We first rewrite (12.123) in terms of the weight-error vector  $\tilde{\mathbf{w}}$ . Thus, subtracting both sides of (12.123) from  $\mathbf{w}_o$ , we obtain

$$\begin{aligned}\mathbf{w}_o - \mathbf{w}(n+1) &= \mathbf{w}_o - \mathbf{w}(n) - \mu\phi(n)e^*(n), \\ \tilde{\mathbf{w}}(n+1) &= \tilde{\mathbf{w}}(n) - \mu\phi(n)e^*(n).\end{aligned}\quad (12.195)$$

Replacing  $e^*(n) = e_a^*(n) + v_o^*(n) = \phi^H(n)\tilde{\mathbf{w}}(n) + v_o^*(n)$  in (12.195), we arrive at

$$\tilde{\mathbf{w}}(n+1) = \left[ \mathbf{I} - \mu\phi(n)\phi^H(n) \right] \tilde{\mathbf{w}}(n) - \mu\phi(n)v_o^*(n). \quad (12.196)$$

**First-order analysis.** Taking expectations on both sides of (12.196), we obtain

$$\begin{aligned}\mathbb{E}\{\tilde{\mathbf{w}}(n+1)\} &= \mathbb{E}\left\{\left[ \mathbf{I} - \mu\phi(n)\phi^H(n) \right] \tilde{\mathbf{w}}(n)\right\} - \mu\mathbb{E}\{\phi(n)v_o^*(n)\} \\ &= \mathbb{E}\left\{\left[ \mathbf{I} - \mu\phi(n)\phi^H(n) \right] \tilde{\mathbf{w}}(n)\right\},\end{aligned}\quad (12.197)$$

where the last equality follows from the fact that  $\phi(n)$  is orthogonal to  $v_o^*(n)$ , according to the orthogonality condition (see Eq. (12.96)). Since  $\tilde{\mathbf{w}}(n)$  is assumed to be independent of  $\phi(n)$  (see Assumption 1), we arrive at

$$\mathbb{E}\{\tilde{\mathbf{w}}(n+1)\} = [\mathbf{I} - \mu\mathbf{R}_\phi]\mathbb{E}\{\tilde{\mathbf{w}}(n)\}. \quad (12.198)$$

This is the same recursion we saw in Box 1. According to linear systems theory, this recursion converges as long as the largest eigenvalue of  $\mathbf{A} = \mathbf{I} - \mu\mathbf{R}_\phi$  has absolute value less than one, which implies (see Box 1)

$$\begin{aligned}|1 - \mu\lambda| < 1 &\Leftrightarrow 0 < \mu < \frac{2}{\lambda_k}, \quad \forall k \Leftrightarrow \\ 0 < \mu &< \frac{2}{\lambda_{\max}},\end{aligned}\quad (12.199)$$

where  $\lambda_k$ ,  $k = 1, 2, \dots, M$  are the eigenvalues of  $\mathbf{R}_\phi$ , and  $\lambda_{\max}$  is its maximum eigenvalue. We should notice that this range for  $\mu$  does not ensure the stability of LMS, since it ensures the convergence of the mean of  $\tilde{\mathbf{w}}(n) = \mathbf{w}_o - \mathbf{w}(n)$  towards 0, but the autocovariance of  $\tilde{\mathbf{w}}(n)$  may still be diverging. We show next that the range for  $\mu$  based on a second-order analysis is indeed more restrict.

**Second-order analysis.** Now, we use (12.196) to find a recursion for  $S(n)$  and (12.185) to evaluate the EMSE of LMS. Multiplying (12.196) by its Hermitian, taking the expectations of both sides, we arrive at

$$\begin{aligned}
 E\{\tilde{\mathbf{w}}(n+1)\tilde{\mathbf{w}}^H(n+1)\} &= E\{\tilde{\mathbf{w}}(n)\tilde{\mathbf{w}}^H(n)\} \\
 &\quad - \overbrace{\mu E\{\tilde{\mathbf{w}}(n)\tilde{\mathbf{w}}^H(n)\phi(n)\phi^H(n)\}}^{\mathcal{A}} \\
 &\quad - \overbrace{\mu E\{\phi(n)\phi^H(n)\tilde{\mathbf{w}}(n)\tilde{\mathbf{w}}^H(n)\}}^{\mathcal{B}} \\
 &\quad + \overbrace{\mu^2 E\{\phi(n)\phi^H(n)\tilde{\mathbf{w}}(n)\tilde{\mathbf{w}}^H(n)\phi(n)\phi^H(n)\}}^{\mathcal{C}} \\
 &\quad + \overbrace{\mu^2 E\{|v_o(n)|^2 \phi(n)\phi^H(n)\}}^{\mathcal{D}} \\
 &\quad - \overbrace{\mu E\{v_o(n)\tilde{\mathbf{w}}(n)\phi^H(n)\}}^{\mathcal{E}} \\
 &\quad - \overbrace{\mu E\{v_o^*(n)\phi(n)\tilde{\mathbf{w}}^H(n)\}}^{\mathcal{F}} \\
 &\quad + \overbrace{\mu^2 E\{v_o(n)\phi(n)\phi^H(n)\tilde{\mathbf{w}}(n)\phi^H(n)\}}^{\mathcal{G}} \\
 &\quad + \overbrace{\mu^2 E\{v_o^*(n)\phi(n)\tilde{\mathbf{w}}^H(n)\phi(n)\phi^H(n)\}}^{\mathcal{H}}. \tag{12.200}
 \end{aligned}$$

Now, using Assumption 1, we can evaluate the terms  $\mathcal{A} - \mathcal{H}$  of (12.200):

**A-** Recalling that Assumption 1 implies that  $\tilde{\mathbf{w}}(n)$  is independent from  $\phi(n)$ , the term  $\mathcal{A}$  can be approximated by

$$\begin{aligned}
 \mathcal{A} &= \mu E\left\{E\left\{\tilde{\mathbf{w}}(n)\tilde{\mathbf{w}}^H(n)\phi(n)\phi^H(n)|\phi(n)\right\}\right\} \\
 &\approx \mu E\left\{E\left\{\tilde{\mathbf{w}}(n)\tilde{\mathbf{w}}^H(n)\right\}\phi(n)\phi^H(n)\right\} \\
 &= \mu S(n)E\left\{\phi(n)\phi^H(n)\right\} = \mu S(n)\mathbf{R}_\phi. \tag{12.201}
 \end{aligned}$$

**B-** Analogously, we obtain for  $\mathcal{B}$

$$\mathcal{B} \approx \mu \mathbf{R}_\phi S(n). \tag{12.202}$$

**C-** Using Assumption 1, the term  $\mathcal{C}$  can be rewritten as

$$\begin{aligned}
 \mathcal{C} &= \mu^2 E\left\{\phi(n)\phi^H(n)\tilde{\mathbf{w}}(n)\tilde{\mathbf{w}}^H(n)\phi(n)\phi^H(n)\right\} \\
 &\approx \mu^2 E\left\{\phi(n)\phi^H(n)S(n)\phi(n)\phi^H(n)\right\}. \tag{12.203}
 \end{aligned}$$

We return to this term further on.

$\mathcal{D}$ - Using the fact that  $v_o(n)$  is independent of  $\phi(n)$  and  $\tilde{\mathbf{w}}(n)$ ,  $\mathcal{D}$  reduces to

$$\mathcal{D} = \mu^2 E\{|v_o(n)|^2 \phi(n) \phi^H(n)\} \approx \mu^2 \sigma_v^2 \mathbf{R}_\phi. \quad (12.204)$$

$\mathcal{E}$ - Using the fact that  $v_o(n)$  is a zero-mean random variable, which is independent of  $\phi(n)$  and  $\tilde{\mathbf{w}}(n)$ ,  $\mathcal{E}$  is a  $M \times M$  null matrix. Using the same arguments, the terms  $\mathcal{F}$ ,  $\mathcal{G}$ , and  $\mathcal{H}$  are also null matrices. We should point out that the zero-mean assumption for  $v_o(n)$  is not necessary, but it really facilitates the analysis. Furthermore, as we saw in Section 1.12.2.1.4, we can enforce  $E\{v_o(n)\} = 0$  using simple methods.

From the previous results, (12.200) reduces to

$$\begin{aligned} \mathbf{S}(n+1) &\approx \mathbf{S}(n) - \mu \mathbf{S}(n) \mathbf{R}_\phi - \mu \mathbf{R}_\phi \mathbf{S}(n) \\ &\quad + \underbrace{\mu^2 E\{\phi(n) \phi^H(n) S(n) \phi(n) \phi^H(n)\}}_{\mathcal{C}} + \mu^2 \sigma_v^2 \mathbf{R}_\phi. \end{aligned} \quad (12.205)$$

This recursion is convenient to obtain closed-form expressions for the EMSE and the MSD of LMS. Observe that the four first terms on the right-hand side of (12.205) are linear in  $\mathbf{S}(n)$ . Assuming that  $\mu$  is sufficiently small, the term  $\mathcal{C}$  can be neglected with respect to the three first terms. Thus, for small step-sizes, (12.205) reduces to

$$\mathbf{S}(n+1) \approx \mathbf{S}(n) - \mu [S(n) \mathbf{R}_\phi + \mathbf{R}_\phi S(n)] + \mu^2 \sigma_v^2 \mathbf{R}_\phi, \quad (12.206)$$

with initialization  $\mathbf{S}(0) = [\mathbf{w}_o - \mathbf{w}(0)] [\mathbf{w}_o - \mathbf{w}(0)]^H$ .

Since we can obtain the EMSE and the MSD from  $\mathbf{S}(n)$  and  $\mathbf{R}_\phi$  through (12.185) and (12.184), we should use recursion (12.206) to compute  $\mathbf{S}(n)$  and then, evaluate  $\zeta(n) = \text{Tr}(\mathbf{S}(n) \mathbf{R}_\phi)$  and  $\chi(n) = \text{Tr}(\mathbf{S}(n))$ . Particularly for  $n \rightarrow \infty$ , since  $\mathbf{S}(n+1) \approx \mathbf{S}(n)$ , we obtain

$$\mathbf{S}(\infty) \mathbf{R}_\phi + \mathbf{R}_\phi \mathbf{S}(\infty) = \mu \sigma_v^2 \mathbf{R}_\phi. \quad (12.207)$$

Taking the trace of both sides of (12.207), we arrive at an analytical expression for the steady-state EMSE of LMS, i.e.,

$$\zeta^{\text{LMS}}(\infty) \approx \frac{\mu \sigma_v^2 \text{Tr}(\mathbf{R}_\phi)}{2} \quad (\text{for sufficiently small } \mu). \quad (12.208)$$

This expression indicates that the EMSE of LMS increases with  $\mu$  and with the length of the filter. The dependence with the filter length is through the trace of  $\mathbf{R}_\phi$ . It is more evident when the class of filters we are considering is FIR, that is, when  $\phi(n) = [x(n) \dots x(n-M+1)]^T$  (a tapped-delay line). In this case, if  $\{x(n)\}$  is stationary, then  $\text{Tr}(\mathbf{R}_\phi) = M E\{x^2(n)\}$ ,  $M$  times the average power of  $x(n)$ .

Turning now to the filter coefficients, if we multiply both sides of (12.207) from the right by  $\mathbf{R}_\phi^{-1}$ , taking the trace of both sides, and recalling that  $\text{Tr}(\mathbf{AB}) = \text{Tr}(\mathbf{BA})$ , we obtain an expression for the steady-state MSD of LMS, i.e.,

$$\chi^{\text{LMS}}(\infty) \approx \frac{\mu \sigma_v^2 M}{2} \quad (\text{for sufficiently small } \mu). \quad (12.209)$$

Again, the smaller the step-size  $\mu$  and the filter length  $M$ , the smaller the MSD of LMS.

These results explain what we observed in the simulations in Section 1.12.1.2 (Figures 12.9 and 12.10): for larger values of  $\mu$  the filter converges faster, but hovers around the optimum solution in a larger region. The size of this region is what the MSD attempts to measure—the EMSE measures how much this hovering affects the error.

These quantities are important in practical situations. For example, in an actual implementation of an acoustic echo canceler, when the near-end user is speaking, his voice is part of  $v(n)$ . Since the near-end speech is normally stronger than the echo,  $\sigma_v^2$  tends to be quite large when the near-end speaker is talking. If the adaptive filter were allowed to keep adapting at these moments, (12.208) shows that the filter estimates would wander too far from the optimum. To avoid this problem, the step-size is reduced to zero whenever the near-end user is speaking. A *double-talk detector* is used to decide when to stop adaptation.

It can be shown that (12.206) is stable for sufficiently small  $\mu$ . However, (12.206) cannot be used to find a range of values of  $\mu$  that guarantee stability, due to the approximations made, particularly the discarding of term  $\mathcal{C}$ . Thus, in order to study the stability of LMS, we consider next an approximation for this term, based the assumption that the input vector is Gaussian. This assumption allows us to approximate  $\mathcal{C}$  as

$$\mathcal{C} \approx \mathbf{R}_\phi \text{Tr}(S(n)\mathbf{R}_\phi) + \beta \mathbf{R}_\phi S(n)\mathbf{R}_\phi, \quad (12.210)$$

where as usual,  $\beta = 1$  (resp.,  $\beta = 2$ ) for complex (resp., real) data. See Box 7 for the derivation of (12.210).

Replacing (12.210) in (12.205), we arrive at

$$\begin{aligned} S(n+1) &\approx S(n) - \mu [S(n)\mathbf{R}_\phi + \mathbf{R}_\phi S(n)] \\ &\quad + \mu^2 [\mathbf{R}_\phi \text{Tr}(S(n)\mathbf{R}_\phi) + \beta \mathbf{R}_\phi S(n)\mathbf{R}_\phi + \sigma_v^2 \mathbf{R}_\phi]. \end{aligned} \quad (12.211)$$

The stability of (12.211) is determined through a recursion for the vector  $s'(n)$ , which contains the elements of the diagonal of the rotated matrix  $S'(n) = \mathbf{U}^H S(n) \mathbf{U}$  (see Section 1.12.4.2). A recursion for  $S'(n)$  can be obtained by multiplying (12.211) from the left by  $\mathbf{U}^H$  and from the right by  $\mathbf{U}$  and recalling that  $\mathbf{U}\mathbf{U}^H = \mathbf{I}$ , which leads to

$$\begin{aligned} S'(n+1) &\approx S'(n) - \mu [S'(n)\Lambda + \Lambda S'(n)] \\ &\quad + \mu^2 [\Lambda \text{Tr}(\Lambda S'(n)) + \beta \Lambda S'(n)\Lambda] + \mu^2 \sigma_v^2 \Lambda, \end{aligned} \quad (12.212)$$

where  $\Lambda$  is defined as in (12.186). Thus, a recursion for  $s'(n+1)$  is given by

$$s'(n+1) = [\mathbf{I} - 2\mu\Lambda + \mu^2 (\beta\Lambda^2 + \mathbf{U}^T)] s'(n) + \mu^2 \sigma_v^2 \mathbf{I}, \quad (12.213)$$

where  $\mathbf{I}$  is defined in (12.192).

The system matrix  $A$  of (12.213) is given by

$$A = \mathbf{I} - 2\mu\Lambda + \mu^2 (\beta\Lambda^2 + \mathbf{U}^T) = (\mathbf{I} - \mu\Lambda)^2 + \mu^2(\beta - 1)\Lambda^2 + \mu^2 \mathbf{U}^T.$$

Although it is possible to obtain the exact values of all eigenvalues of  $\mathbf{A}$ , as done in [36], we follow here a much simpler, approximate route. We can use Fact 7 in Box 3 to find an upper bound for the largest eigenvalue  $\nu_i$  of  $\mathbf{A}$ , using the 1-norm of  $\mathbf{A}$ :

$$\max_{0 \leq i \leq M-1} |\nu_i| \leq \|\mathbf{A}\|_1 = \max_{0 \leq i \leq M-1} \sum_{j=0}^{M-1} |a_{ij}|,$$

where  $a_{ij}$  are the entries of  $\mathbf{A}$ . If we find a range of  $\mu$  for which  $\|\mathbf{A}\|_1 \leq 1$ , then the recursion will be stable. This will be of course a conservative condition (sufficient, but not necessary).

Now note that the  $i$ th column of  $\mathbf{A}$  has entries  $\lambda_i \lambda_j$  if  $i \neq j$ , and  $(1 - \mu \lambda_i)^2 + \mu^2(\beta - 1)\lambda_i^2 + \mu^2\lambda_i^2$  in the term corresponding to the diagonal. Since all terms are positive, the 1-norm is

$$\begin{aligned} & \max_{0 \leq i \leq M-1} \left[ (1 - \mu \lambda_i)^2 + \mu^2(\beta - 1)\lambda_i^2 + \mu^2\lambda_i \sum_{j=0}^{M-1} \lambda_j \right] \\ &= \max_{0 \leq i \leq M-1} \left[ (1 - \mu \lambda_i)^2 + \mu^2(\beta - 1)\lambda_i^2 + \mu^2\lambda_i \text{Tr}(\mathbf{\Lambda}) \right]. \end{aligned}$$

Recall that  $\text{Tr}(\mathbf{\Lambda}) = \text{Tr}(\mathbf{R}_\phi)$  (Fact 1 from Box 3). Therefore, the recursion will be stable if

$$1 - 2\mu\lambda_i + \mu^2\lambda_i^2 + \mu^2(\beta - 1)\lambda_i^2 + \mu^2\lambda_i \text{Tr}(\mathbf{R}_\phi) \leq 1, \quad 0 \leq i \leq M - 1.$$

Simplifying, we obtain the condition

$$\mu \leq \frac{2}{\beta\lambda_i + \text{Tr}(\mathbf{R}_\phi)}, \quad 0 \leq i \leq M - 1.$$

The smallest bound is for  $\lambda_i = \lambda_{\max}$ :

$$\mu \leq \frac{2}{\beta\lambda_{\max} + \text{Tr}(\mathbf{R}_\phi)}. \quad (12.214)$$

If we replace  $\lambda_{\max}$  by  $\text{Tr}(\mathbf{R}_\phi) \geq \lambda_{\max}$  in the denominator, we obtain a simpler, but more conservative condition:

$$\mu \leq \frac{2}{(\beta + 1)\text{Tr}(\mathbf{R}_\phi)}. \quad (12.215)$$

For real data, this range reduces to

$$0 < \mu < \frac{2}{3\text{Tr}(\mathbf{R}_\phi)} \quad (\text{real data}) \quad (12.216)$$

and for complex data to

$$0 < \mu < \frac{1}{\text{Tr}(\mathbf{R}_\phi)} \quad (\text{complex data}). \quad (12.217)$$

**Table 12.6** Parameters of LMS, NLMS, and RLS Algorithms

Algorithm	$\rho(n)$	$\mathbf{M}^{-1}(n)$
LMS	$\mu$	$\mathbf{I}$
NLMS	$\frac{\tilde{\mu}}{\varepsilon + \ \boldsymbol{\phi}(n)\ ^2}$	$\mathbf{I}$
RLS	$1 - \lambda$	$(1 - \lambda) \sum_{\ell=1}^n \lambda^{n-\ell} \boldsymbol{\phi}(\ell) \boldsymbol{\phi}^H(\ell)$

If the input is a tapped-delay line as in (12.113),  $\text{Tr}(\mathbf{R}_\phi) = \sum_{k=0}^{M-1} \mathbb{E}\{|x(n-k)|^2\}$ . If  $\{x(n)\}$  is a stationary sequence, the stability condition for LMS is easy to obtain: we need to choose  $\mu$  in the range

$$0 < \mu < \frac{2}{(\beta + 1) \times M \times (\text{average power of } x(n))}. \quad (12.218)$$

This concludes our stability analysis for LMS. We now show how to extend these results to NLMS and RLS, in a unified way. At the end of the next section, we give examples comparing the models to simulated results.

#### 1.12.4.4 A unified statistical analysis

In this section, we assume a nonstationary environment, where the optimal solution varies according to the random walk model (see Assumption 2). We start by obtaining a general update equation for the LMS, NLMS, and RLS algorithms, in order to provide a unified statistical analysis for these algorithms.

##### 1.12.4.4.1 A general update equation

In order to provide a unified analysis for the LMS, NLMS and RLS algorithms, we consider the following general update equation

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \rho(n) \mathbf{M}(n) \boldsymbol{\phi}(n) e^*(n), \quad (12.219)$$

where  $\rho(n)$  is a step-size,  $\mathbf{M}(n)$  is a non-singular matrix with hermitian symmetry ( $\mathbf{M}^H(n) = \mathbf{M}(n)$ ), and  $e(n) = d(n) - \mathbf{w}^H(n) \boldsymbol{\phi}(n)$  is the estimation error. Many adaptive algorithms can be written as in (12.219), by proper choices of  $\rho(n)$  and  $\mathbf{M}(n)$ . The LMS, NLMS, and RLS algorithms employ the step-sizes  $\rho(n)$  and the matrices  $\mathbf{M}(n)$  as in Table 12.6, where  $\mathbf{I}$  is the  $M \times M$  identity matrix,  $\mu$  and  $0 < \tilde{\mu} < 2$  are step-sizes, and  $0 \ll \lambda < 1$  is a forgetting factor. For RLS,  $\mathbf{M}(n) = (1 - \lambda)^{-1} \mathbf{P}(n)$  (see Eq. (12.162)). Note that, since  $(1 - \lambda)$  plays the role of step-size in RLS, we multiply the matrix  $\mathbf{P}(n)$  by  $(1 - \lambda)^{-1}$ , keeping the update equation of the RLS weights as in (12.167).

We must rewrite (12.219) in terms of the weight-error vector  $\tilde{\mathbf{w}}$ . Thus, subtracting both sides of (12.219) from  $\mathbf{w}_o(n+1) = \mathbf{w}_o(n) + \mathbf{q}(n)$  (Eq. (12.182)), we obtain

$$\begin{aligned} \mathbf{w}_o(n+1) - \mathbf{w}(n+1) &= \mathbf{w}_o(n) + \mathbf{q}(n) - \mathbf{w}(n) - \rho(n) \mathbf{M}(n) \boldsymbol{\phi}(n) e^*(n), \\ \tilde{\mathbf{w}}(n+1) &= \tilde{\mathbf{w}}(n) - \rho(n) \mathbf{M}(n) \boldsymbol{\phi}(n) e^*(n) + \mathbf{q}(n). \end{aligned} \quad (12.220)$$

Replacing  $e^*(n) = e_a^*(n) + v^*(n) = \boldsymbol{\phi}^H(n)\tilde{\mathbf{w}}(n) + v^*(n)$  in (12.220), we arrive at

$$\tilde{\mathbf{w}}(n+1) = \left[ \mathbf{I} - \rho(n)\mathbf{M}(n)\boldsymbol{\phi}(n)\boldsymbol{\phi}^H(n) \right] \tilde{\mathbf{w}}(n) - \rho(n)\mathbf{M}(n)\boldsymbol{\phi}(n)v^*(n) + \mathbf{q}(n). \quad (12.221)$$

We next use recursion (12.221) to evaluate the EMSE and the MSD of LMS, NLMS, and RLS.

#### 1.12.4.4.2 Alternative analysis methods

Closed-form expressions for the EMSE and MSD can be obtained in two ways:

- i. Finding a recursion for the correlation matrix of the weight-error vector, denoted by  $\mathbf{S}(n)$ . The EMSE and MSE can be easily computed given  $\mathbf{S}(n)$ , as we saw in Section 1.12.4.2. This is the earlier approach in the literature [1,2] and therefore, we refer to it here as *traditional* method.
- ii. Using the energy conservation analysis of [3,76–78]. The energy conservation approach relies on an energy conservation relation that holds for a large class of adaptive filters. The energy conservation method presents some advantages when compared to the traditional one. For example, using energy conservation, one can obtain steady-state results directly, bypassing several of the difficulties encountered in obtaining them as a limiting case of a transient analysis. This method can also be used in transient analyses of adaptive algorithms (see, e.g., Part V of [3]).

It is important to understand that both methods involve different sets of approximations (assumptions), so they do not always arrive at the same expressions. Generally, they tend to be equal in the limit of slow adaptation (i.e., if  $\rho(n) \rightarrow 0$  in (12.221)). For larger values of  $\rho(n)$ , which method will provide the best approximation depends on the algorithm. As for the work necessary to arrive at the final answers, the energy conservation approach is almost always easier to use if one is interested only in steady-state results. If one is interested in transient performance and stability studies, then the traditional method may be simpler, depending on the algorithm under study.

To give an overview of both methods, we first use the traditional method to obtain the transient and steady-state performance of the LMS, NLMS, and RLS algorithms. This is an extension of what we did for LMS in Section 1.12.4.3, taking advantage of the similarities between the algorithms. In the sequel, we employ the energy conservation method to obtain closed-form expressions for the steady-state EMSE of the same algorithms.

In this section we allow the environment to be nonstationary, i.e., the optimal solution  $\mathbf{w}_o$  is time-variant. The results for stationary environments can be obtained simply by making  $\mathbf{Q} = \mathbf{0}$  in the equations below. In order to simplify the arguments, we require that the regressor sequence  $\{\boldsymbol{\phi}(n)\}$  be wide-sense stationary, that is, we assume that  $\mathbf{R}_{\boldsymbol{\phi}}$  is constant.

#### 1.12.4.4.3 Analysis with the traditional method

The traditional analysis method consists of finding a recursion for  $\mathbf{S}(n)$ , and using (12.184) and (12.185) to evaluate the MSD and the EMSE, respectively. A recursion for  $\mathbf{S}(n)$  can be obtained by multiplying (12.221) by its Hermitian, taking the expectations of both sides, and recalling that Assumption 1 implies that  $\tilde{\mathbf{w}}(n)$  is independent of  $\boldsymbol{\phi}(n)$  and of the zero-mean  $v_o(n)$ . Furthermore, using the fact that

$E\{\tilde{w}(n)q^H(n)\} = \mathbf{0}$  since the sequence  $\{q(n)\}$  is iid (Assumption 2), we arrive at

$$\begin{aligned}
 E\{\tilde{w}(n+1)\tilde{w}^H(n+1)\} &= E\{q(n)q^H(n)\} + E\{\tilde{w}(n)\tilde{w}^H(n)\} \\
 &\quad - \overbrace{E\{\rho(n)\tilde{w}(n)\tilde{w}^H(n)\phi(n)\phi^H(n)M(n)\}}^{\mathcal{A}} \\
 &\quad - \overbrace{E\{\rho(n)M(n)\phi(n)\phi^H(n)\tilde{w}(n)\tilde{w}^H(n)\}}^{\mathcal{B}} \\
 &\quad + \overbrace{E\{\rho^2(n)M(n)\phi(n)\phi^H(n)\tilde{w}(n)\tilde{w}^H(n)\phi(n)\phi^H(n)M(n)\}}^{\mathcal{C}} \\
 &\quad + \overbrace{E\{\rho^2(n)|v_o(n)|^2M(n)\phi(n)\phi^H(n)M(n)\}}^{\mathcal{D}}. \tag{12.222}
 \end{aligned}$$

To simplify (12.222), we also need two additional assumptions:

**Assumption 3.** Matrix  $M(n)$  varies slowly in relation to  $\tilde{w}(n)$ . Thus, when  $M(n)$  appears inside the expectations of (12.222), we simply replace it by its mean. For LMS and NLMS, this assumption is not necessary, since  $M(n) = I$ . For RLS,  $M(n) = (1 - \lambda)^{-1}P(n) \approx (1 - \lambda)^{-1}E\{P(n)\}$  if  $\lambda \approx 1$ ;

**Assumption 4.** The input regressor vector  $\phi(n)$  is assumed to be Gaussian. This assumption makes the analysis more tractable, since Gaussianity facilitates the computation of the expected values in  $\mathcal{C}$ .

Now, using the Assumptions 1–4, we can evaluate the terms  $\mathcal{A}$ – $\mathcal{D}$  of (12.222):

**A-** The term  $\mathcal{A}$  can be approximated by

$$\begin{aligned}
 \mathcal{A} &= E\left\{E\left\{\rho(n)\tilde{w}(n)\tilde{w}^H(n)\phi(n)\phi^H(n)M(n)|\phi(n)\right\}\right\} \\
 &\approx E\left\{\rho(n)E\left\{\tilde{w}(n)\tilde{w}^H(n)\right\}\phi(n)\phi^H(n)\right\}E\{M(n)\} \\
 &= S(n)E\left\{\rho(n)\phi(n)\phi^H(n)\right\}E\{M(n)\}. \tag{12.223}
 \end{aligned}$$

For LMS, this term reduces to

$$\mathcal{A}^{\text{LMS}} \approx \mu S(n)R_\phi. \tag{12.224}$$

For NLMS, we must obtain an approximation for

$$E\left\{\rho(n)\phi(n)\phi^H(n)\right\} = E\left\{\frac{\tilde{\mu}\phi(n)\phi^H(n)}{\varepsilon + \phi^H(n)\phi(n)}\right\}. \tag{12.225}$$

It is possible to evaluate this expected value exactly (see [61, 63, 64]), but our intention here is to obtain the simplest possible model. Therefore, we will use two additional approximations:

**Assumption 5.** The number of coefficients  $M$  is large enough for each element  $\phi(n)\phi^H(n)$  in the numerator to be approximately independent from the denominator  $\sum_{k=0}^{M-1} |\phi(n-k)|^2$ .

This is equivalent to apply the averaging principle proposed in [79], since for large  $M$ ,  $\|\boldsymbol{\phi}(n)\|^2$  tends to vary slowly compared to the individual entries of  $\boldsymbol{\phi}(n)\boldsymbol{\phi}^H(n)$ .

Thus, (12.225) can be approximated as

$$E \left\{ \frac{\boldsymbol{\phi}(n)\boldsymbol{\phi}^H(n)}{\varepsilon + \boldsymbol{\phi}^H(n)\boldsymbol{\phi}(n)} \right\} \approx E \left\{ \frac{1}{\varepsilon + \boldsymbol{\phi}^H(n)\boldsymbol{\phi}(n)} \right\} E \left\{ \boldsymbol{\phi}(n)\boldsymbol{\phi}^H(n) \right\}. \quad (12.226)$$

Under Assumption 5, the first expected value in (12.226) can be approximated by:

$$E \left\{ \frac{1}{\varepsilon + \boldsymbol{\phi}^H(n)\boldsymbol{\phi}(n)} \right\} \approx \frac{1}{E\{\varepsilon + \boldsymbol{\phi}^H(n)\boldsymbol{\phi}(n)\}} = \frac{1}{\varepsilon + \text{Tr}(\mathbf{R}_\phi)}. \quad (12.227)$$

An alternative, more accurate approximation is obtained when  $\boldsymbol{\phi}(n)$  is Gaussian and a tapped-delay line:

**Assumption 6.** The regressor  $\boldsymbol{\phi}(n)$  is formed by a tapped-delay line with Gaussian entries as in (12.113), and  $\varepsilon = 0$ .

Under Assumptions 4, 5, and 6 it can be shown (see [65] for details) that

$$E \left\{ \frac{1}{\varepsilon + \boldsymbol{\phi}^H(n)\boldsymbol{\phi}(n)} \right\} \approx \frac{1}{\sigma_x^2(M-2)}. \quad (12.228)$$

Both approximations are only valid for long filters. However, (12.228) shows that NLMS needs a large regularization constant if  $M < 3$ , which is verified in practice [63]. We will present the final results for NLMS in terms of Assumption 6, but recall that a less precise, but more general option is available using only Assumption 4 and approximations such as (12.227).

Thus, the term  $\mathcal{A}$  for NLMS reduces to (using (12.228))

$$\mathcal{A}^{\text{NLMS}} \approx \frac{\tilde{\mu}}{\sigma_x^2(M-2)} \mathbf{S}(n) \mathbf{R}_\phi. \quad (12.229)$$

Finally, for RLS, we obtain

$$\mathcal{A}^{\text{RLS}} \approx \mathbf{S}(n) \mathbf{R}_\phi \bar{\mathbf{P}}(n), \quad (12.230)$$

where  $\bar{\mathbf{P}}(n) \triangleq E\{\mathbf{R}_\phi^{-1}(n)\}$ , which we will evaluate later on.

**B-** Analogously, we obtain for **B**

$$\mathcal{B} \approx E\{\mathbf{M}(n)\} E \left\{ \rho(n) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \right\} \mathbf{S}(n). \quad (12.231)$$

Particularizing for each algorithm, we have

$$\mathcal{B}^{\text{LMS}} \approx \mu \mathbf{R}_\phi \mathbf{S}(n), \quad (12.232)$$

$$\mathcal{B}^{\text{NLMS}} \approx \frac{\tilde{\mu}}{\sigma_x^2(M-2)} \mathbf{R}_\phi \mathbf{S}(n), \quad (12.233)$$

and

$$\mathcal{B}^{\text{RLS}} \approx \bar{\mathbf{P}}(n) \mathbf{R}_\phi \mathbf{S}(n). \quad (12.234)$$

**C-** The term  $\mathcal{C}$  can be approximated by

$$\begin{aligned}\mathcal{C} &= \mathbb{E} \left\{ \rho^2(n) \mathbf{M}(n) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \tilde{\mathbf{w}}(n) \tilde{\mathbf{w}}^H(n) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \mathbf{M}(n) \right\} \\ &\approx \mathbb{E}\{\mathbf{M}(n)\} \mathbb{E} \left\{ \rho^2(n) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \mathbf{S}(n) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \right\} \mathbb{E}\{\mathbf{M}(n)\}.\end{aligned}\quad (12.235)$$

Under the Gaussianity assumption 4, it holds that (see Box 7)

$$\mathbb{E} \left\{ \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \mathbf{S}(n) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \right\} = \mathbf{R}_\phi \text{Tr}(\mathbf{S}(n) \mathbf{R}_\phi) + \beta \mathbf{R}_\phi \mathbf{S}(n) \mathbf{R}_\phi, \quad (12.236)$$

where  $\beta = 1$  (resp.,  $\beta = 2$ ) for complex (resp. real) data. Thus, for LMS we have

$$\mathcal{C}^{\text{LMS}} \approx \mu^2 [\mathbf{R}_\phi \text{Tr}(\mathbf{S}(n) \mathbf{R}_\phi) + \beta \mathbf{R}_\phi \mathbf{S}(n) \mathbf{R}_\phi]. \quad (12.237)$$

For NLMS, using the same arguments to get (12.226), the following approximation holds for large  $M$ :

$$\begin{aligned}\mathbb{E} \left\{ \rho^2(n) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \mathbf{S}(n) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \right\} \\ \approx \tilde{\mu}^2 \mathbb{E} \left\{ \frac{1}{[\boldsymbol{\phi}^H(n) \boldsymbol{\phi}(n)]^2} \right\} \mathbb{E} \left\{ \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \mathbf{S}(n) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \right\}.\end{aligned}\quad (12.238)$$

Under Assumption 5, the first expectation on the r.h.s. of (12.238) is given by

$$\mathbb{E} \left\{ \frac{1}{[\boldsymbol{\phi}^H(n) \boldsymbol{\phi}(n)]^2} \right\} = \frac{1}{\varepsilon + \text{Tr}(\mathbf{R}_\phi) + \beta \text{Tr}(\mathbf{R}_\phi^2)}. \quad (12.239)$$

On the other hand, under Assumption 6, we obtain [65]

$$\mathbb{E} \left\{ \frac{1}{[\boldsymbol{\phi}^H(n) \boldsymbol{\phi}(n)]^2} \right\} = \frac{1}{\sigma_x^4(M-2)(M-4)}. \quad (12.240)$$

Replacing (12.240) and (12.236) in (12.238), we arrive at

$$\mathcal{C}^{\text{NLMS}} \approx \frac{\tilde{\mu}^2}{\sigma_x^4(M-2)(M-4)} [\mathbf{R}_\phi \text{Tr}(\mathbf{S}(n) \mathbf{R}_\phi) + \beta \mathbf{R}_\phi \mathbf{S}(n) \mathbf{R}_\phi]. \quad (12.241)$$

Finally, for RLS we obtain

$$\mathcal{C}^{\text{RLS}} \approx \overline{\mathbf{P}}(n) [\mathbf{R}_\phi \text{Tr}(\mathbf{S}(n) \mathbf{R}_\phi) + \beta \mathbf{R}_\phi \mathbf{S}(n) \mathbf{R}_\phi] \overline{\mathbf{P}}(n). \quad (12.242)$$

**D-** Using the fact that  $v_o(n)$  is independent of  $\boldsymbol{\phi}(n)$  and  $\tilde{\mathbf{w}}(n)$ ,  $\mathcal{D}$  reduces to

$$\begin{aligned}\mathcal{D} &= \mathbb{E}\{\rho^2(n)|v_o(n)|^2 \mathbf{M}(n) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \mathbf{M}(n)\} \\ &\approx \sigma_v^2 \mathbb{E}\{\mathbf{M}(n)\} \mathbb{E}\{\rho^2(n) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n)\} \mathbb{E}\{\mathbf{M}(n)\}.\end{aligned}\quad (12.243)$$

Particularizing for each algorithm, we obtain

$$\mathcal{D}^{\text{LMS}} \approx \mu^2 \sigma_v^2 \mathbf{R}_\phi(n), \quad (12.244)$$

$$\mathcal{D}^{\text{NLMS}} \approx \frac{\tilde{\mu}^2}{\sigma_x^4(M-2)(M-4)} \sigma_v^2 \mathbf{R}_\phi(n), \quad (12.245)$$

where we could also have used (12.239), and

$$\mathcal{D}^{\text{RLS}} \approx \sigma_v^2 \bar{\mathbf{P}}(n) \mathbf{R}_\phi \bar{\mathbf{P}}(n). \quad (12.246)$$

From the previous results, (12.222) reduces to

$$\begin{aligned} \mathbf{S}(n+1) &\approx \mathbf{S}(n) - \mathbb{E}\{\rho(n)\} [\mathbf{S}(n) \mathbf{R}_\phi \mathbb{E}\{\mathbf{M}(n)\} + \mathbb{E}\{\mathbf{M}(n)\} \mathbf{R}_\phi \mathbf{S}(n)] \\ &\quad + \mathbb{E}\{\rho^2(n)\} \mathbb{E}\{\mathbf{M}(n)\} [\mathbf{R}_\phi \text{Tr}(\mathbf{S}(n) \mathbf{R}_\phi) + \beta \mathbf{R}_\phi \mathbf{S}(n) \mathbf{R}_\phi] \mathbb{E}\{\mathbf{M}(n)\} \\ &\quad + \sigma_v^2 \mathbb{E}\{\rho^2(n)\} \mathbb{E}\{\mathbf{M}(n)\} \mathbf{R}_\phi \mathbb{E}\{\mathbf{M}(n)\} + \mathbf{Q} \end{aligned} \quad (12.247)$$

with initialization  $\mathbf{S}(0) = [\mathbf{w}_o(0) - \mathbf{w}(0)] [\mathbf{w}_o(0) - \mathbf{w}(0)]^H$ .

For RLS, we still need an approximation for  $\bar{\mathbf{P}}(n) = \mathbb{E}\{\mathbf{P}(n)\}$ . Initializing the estimate of the autocorrelation matrix with  $\widehat{\mathbf{R}}_\phi(-1) = \delta \mathbf{I}$ , we will have at iteration  $n$

$$\widehat{\mathbf{R}}_\phi(n) = \lambda^n \delta \mathbf{I} + \sum_{\ell=1}^n \lambda^{n-\ell} \boldsymbol{\phi}(\ell) \boldsymbol{\phi}^H(\ell). \quad (12.248)$$

Taking the expectations of both sides of (12.248), we obtain

$$\mathbb{E}\{\widehat{\mathbf{R}}_\phi(n)\} = \lambda^n \delta \mathbf{I} + \mathbf{R}_\phi \frac{1 - \lambda^n}{1 - \lambda}. \quad (12.249)$$

For  $\lambda \approx 1$ , the variance of  $\widehat{\mathbf{R}}_\phi(n)$  is small, and we can approximate  $\bar{\mathbf{P}}(n) \approx [\mathbb{E}\{\widehat{\mathbf{R}}_\phi(n)\}]^{-1}$ , so that

$$\bar{\mathbf{P}}(n) \approx \left[ \lambda^n \delta \mathbf{I} + \mathbf{R}_\phi \frac{1 - \lambda^n}{1 - \lambda} \right]^{-1}. \quad (12.250)$$

This approximation is good for large  $n$  and in steady-state. During the initial phases of the transient, however, the approximation will only be reasonable if  $\delta$  is large enough to make the last term in (12.249) small compared to  $\lambda^n \delta \mathbf{I}$ . This is because for  $n < M$ , the term  $\sum_{\ell=1}^n \lambda^{n-\ell} \boldsymbol{\phi}(\ell) \boldsymbol{\phi}^H(\ell)$  in (12.248) will be singular, and thus will not be well approximated by  $(1 - \lambda^n) \mathbf{R}_\phi / (1 - \lambda)$ .

Using the previous approximations, (12.247) can be particularized for the LMS, NLMS, and RLS algorithms as shown in Table 12.7. Since we can obtain the EMSE and the MSD from  $\mathbf{S}(n)$  and  $\mathbf{R}_\phi$  through (12.185) and (12.184), we should use the recursions of Table 12.7 to compute  $\mathbf{S}(n)$  and then evaluate  $\zeta(n) = \text{Tr}(\mathbf{S}(n) \mathbf{R}_\phi)$  and  $\chi(n) = \text{Tr}(\mathbf{S}(n))$ .

**Example 3.** To verify the accuracy of the expressions of Table 12.7, we consider a system identification application in a stationary environment ( $\mathbf{Q} = \mathbf{0}$ ). The optimal solution is a lowpass FIR filter with linear

**Table 12.7** Recursions for Covariance Matrix  $\mathbf{S}(n+1)$ . The Expressions for NLMS Assume that the Regressor is a Tapped-Delay Line. Alternative Expressions for NLMS are Available Using (12.227) and (12.239)

Algorithm	$\mathbf{S}(n+1)$
LMS	$\mathbf{S}(n+1) \approx \mathbf{S}(n) - \mu [\mathbf{S}(n)\mathbf{R}_\phi + \mathbf{R}_\phi\mathbf{S}(n)]$ $+ \mu^2 [\mathbf{R}_\phi \text{Tr}(\mathbf{S}(n)\mathbf{R}_\phi) + \beta \mathbf{R}_\phi \mathbf{S}(n)\mathbf{R}_\phi + \sigma_v^2 \mathbf{R}_\phi] + \mathbf{Q}$
NLMS	$\mathbf{S}(n+1) \approx \mathbf{S}(n) - \frac{\tilde{\mu}}{\sigma_x^2(M-2)} [\mathbf{S}(n)\mathbf{R}_\phi + \mathbf{R}_\phi\mathbf{S}(n)]$ $+ \frac{\tilde{\mu}^2}{\sigma_x^4(M-2)(M-4)} [\mathbf{R}_\phi \text{Tr}(\mathbf{S}(n)\mathbf{R}_\phi) + \beta \mathbf{R}_\phi \mathbf{S}(n)\mathbf{R}_\phi + \sigma_v^2 \mathbf{R}_\phi] + \mathbf{Q}$
RLS	$\mathbf{S}(n+1) \approx \mathbf{S}(n) - [\mathbf{S}(n)\mathbf{R}_\phi \bar{\mathbf{P}}(n) + \bar{\mathbf{P}}(n)\mathbf{R}_\phi \mathbf{S}(n)]$ $+ \bar{\mathbf{P}}(n) [\mathbf{R}_\phi \text{Tr}(\mathbf{S}(n)\mathbf{R}_\phi) + \beta \mathbf{R}_\phi \mathbf{S}(n)\mathbf{R}_\phi + \sigma_v^2 \mathbf{R}_\phi] \bar{\mathbf{P}}(n) + \mathbf{Q}$

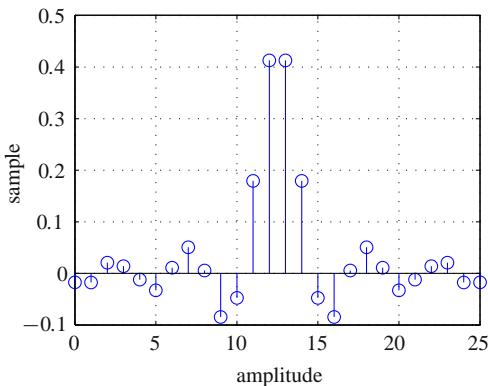

phase, whose coefficients are shown in Figure 12.29. The regressor  $\phi(n)$  is obtained from a process  $x(n)$  generated with a first-order autoregressive model, whose transfer function is  $\sqrt{1-b^2}/(1-bz^{-1})$ . Note that the sequence  $\{\phi(n)\}$  is not iid. This model is fed with an iid Gaussian random process, whose variance is such that  $\text{Tr}(\mathbf{R}_\phi) = 1$ . Moreover, additive iid noise  $v_o(n)$  with variance  $\sigma_v^2 = 0.01$  is added to form the desired signal.

Figure 12.30 shows the EMSE for RLS ( $\lambda = 0.995$ ,  $\delta = 1$ ), NLMS ( $\tilde{\mu} = 0.1$ ,  $\varepsilon = 10^{-5}$ ), and LMS ( $\mu = 0.05$ ), estimated from the ensemble-average of 2000 independent runs. The dashed lines represent the theoretical EMSE computed as  $\zeta(n) = \text{Tr}(\mathbf{S}(n)\mathbf{R}_\phi)$ . We can observe a good agreement between theory and simulation.

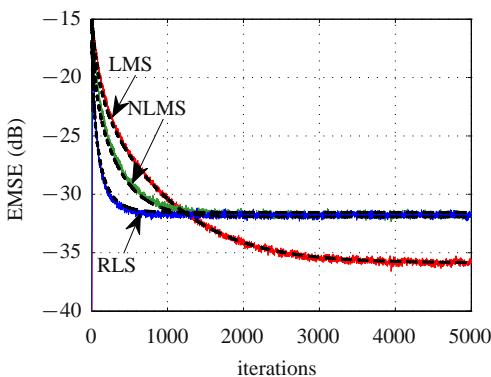

Figure 12.31 shows the EMSE of RLS ( $\lambda = 0.995$ ), assuming different values for  $\delta$ . We can observe that the theoretical EMSE of RLS presents a good agreement with simulation during the initial phases of the transient, but only for large values of  $\delta$  due to the approximation (12.250).

#### 1.12.4.4.4 Steady-state analysis with the energy conservation method

This method (also known as *feedback* approach [78, 80]) is based on an energy conservation relation that holds for a large class of adaptive filters. To obtain this relation for the algorithms of the form (12.219), we first assume a stationary environment ( $\mathbf{q}(n) \equiv \mathbf{0}$ ).

**FIGURE 12.29**

Impulse response  $w_o$  of the unknown lowpass filter.

**FIGURE 12.30**

EMSE for RLS ( $\lambda = 0.995, \delta = 1$ ), NLMS ( $\tilde{\mu} = 0.1, \varepsilon = 10^{-5}$ ), and LMS ( $\mu = 0.05$ );  $b = 0.8, \sigma_v^2 = 10^{-2}, \sigma_q^2 = 0$ ; mean of 2000 independent runs. The dashed lines represent the predicted values of  $\xi(n)$  for each algorithm.

Recall that the excess a posteriori error is given by

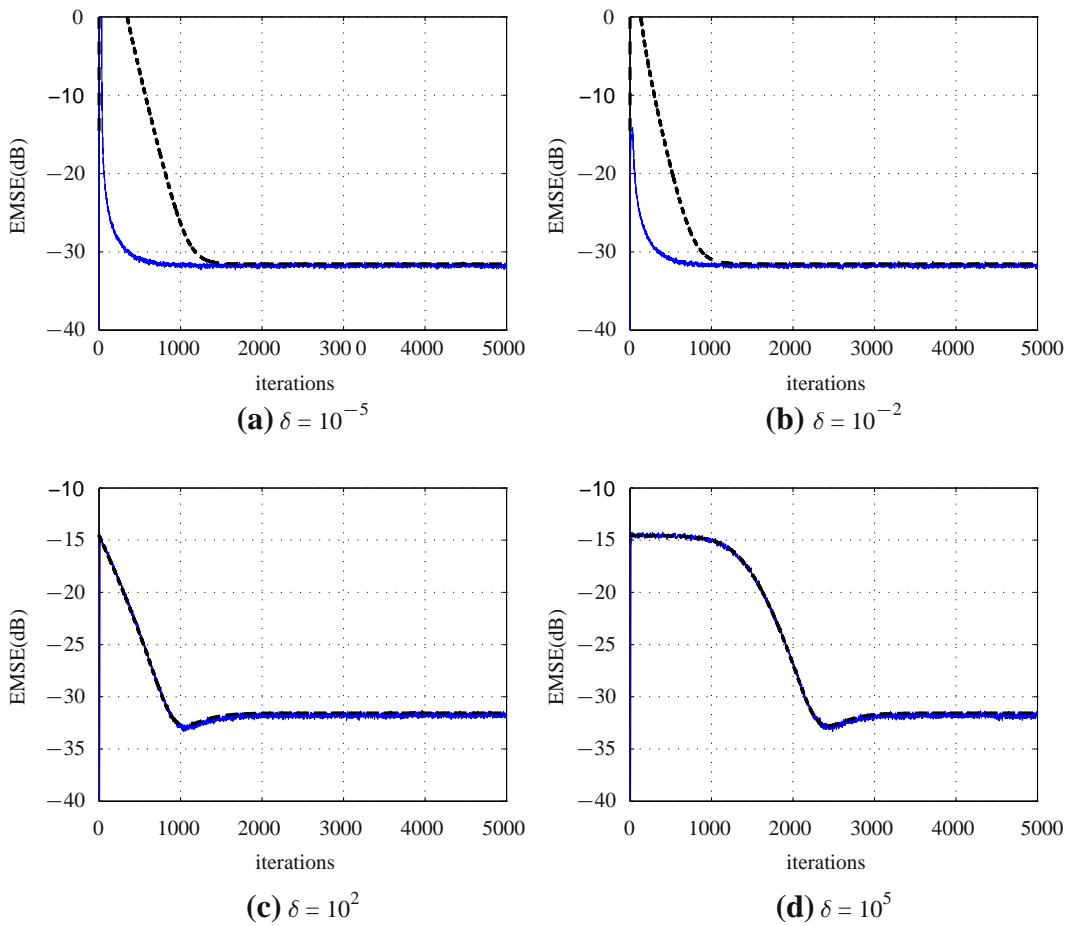

$$e_p(n) = \tilde{w}^H(n+1)\phi(n). \quad (12.251)$$

Then, we multiply both sides of the Hermitian of (12.220) (with  $q(n) \equiv \mathbf{0}$ ) from the right by  $\phi(n)$  to obtain

$$\tilde{w}^H(n+1)\phi(n) = \tilde{w}^H(n)\phi(n) - \rho(n)\phi^H(n)M(n)\phi(n)e(n). \quad (12.252)$$

Using (12.172) and (12.251), (12.252) reduces to

$$e_p(n) = e_a(n) - \rho(n)\|\phi(n)\|_{M(n)}^2 e(n), \quad (12.253)$$

## **FIGURE 12.31**

EMSE for RLS considering  $\lambda = 0.995$  and different values of  $\delta$ ;  $b = 0.8$ ,  $\sigma_v^2 = 10^{-2}$ ,  $\sigma_q^2 = 0$ ; mean of 2000 independent runs. The dashed lines represent the predicted values of  $\zeta(n)$  for each algorithm.

where  $\|\mathbf{u}\|_A^2 = \mathbf{u}^H \mathbf{A} \mathbf{u}$  stands for the Euclidean norm of  $\mathbf{u}$  weighted by the matrix  $\mathbf{A}$ . Using (12.253) to eliminate  $e(n)$  in (12.220) (with  $\mathbf{q}(n) \equiv \mathbf{0}$ ) and assuming that  $\phi(n) \neq \mathbf{0}$ , we get

$$\tilde{\mathbf{w}}(n+1) + \frac{\mathbf{M}(n)\phi(n)}{\|\phi(n)\|_{\mathbf{M}(n)}^2} e_a^*(n) = \tilde{\mathbf{w}}(n) + \frac{\mathbf{M}(n)\phi(n)}{\|\phi(n)\|_{\mathbf{M}(n)}^2} e_p^*(n). \quad (12.254)$$

Defining

$$\bar{\rho}(n) \triangleq \begin{cases} 1/\|\phi(n)\|_{M(n)}^2, & \text{if } \phi(n) \neq \mathbf{0} \\ 0, & \text{otherwise} \end{cases} \quad (12.255)$$

to include the case of zero regressor and equating the squared weighted norms on both sides of (12.254) with  $\mathbf{M}^{-1}(n)$  as a weighting matrix, the cross-terms cancel and we obtain

$$\|\tilde{\mathbf{w}}(n+1)\|_{\mathbf{M}^{-1}(n)}^2 + \bar{\rho}(n)|e_a(n)|^2 = \|\tilde{\mathbf{w}}(n)\|_{\mathbf{M}^{-1}(n)}^2 + \bar{\rho}(n)|e_p(n)|^2. \quad (12.256)$$

This relation shows how the weighted energies of the weight-error vectors at two successive time instants are related to the energies of the excess *a priori* and excess *a posteriori* errors. This relation is the reason why this approach is known as the energy conservation method—(12.256) relates the (weighted) coefficient error energies at instants  $n$  and  $n+1$  to the *a priori* and *a posteriori* errors. In [3], this energy conservation relation is used extensively to find models for a wide class of adaptive filters. We follow here a shorter route, however, and derive in a more direct way the relations necessary for the study of just LMS, NLMS and RLS.

We can obtain the steady-state EMSE by computing the squared weighted norms on both sides of (12.220) with  $\mathbf{M}^{-1}(n)$  as a weighting matrix, which leads to

$$\begin{aligned} \|\tilde{\mathbf{w}}(n+1)\|_{\mathbf{M}^{-1}(n)}^2 &= \|\tilde{\mathbf{w}}(n)\|_{\mathbf{M}^{-1}(n)}^2 + \rho^2(n)|e(n)|^2\|\phi(n)\|_{\mathbf{M}(n)}^2 \\ &\quad - \rho(n)[e_a(n)e^*(n) + e_a^*(n)e(n)] + \|\mathbf{q}(n)\|_{\mathbf{M}^{-1}(n)}. \end{aligned} \quad (12.257)$$

By taking expectations on both sides of (12.257), we arrive at (we already used Assumption 2 to eliminate cross-terms with  $\mathbf{q}(n)$  on the right-hand side)

$$\begin{aligned} \overbrace{\mathbb{E}\left\{\|\tilde{\mathbf{w}}(n+1)\|_{\mathbf{M}^{-1}(n)}^2\right\}}^{\mathcal{A}} &= \overbrace{\mathbb{E}\left\{\|\tilde{\mathbf{w}}(n)\|_{\mathbf{M}^{-1}(n)}^2\right\}}^{\mathcal{B}} \\ &\quad + \overbrace{\mathbb{E}\left\{\rho^2(n)|e(n)|^2\|\phi(n)\|_{\mathbf{M}(n)}^2\right\}}^{\mathcal{C}} \\ &\quad - \overbrace{\mathbb{E}\left\{\rho(n)[e_a(n)e^*(n) + e_a^*(n)e(n)]\right\}}^{\mathcal{D}} \\ &\quad + \overbrace{\|\mathbf{q}(n)\|_{\mathbf{M}^{-1}(n)}}^{\mathcal{E}}. \end{aligned} \quad (12.258)$$

To proceed, we have to assume again that matrix  $\mathbf{M}^{-1}(n)$  varies slowly in relation to  $\tilde{\mathbf{w}}(n)$  and  $\mathbf{q}(n)$ , as in Assumption 3. Since now we are dealing only with the steady-state, this approximation is in general good. Instead of Assumption 1, in energy conservation analysis the following assumptions are used:

**Assumption 7.**  $\|\phi(n)\|_{\mathbf{M}(n)}^2$  is independent of  $e_a(n)$  at the steady-state.

**Assumption 8.** The noise sequence  $\{\mathbf{v}_o(n)\}$  is iid and independent of the input sequence  $\{\phi(n)\}$ .

Assumption 7 is referred to in the literature as *separation principle* and is reasonable in steady-state since for large  $n$ ,  $e_a(n)$  tends to be less sensitive to the regressor data, in particular for long filters. Assumption 8 is a weakened version of Assumption 1, which is necessary to relate the MSE with the EMSE through (12.181).

Under model 2 and Assumptions 3 and 7, we can now evaluate the terms  $\mathcal{A} - \mathcal{E}$ :

**A-** Using 3, we obtain

$$\mathcal{A} \approx E \left\{ \| \tilde{\mathbf{w}}(n+1) \|_{E\{\mathbf{M}^{-1}(n)\}}^2 \right\}. \quad (12.259)$$

For LMS and NLMS, we have

$$\mathcal{A}^{LMS} = \mathcal{A}^{NLMS} \approx E \left\{ \| \tilde{\mathbf{w}}(n+1) \|^2 \right\}. \quad (12.260)$$

For RLS,

$$\mathcal{A}^{RLS} \approx E \left\{ \| \tilde{\mathbf{w}}(n+1) \|_{\mathbf{R}_\phi}^2 \right\}. \quad (12.261)$$

**B-** Assuming that the filter is stable and reaches a steady-state, we have

$$\mathcal{B} = E \left\{ \| \tilde{\mathbf{w}}(n) \|_{\mathbf{M}^{-1}(n)}^2 \right\} \approx E \left\{ \| \tilde{\mathbf{w}}(n+1) \|_{\mathbf{M}^{-1}(n)}^2 \right\}. \quad (12.262)$$

**C-** Given that  $e(n) = e_a(n) + v_o(n)$  and since  $v_o(n)$  is assumed independent of  $e_a(n)$  (Assumption 8), we obtain

$$E\{|e(n)|^2\} \approx E\{|e_a(n)|^2\} + \sigma_v^2.$$

Then, using Assumptions 3 and 8, we arrive at

$$\mathcal{C} \approx E \left\{ \rho^2(n) \boldsymbol{\phi}^H(n) E\{\mathbf{M}(n)\} \boldsymbol{\phi}(n) \right\} \left( E\{|e_a(n)|^2\} + \sigma_v^2 \right). \quad (12.263)$$

For LMS, this term reduces to

$$\mathcal{C}^{LMS} \approx \mu^2 \text{Tr}(\mathbf{R}_\phi) \left( E\{|e_a(n)|^2\} + \sigma_v^2 \right). \quad (12.264)$$

For NLMS,

$$\mathcal{C}^{NLMS} \approx \tilde{\mu}^2 E \left\{ \frac{1}{\varepsilon + \boldsymbol{\phi}^H(n) \boldsymbol{\phi}(n)} \right\} \left( E\{|e_a(n)|^2\} + \sigma_v^2 \right), \quad (12.265)$$

which for long filters and Gaussian tapped-delay line regressors can be approximated as (see Eq. (12.228), and the alternative (12.227) for general regressors)

$$\mathcal{C}^{NLMS} \approx \frac{\tilde{\mu}^2}{\sigma_x^2(M-2)} \left( E\{|e_a(n)|^2\} + \sigma_v^2 \right). \quad (12.266)$$

Finally, for RLS we obtain

$$\mathcal{C}^{RLS} \approx (1-\lambda)^2 M \left( E\{|e_a(n)|^2\} + \sigma_v^2 \right). \quad (12.267)$$

**D-** Using the same arguments,  $\mathcal{D}$  reduces to

$$\mathcal{D} \approx 2E\{\rho(n)\}E\{|e_a(n)|^2\}. \quad (12.268)$$

For LMS,  $\mathcal{D}^{LMS} \approx 2\mu E\{|e_a(n)|^2\}$ . Using (Eq. (12.228)) for NLMS, we get

$$\mathcal{D}^{NLMS} \approx \frac{2\tilde{\mu}^2}{\sigma_x^2(M-2)} E\{|e_a(n)|^2\}.$$

For RLS, this term is given by  $\mathcal{D}^{RLS} \approx 2(1-\lambda)E\{|e_a(n)|^2\}$ .

**Table 12.8** Expressions for the Steady-State EMSE Obtained from the Energy Conservation Method for LMS, NLMS, and RLS

Algorithm	$\xi(\infty)$	$\xi(\infty)$
LMS	for a wider range of $\mu$ , $\tilde{\mu}$ , and $\lambda$ $\frac{\mu\sigma_V^2 \text{Tr}(\mathbf{R}_\phi) + \mu^{-1} \text{Tr}(\mathbf{Q})}{2 - \mu \text{Tr}(\mathbf{R}_\phi)}$	for small $\mu$ and $\tilde{\mu}$ , and $\lambda \approx 1$ $\frac{\mu\sigma_V^2 \text{Tr}(\mathbf{R}_\phi) + \mu^{-1} \text{Tr}(\mathbf{Q})}{2}$
NLMS	$\frac{\tilde{\mu}\sigma_V^2 + \tilde{\mu}^{-1}\sigma_X^2(M-2)\text{Tr}(\mathbf{Q})}{2 - \tilde{\mu}}$	$\frac{\tilde{\mu}\sigma_V^2 + \tilde{\mu}^{-1}\sigma_X^2(M-2)\text{Tr}(\mathbf{Q})}{2}$
RLS	$\frac{\sigma_V^2(1-\lambda)M + \frac{\text{Tr}(\mathbf{Q}\mathbf{R}_\phi)}{1-\lambda}}{2 - (1-\lambda)M}$	$\frac{\sigma_V^2(1-\lambda)M + \frac{\text{Tr}(\mathbf{Q}\mathbf{R}_\phi)}{1-\lambda}}{2}$

$\mathcal{E}$ - Using Assumption 3 and recalling that  $\text{Tr}(\mathbf{AB}) = \text{Tr}(\mathbf{BA})$ , we obtain

$$\mathcal{E} \approx \mathbb{E} \left\{ \mathbf{q}^H(n) \mathbb{E}\{\mathbf{M}^{-1}(n)\} \mathbf{q}(n) \right\} = \text{Tr} \left( \mathbb{E} \left\{ \mathbf{M}^{-1}(n) \right\} \mathbb{E} \{ \mathbf{q}(n) \mathbf{q}^H(n) \} \right).$$

For LMS and NLMS this reduces to

$$\mathcal{E}^{\text{LMS}} = \mathcal{E}^{\text{NLMS}} \approx \text{Tr}(\mathbf{Q}). \quad (12.269)$$

For RLS,

$$\mathcal{E}^{\text{RLS}} \approx \text{Tr}(\mathbf{R}_\phi \mathbf{Q}). \quad (12.270)$$

Using these approximations in (12.258), we arrive at the following steady-state approximation

$$\mathbb{E}\{|e_a(n)|^2\} \approx \frac{\sigma_v^2 \mathbb{E}\{\rho^2(n) \boldsymbol{\phi}^H(n) \mathbb{E}\{\mathbf{M}(n)\} \boldsymbol{\phi}(n)\} + \text{Tr}(\mathbf{Q} \mathbb{E}\{\mathbf{M}^{-1}(n)\})}{2\mathbb{E}\{\rho(n)\} - \mathbb{E}\{\rho^2(n) \boldsymbol{\phi}^H(n) \mathbb{E}\{\mathbf{M}(n)\} \boldsymbol{\phi}(n)\}}. \quad (12.271)$$

Particularizing (12.271) for LMS, NLMS, and RLS, we obtain the results of the second column of Table 12.8, which hold over a wide range of step-sizes and forgetting factors.

#### 1.12.4.4.5 Relation between the results obtained with both analysis methods

As we explained before, each method is based on a different set of approximations. We now show how they are related.

The energy conservation method is capable of obtaining closed-form expressions for the EMSE using less restrictive assumptions, in particular  $\boldsymbol{\phi}(n)$  is not required to be Gaussian. These results are equivalent to those obtained for LMS and RLS using the traditional analysis, taking the recursions of Table 12.7 to the limit as  $n \rightarrow \infty$ , and assuming  $\beta = 0$  (recall that the values of  $\beta$  used for the traditional analysis are only valid if  $\boldsymbol{\phi}(n)$  is Gaussian). The assumption of  $\beta = 0$  implies the following approximation:

$$\mathbb{E} \left\{ \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \mathbf{S}(n) \boldsymbol{\phi}(n) \boldsymbol{\phi}^H(n) \right\} \approx \mathbf{R}_\phi \text{Tr}(\mathbf{S}(n) \mathbf{R}_\phi).$$

**Table 12.9** Expressions for the Optimal Adaptation Parameters ( $\rho_o$ ) and Minimum Steady-State EMSE ( $\zeta_{\min}(\infty)$ ) Obtained from the Expressions of the Third Column of Table 12.8

Algorithm	$\rho_o$	$\zeta_{\min}(\infty)$
LMS	$\mu_o = \sqrt{\frac{\text{Tr}(\mathbf{Q})}{\sigma_v^2 \text{Tr}(\mathbf{R}_\phi)}}$	$\sqrt{\sigma_v^2 \text{Tr}(\mathbf{R}_\phi) \text{Tr}(\mathbf{Q})}$
NLMS	$\tilde{\mu}_o = \sqrt{\frac{(M-2)\sigma_x^2 \text{Tr}(\mathbf{Q})}{\sigma_v^2}}$	$\sqrt{\sigma_v^2 \sigma_x^2 (M-2) \text{Tr}(\mathbf{Q})}$
RLS	$1 - \lambda_o = \sqrt{\frac{\text{Tr}(\mathbf{Q}\mathbf{R}_\phi)}{M\sigma_v^2}}$	$\sqrt{\sigma_v^2 M \text{Tr}(\mathbf{Q}\mathbf{R}_\phi)}$

For small step-sizes, this approximation does not have a large impact, since we are disregarding a term of  $\mathcal{O}(\mu^2)$ , that is small compared to other  $\mathcal{O}(\mu)$  terms. For NLMS, in order to recover (12.271) using the traditional method, we would choose  $\beta = 0$  and make

$$\mathbb{E} \left\{ \frac{1}{[\varepsilon + \boldsymbol{\phi}^H(n)\boldsymbol{\phi}(n)]^2} \right\} \approx \left[ \mathbb{E} \left\{ \frac{1}{\varepsilon + \boldsymbol{\phi}^H(n)\boldsymbol{\phi}(n)} \right\} \right]^2,$$

which leads to reasonable results at the steady-state for long filters.

For small step-sizes (or forgetting factors close to one), the denominator of (12.271) can be approximated by  $2\mathbb{E}\{\rho(n)\}$ . In this case, the expressions of the second column reduce to those of the third column of Table 12.8. Again, these results can be obtained from the recursions of Table 12.7, disregarding the term  $\mathcal{C}$  (Eq. (12.235)), which will be negligible compared to  $\mathcal{B}$  in (12.222) if  $\rho \approx 0$ .

The results for steady-state analysis using the traditional method are commonly obtained as the limiting case of a transient analysis. Although this procedure is adequate for understanding both the steady-state and the transient behavior of an adaptive algorithm, it tends to be more laborious than using the energy conservation method to analyze the steady-state behavior. This is one of the largest advantages of this last method.

#### 1.12.4.4.6 Optimal step-size for tracking

From the results of the third column of Table 12.8, we can observe that the expressions for the steady-state EMSE have two terms: one for the stationary environment, that increases as the step-size increases, and another that appears in the nonstationary case, and increases as the step-size decreases. Therefore, there exist optimal adaptation parameters  $\rho_o$ , that minimize the EMSE. These parameters are  $\mu_o$ ,  $\tilde{\mu}_o$ , and  $1 - \lambda_o$  for LMS, NLMS, and RLS, respectively. The corresponding minima, denoted by  $\zeta_{\min}(\infty)$ , can also be evaluated. All these results are summarized in Table 12.9. The results for a wider range of adaptation parameters lead to more complicated expressions for  $\rho_o$  and  $\zeta_o(\infty)$  (see, e.g., [3]).

We can use the results of Table 12.9 to compare the tracking performance of the algorithms. For instance, comparing the minimum EMSE for LMS to that of RLS, we obtain the ratio

$$\frac{\zeta_{\min}^{\text{RLS}}}{\zeta_{\min}^{\text{LMS}}} = \sqrt{\frac{M \text{Tr}(\mathbf{Q}\mathbf{R}_\phi)}{\text{Tr}(\mathbf{R}_\phi) \text{Tr}(\mathbf{Q})}}. \quad (12.272)$$

Clearly, the results of this comparison depend on the environment. There are situations where RLS has superior tracking capability compared to LMS, and vice versa. This is highlighted considering three different choices for matrix  $\mathbf{Q}$ . It can be shown [81] that

- i. If  $\mathbf{Q}$  is a multiple of  $\mathbf{I}$ : the performance of LMS is similar to that of RLS;
- ii. If  $\mathbf{Q}$  is a multiple of  $\mathbf{R}_\phi$ : LMS is superior; and
- iii. If  $\mathbf{Q}$  is a multiple of  $\mathbf{R}_\phi^{-1}$ : RLS is superior.

These choices for  $\mathbf{Q}$  do not model practical situations, but they highlight that, even though the convergence rate of RLS is in general much higher than that of LMS, this advantage, unexpectedly, does not necessarily follow to the problem of tracking a slowly-varying parameter vector.

**Example 4.** To verify the accuracy of the expressions of Tables 12.8 and 12.9, we use the LMS, NLMS, and RLS filters to identify the same lowpass FIR system of Figure 12.29. Now, the environment is assumed nonstationary with  $\mathbf{Q} = 10^{-6}\mathbf{I}$ . The input signal and minimum MSE ( $\sigma_v^2$ ) are the same of Example 3.

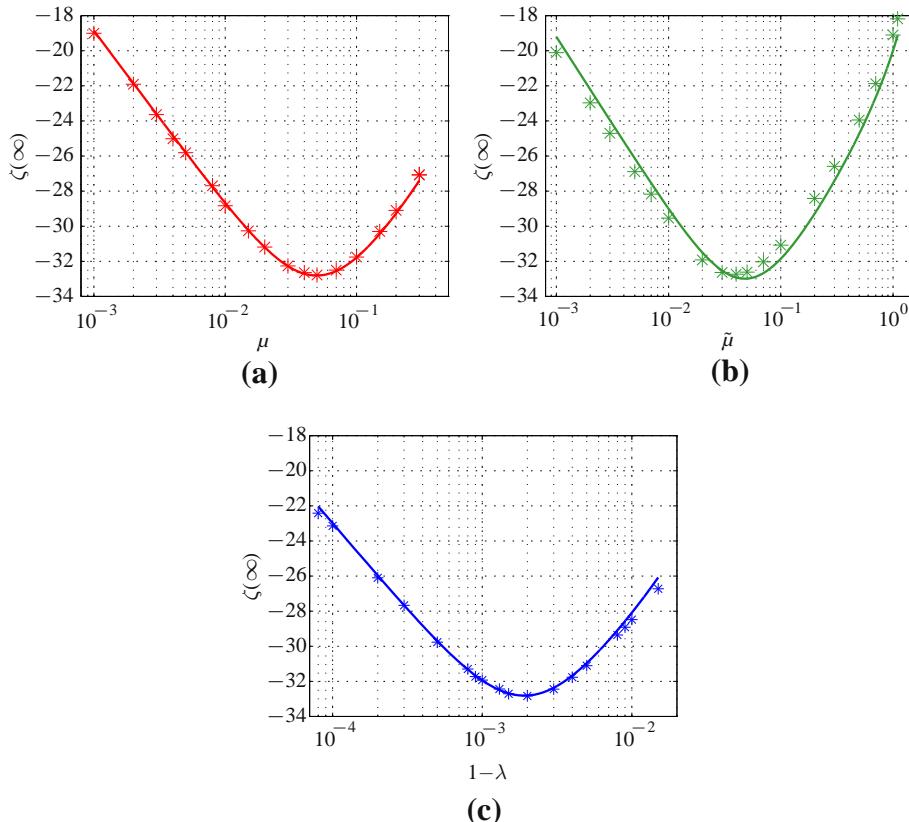

Figure 12.32 shows the measured steady-state EMSE with varying adaptation factors considering the theoretical and experimental results for LMS, NLMS, and RLS. Each value of experimental EMSE was obtained from the ensemble-average of 100 independent runs. The theoretical minimum EMSE predicted by the expressions of Table 12.9 are  $\xi_o^{\text{LMS}}(\infty) = \xi_o^{\text{RLS}}(\infty) = -32.9251$  dB and  $\xi_o^{\text{NLMS}}(\infty) = -33.0989$  dB, which correspond to the optimal adaptation parameters  $\mu_o = 5.1 \times 10^{-2}$ ,  $\tilde{\mu}_o = 4.9 \times 10^{-2}$  and  $1 - \lambda_o = 2 \times 10^{-3}$  ( $\lambda_o = 0.998$ ). The experimental values for  $\xi_{\min}(\infty)$  and  $\rho_o$  are close to the predicted by the expressions of Table 12.9 as shown in Figure 12.32.

**Example 5.** Again, we consider a system identification application but with the initial optimal solution given by

$$\mathbf{w}_o^T(0) = [0.5349 \ 0.9527 \ -0.9620 \ -0.0158 \ -0.1254].$$

The input signal is assumed to be colored Gaussian noise with variance  $\sigma_x^2 = 0.2$ . This signal is obtained from the filtering of a white Gaussian noise by a first-order autoregressive model ( $b = 0.8$ ). We also assume that the minimum MSE is  $\sigma_v^2 = 0.01$ .

As predicted by (12.272), the performance of RLS and LMS are similar when  $\mathbf{Q} = \sigma_q^2\mathbf{I}$ . Thus, assuming  $\mathbf{Q} = 10^{-6}\mathbf{I}$ , we computed  $\mu_o$  and  $\lambda_o$  from the expressions of Table 12.9 and used these parameters in the adaptation, such that the same minimum EMSE could be achieved by both algorithms in this situation. Figure 12.33 shows the EMSE estimated from the ensemble-average of 5000 independent runs for RLS ( $\lambda = \lambda_o = 0.9955$ ,  $\delta = 4.5 \times 10^{-3}$ ) and LMS ( $\mu = \mu_o = 0.0224$ ). At every  $7 \times 10^4$  iterations, the nonstationary environment is changed. During the first  $7 \times 10^4$  iterations,  $\mathbf{Q} = 10^{-6}\mathbf{R}_\phi$  and LMS presents a slightly better tracking performance than that of RLS. When  $\mathbf{Q} = 10^{-6}\mathbf{R}_\phi^{-1}$ , this behavior changes: RLS becomes better than LMS. Finally for  $\mathbf{Q} = 10^{-6}\mathbf{I}$ , RLS and LMS present similar performance. The dashed lines represent the theoretical values of  $\zeta(\infty)$  for each algorithm, predicted from the expressions of the second column of Table 12.8.

**FIGURE 12.32**

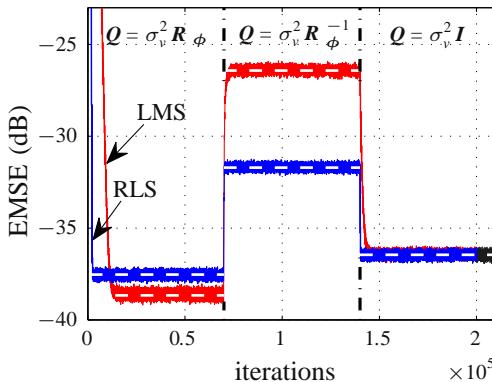

Theoretical and experimental EMSE as a function of the adaptation parameter for a) LMS, b) NLMS, and c) RLS. The asterisks represent simulation results and the solid lines represent the theoretical models.

### Box 7: Fourth-order moments of Gaussian vectors

The second-order moments of a random sequence are related to its average power (of course, this is an approximation unless the sequence is stationary and ergodic.) This makes second-order moments intuitive to work with and relatively easy to evaluate in practice. Therefore, when studying an adaptive filter, it is common to try to describe its performance in terms of the autocorrelation of the input sequence  $\mathbf{x}(n)$ .

During the analysis of LMS, one encounters a term that contains fourth-order powers of the input vector  $\mathbf{x}(n)$ :

$$\mathbf{F} \stackrel{\Delta}{=} \mathbb{E}\{\mathbf{x}(n)\mathbf{x}^H(n)\tilde{\mathbf{w}}(n)\tilde{\mathbf{w}}^H(n)\mathbf{x}(n)\mathbf{x}^H(n)\}. \quad (12.273)$$

**FIGURE 12.33**

EMSE for RLS ( $\lambda = 0.9955$ ,  $\delta = 4.5 \times 10^{-3}$ ), and LMS ( $\mu = 0.0224$ );  $b = 0.8$ ,  $\sigma_v^2 = 10^{-2}$ ,  $\sigma_q^2 = 10^{-6}$ ; mean of 5000 independent runs. The dashed lines represent the predicted values of  $\zeta(\infty)$  for each algorithm.

In order to evaluate a term such as this, one needs to know much more information about the statistics of  $x(n)$  than is provided simply by its mean and autocorrelation. However, in general this additional information is not available, and one assumes that the signals are Gaussian in order to proceed.

Why not any other distribution? First, because many processes in Nature are indeed approximately Gaussian. Second, because uncorrelated Gaussian variables are also independent, which is of great help when evaluating fourth-order terms, such as  $E\{x^2(n)x^2(n-1)\}$  or  $E\{x^3(n)x(n-2)\}$ .

Although in many cases the input sequence is not Gaussian (for example, speech does not follow a Gaussian distribution), this approximation describes the most important features of adaptive filter learning with reasonable accuracy, and leads to a relatively simple model.

In order to simplify the notation, we will write simply  $x$  and  $\tilde{w}$  instead of  $x(n)$  and  $\tilde{w}(n)$  in the following. Assume then that  $x$  is a Gaussian random vector, with autocorrelation  $E\{xx^H\} = R$ , and that  $\tilde{w}$  is another vector independent of  $x$ , and with autocorrelation  $E\{\tilde{w}\tilde{w}^H\} = S$  (we do not need to know the exact distribution of  $\tilde{w}$ .) Assume also that all variables have zero mean. Our goal is to evaluate

$$F = E\{xx^H\tilde{w}\tilde{w}^Hxx^H\}.$$

Since  $\tilde{w}$  is independent of  $x$ , we can write

$$F = E\{xx^H\tilde{w}\tilde{w}^Hxx^H\} = E\{xx^H E\{\tilde{w}\tilde{w}^H\} xx^H\} = E\{xx^H S xx^H\}. \quad (12.274)$$

The autocorrelation of  $x$  is in general a full matrix, that is,

$$R = \begin{bmatrix} r_{11} & r_{12} & \dots & r_{1M} \\ r_{12}^* & r_{22} & \dots & r_{2M} \\ \vdots & \vdots & \ddots & \vdots \\ r_{1M}^* & r_{2M}^* & \dots & r_{MM} \end{bmatrix},$$

that is, in general the elements of  $\mathbf{x}$  are correlated.  $\mathbf{R}$  has hermitian symmetry and is non-negative definite, which implies that there exists a unitary matrix  $\mathbf{U}$  such that

$$\mathbf{U}^H \mathbf{R} \mathbf{U} = \mathbf{\Lambda} = \begin{bmatrix} \lambda_1 & 0 & \dots & 0 \\ 0 & \lambda_2 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & \lambda_M \end{bmatrix},$$

where  $\lambda_i \geq 0$  for  $i = 1, \dots, M$ . Define  $\mathbf{x}' = \mathbf{U}^H \mathbf{x}$ . Then  $E\{\mathbf{x}' \mathbf{x}'^H\} = E\{\mathbf{U}^H \mathbf{x} \mathbf{x}^H \mathbf{U}\} = \mathbf{U}^H E\{\mathbf{x} \mathbf{x}^H\} \mathbf{U} = \mathbf{\Lambda}$ , and we see that the entries of  $\mathbf{x}'$  are uncorrelated. Since  $\mathbf{x}$  is Gaussian, and a linear transformation of a Gaussian vector is also Gaussian, this means that the entries of  $\mathbf{x}'$  are independent of each other. Multiplying (12.274) by  $\mathbf{U}^H$  on the left and  $\mathbf{U}$  on the right, and recalling that  $\mathbf{U}^H \mathbf{U} = \mathbf{U} \mathbf{U}^H = \mathbf{I}$ , we obtain

$$\mathbf{F}' \stackrel{\Delta}{=} \mathbf{U}^H \mathbf{F} \mathbf{U} = E\{\mathbf{U}^H \mathbf{x} \mathbf{x}^H \underbrace{\mathbf{U} \mathbf{U}^H}_{=\mathbf{I}} \mathbf{S} \underbrace{\mathbf{U} \mathbf{U}^H}_{=\mathbf{I}} \mathbf{x} \mathbf{x}^H \mathbf{U}\} = E\{\mathbf{x}' \mathbf{x}'^H \mathbf{U}^H \mathbf{S} \mathbf{U} \mathbf{x}' \mathbf{x}'^H \mathbf{U}\}.$$

Defining  $\bar{\mathbf{S}} = \mathbf{U}^H \mathbf{S} \mathbf{U}$ , we can expand  $\mathbf{F}'$  in terms of the elements  $s'_{ij}$  of  $\bar{\mathbf{S}}$  and  $x'_k$  of  $\mathbf{x}'$ . Each element of  $\mathbf{F}'$  will have terms of the form

$$E\{x'_{k_1} x'_{k_2} x'^{*}_{k_3} x'^{*}_{k_4}\} s'_{ij}.$$

If the signals are real, then, as  $x'_{k_1}$  is independent of  $x'_{k_2}$  if  $k_1 \neq k_2$ , these expected values will be nonzero only if  $k_1 = k_2 = k_3 = k_4$  or if  $k_1 = k_3$  and  $k_2 = k_4$ , or  $k_1 = k_4$  and  $k_2 = k_3$ , or if  $k_1 = k_2$  and  $k_3 = k_4$ . Evaluating all such terms that appear in the expression for  $\mathbf{F}'$  will result in

$$\mathbf{F}'|_{\text{real signals}} = \mathbf{R} \text{Tr}(\mathbf{S} \mathbf{R}) + 2 \mathbf{R} \mathbf{S} \mathbf{R}. \quad (12.275)$$

If, on the other hand, the signals are complex-valued, then we need to know how the real and imaginary parts of each entry of  $\mathbf{x}$  relate to each other. One common assumption is that  $\mathbf{x}$  is *circularly*-Gaussian. We explain more about this in Section 1.12.2.1. For now, we only remark that if this is the case, the real and imaginary parts of each entry of  $\mathbf{x}$  and of  $\mathbf{x}'$  are such that  $E\{x_k^2\} = E\{x_k'^2\} = 0$  for all  $k$  (note that  $E\{|x_k|^2\} = r_{kk}$ ,  $E\{|x'_k|^2\} = \lambda_k$  are still nonzero.) This will result in a different expression for  $\mathbf{F}'$ :

$$\mathbf{F}'|_{\text{complex signals}} = \mathbf{R} \text{Tr}(\mathbf{S} \mathbf{R}) + \mathbf{R} \mathbf{S} \mathbf{R}. \quad (12.276)$$

## 1.12.5 Extensions and current research

In this section we briefly describe some important extensions to the basic adaptive filtering algorithms, as well as some promising current research topics. The intention is not to describe in any detail all these techniques, but rather to give a list of key references where the interested reader may find more information.

It is usual when starting such lists to put a disclaimer, that the authors do not claim to have included all the important contributions, nor that their list is really of the most important contributions to an area.

This is not intended for legal purposes, nor false modesty: the size of the literature is indeed so large (a search on “adaptive filter” on Google gives over one million hits) that we cannot claim to know with certainty the best of it all. We included therefore the techniques that we found useful during our own research and experience, which is perforce limited.

### 1.12.5.1 Finite-precision arithmetic

Any operation made using finite-precision arithmetic may involve errors. For example, the product of  $a = 0.957$  and  $b = 0.542$  would result in  $c = 0.518694$ . However, if all numbers were stored keeping only three digits, the final result would be  $\bar{c} = 0.519$ , with an error of  $c - \bar{c} = -3.06 \times 10^{-4}$  [82, 83]. These *quantization* errors will accumulate and modify the behavior of an adaptive filter in important ways. A precise analysis of the effect of quantization errors is quite complicated, since these errors are highly nonlinear functions of the variables.

When finite-precision arithmetic effects are studied, it is usually important to know exactly how and in which order the arithmetic operations are performed. In particular, the exact numerical representation used is important: fixed-point vs. floating-point, truncation vs. rounding, etc. For this reason, it is more difficult to perform analyses that are equally valid for a large class of filters. The most important differences are between gradient-based algorithms (i.e., algorithms similar to LMS and NLMS) and Hessian-based algorithms (i.e., algorithms similar to RLS). We will give references to works treating both cases, starting with LMS.

#### 1.12.5.1.1 Finite-precision effects in LMS

The simplest models for adaptive filters in finite-precision arithmetic treat the quantization error as random noise, uniformly distributed and independent of all variables [84–87]. These models show that the quantization errors will add another term to the EMSE. However, this term does not converge to zero when the step-size is reduced to zero, even in a stationary environment: quite the opposite, it is inversely proportional to the step-size (similar to the EMSE in a nonstationary environment).

Another important undesirable effect is that the product  $\mu e(n)$  may be rounded down to zero when  $e(n)$  becomes small (underflow), virtually stopping the adaptation. When the step-size is small, this may happen when the filter is rather far from the optimum solution. Therefore, there is an optimum value for the step-size—neither too large, to avoid increasing the misadjustment, neither too small, to avoid underflow and excessive growth of the EMSE. A similar effect happens in RLS [1, p. 595].

This underflow problem, which is usually known as *stopping phenomenon*, was studied in more detail in [88–91], using a nonlinear model. These works show that the adaptation does not really stop, but rather convergence is reduced to a very low rate. Note that this phenomenon is less important in floating-point arithmetic, since floating-point is able to represent much smaller numbers without underflow than fixed-point arithmetic.

Finite precision effects may have worse consequences, in particular they may make the adaptive filter unstable. In the case of LMS, this phenomenon is rare, and will only happen when the regressor sequence  $\{\phi\}$  has a very ill-conditioned covariance matrix, and the noise  $v_o$  has a nonzero mean (this nonzero mean may itself appear due to quantization errors) [92–94]. This problem is not difficult to solve, using regularization as described in Section 1.12.5.2. The problem of numerical stability in RLS is much more serious and harder to solve, and has received much attention, as we see next.

In addition to studying the effect of quantization errors in the performance of an adaptive filter, another important topic is how to reduce the computational cost of a filter, taking advantage of implementation details. One such approach is to replace the error  $e(n)$  in the LMS recursion by its sign, i.e., to use the recursion

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \mu \text{sign}(e(n)) \boldsymbol{\phi}(n), \quad (12.277)$$

where  $\text{sign}(\cdot)$  is the sign function, defined by

$$\text{sign}(e) = \begin{cases} 1, & \text{if } e > 0, \\ 0, & \text{if } e = 0, \\ -1, & \text{if } e < 0. \end{cases} \quad (12.278)$$

The resulting algorithm, known as *sign-LMS*, has a smaller computational cost, if  $\mu$  is restricted to be a power of two, that is, if  $\mu = 2^k$  for an integer (usually negative)  $k$ . In this case,  $\mu \text{sign}(e(n))$  is always equal to  $\pm 2^k$  (or zero), and the product  $[\mu \text{sign}(e(n))] \boldsymbol{\phi}(n)$  can be implemented in fixed-point arithmetic as  $M$  shifts, instead of  $M$  multiplications. In floating-point arithmetic, the multiplications are replaced by sums, since we would need to add  $k$  to the exponent terms of all entries of  $\boldsymbol{\phi}(n)$ . This algorithm is very robust (see also Section 1.12.5.4), although its convergence rate under Gaussian inputs is considerably slower than that of LMS. Sign-LMS was thoroughly studied in [81, 95–98].

Another possibility, that works surprisingly well, reducing the computational cost with only a slight decrease in convergence speed is the *power-of-two LMS* algorithm [99]. In it, the error is rounded to the nearest power of two, using the function:

$$f(e) = \begin{cases} \text{sign}(e), & |e| \geq 1, \\ \text{sign}(e)2^{\lfloor \ln(|e|) \rfloor}, & 2^{-B+1} \leq |e| < 1, \\ 0, & |e| < 2^{-B+1}, \end{cases}$$

where  $B$  is the number of bits used to represent the error, and  $\lfloor x \rfloor$  returns the largest integer smaller than  $x$ . In this case,  $\mu$  should also be a power of two.

### 1.12.5.1.2 Finite-precision effects in RLS

As we briefly described in Section 1.12.3.3.1, the conventional RLS is numerically unstable in finite precision arithmetic and has  $\mathcal{O}(M^2)$  complexity. To solve these problems, different versions of RLS were proposed in the literature. Many of these versions are based on coordinate transformations of the state-space representation of the conventional RLS algorithm. This representation can be obtained by replacing  $\mathbf{k}(n)$  by  $\mathbf{P}(n)\boldsymbol{\phi}(n)$  in (12.166), i.e.,

$$\mathbf{w}(n+1) = \lambda \mathbf{P}(n) \hat{\mathbf{r}}_{d\boldsymbol{\phi}}(n-1) + \mathbf{P}(n) \boldsymbol{\phi}(n) d^*(n). \quad (12.279)$$

Recalling that  $\mathbf{w}(n) = \mathbf{P}(n-1) \hat{\mathbf{r}}_{d\boldsymbol{\phi}}(n-1)$ , we can replace  $\hat{\mathbf{r}}_{d\boldsymbol{\phi}}(n-1)$  in (12.279) as a function of  $\mathbf{P}^{-1}(n-1)$  and  $\mathbf{w}(n)$ , which leads to

$$\mathbf{w}(n+1) = \lambda \mathbf{P}(n) \mathbf{P}^{-1}(n-1) \mathbf{w}(n) + \mathbf{P}(n) \boldsymbol{\phi}(n) d^*(n). \quad (12.280)$$

This equation in conjunction with the definition of the *a priori* error  $e(n)$  characterize the adaptation and filtering operations of the RLS algorithm and constitute its state-space representation, i.e.,

$$\begin{bmatrix} \mathbf{w}(n+1) \\ e^*(n) \end{bmatrix} = \begin{bmatrix} \lambda \mathbf{P}(n) \mathbf{P}^{-1}(n-1) & \mathbf{P}(n) \phi(n) \\ -\phi^H(n) & 1 \end{bmatrix} \begin{bmatrix} \mathbf{w}(n) \\ d^*(n) \end{bmatrix}. \quad (12.281)$$

In this representation,  $\mathbf{w}(n)$  is the state,  $e^*(n)$  is the output, and  $d^*(n)$  is the input.

Performing a coordinate transformation, (12.281) can be transformed to an unlimited number of systems with the same input-output relation, and hence solving the same least-squares problem (that is, the output error is always the same). Although all these realizations are equivalent in infinite precision arithmetic, the numerical behavior will vary from one coordinate system to another. Thus, the numerical instability of the conventional RLS can be avoided by choosing a convenient transformation of (12.281) [40, 100].

An alternative method of implementing RLS is based on the QR decomposition (QRD) [14] to triangularize the input data matrix. The main advantages of QRD-RLS-based algorithms are the possibility of implementation in systolic arrays (e.g., [101]) and the improved numerical behavior in finite precision arithmetic. Some versions require  $\mathcal{O}(M^2)$  operations per iteration, but others have a reduced computational cost of  $\mathcal{O}(M)$ . The low-cost versions of QRD-RLS algorithms are known as *fast-QR* algorithms. Some important references on this subject are [38, 101–116]. A good tutorial on QRD-RLS-based algorithms can be found in [43], where the most recent developments as well as the basic concepts are covered.

Another important class of fast algorithms solves the least-squares problem in a recursive form based on the lattice realization. These algorithms are very attractive due to the possible modular implementation and low cost ( $\mathcal{O}(M)$ ). Lattice-RLS-based algorithms are derived by solving the forward and backward linear prediction problems and require time-update and order-update recursions. They explore the time-shift property of the input signal vector (such as in (12.113)) and do not compute explicitly the filter weights. Recall that many applications do not require the computation of the filter weights and have regressors that satisfy the time-shift property as, for example, channel equalization and interference cancellation (see Section 1.12.1.3). In these applications, a fast RLS algorithm can be a reasonable choice since it presents a good tradeoff between convergence rate and computational cost. One of these algorithms is the modified EF-LSL (error-feedback least-squares lattice algorithm) that presents reliable numerical properties when implemented in finite-precision arithmetic [5]. This algorithm was proposed for echo-cancellation applications and was used in the example of Section 1.12.1.1. Some lattice-RLS-based algorithms can be found in the references [5, 117–124].

More recently, lattice-RLS algorithms have been generalized to filter structures other than tapped-delay lines, in particular, to Laguerre filters [125–127].

Other fast algorithms that solve the least-squares problem in a recursive form are the fast transversal RLS (FTRL) algorithms. Unlike the lattice-based algorithms, the FTRL algorithms require only time-recursive equations and therefore, compute explicitly the filter weights. The main drawback of these algorithms is that they are very sensitive to quantization effects and become unstable if certain actions are not taken [1]. The list of fast transversal RLS algorithms is vast. Some of the most important versions can be found in the references [128–134].

### 1.12.5.1.3 DCD-RLS

The DCD-RLS algorithm, proposed in [44], is a low-complexity alternative to the RLS algorithm, based on the dichotomous coordinate-descent (DCD) algorithm for function minimization proposed in [135]. The DCD algorithm is designed to be easily implementable in hardware (such as FPGAs, for example), and thus avoids multiplications, divisions and other operations that are costly to implement in hardware—most of its operations are additions and comparisons.

The RLS weight vector estimates are given by the solution of the following set of linear equations, which we repeat from Section 1.12.3.3:

$$\widehat{\mathbf{R}}_{\phi}(n)\mathbf{w}(n+1) = \widehat{\mathbf{r}}_{d\phi}(n), \quad (12.282)$$

where  $\widehat{\mathbf{R}}_{\phi}(n)$  and  $\widehat{\mathbf{r}}_{d\phi}(n)$  are given by the recursions

$$\widehat{\mathbf{R}}_{\phi}(n) = \lambda \widehat{\mathbf{R}}_{\phi}(n-1) + \phi(n)\phi^H(n), \quad (12.283)$$

and

$$\widehat{\mathbf{r}}_{d\phi}(n) = \lambda \widehat{\mathbf{r}}_{d\phi}(n-1) + d^*(n)\phi(n). \quad (12.284)$$

The difficulty in solving these expressions is that a general solution for (12.282) involves a number of operations of the order of  $M^3(\mathcal{O}(M^3))$  for a filter with  $M$  coefficients. This is usually too costly for practical applications, except perhaps for very short filters. The classical RLS algorithm described in Section 1.12.3.3 solves this problem partially by using the matrix inversion lemma to compute the inverse of  $\widehat{\mathbf{R}}_{\phi}(n)$  recursively using the already computed inverse of  $\widehat{\mathbf{R}}_{\phi}(n-1)$ . This reduces the total number of computations to  $\mathcal{O}(M^2)$ . However, the resulting algorithm is still difficult to implement in practice, because numerical errors may easily cause divergence.

The DCD-RLS algorithm avoids both these problems by using a couple of clever tricks. First, assume that you have a good approximation  $\hat{\mathbf{w}}(n)$  for  $\mathbf{w}(n)$ . Then you could use a recursive algorithm to find an approximation  $\hat{\mathbf{w}}(n+1)$  to the solution of (12.282), using your current approximation  $\hat{\mathbf{w}}(n)$  as an initial condition. Since the initial condition is already close to the solution, you would need only a few iterations of your recursive algorithm to obtain  $\hat{\mathbf{w}}(n+1)$ . However, this idea only helps if each iteration of the recursive algorithm is very cheap to compute. We explain next how this can be done using DCD.

#### DCD minimization of quadratic functions

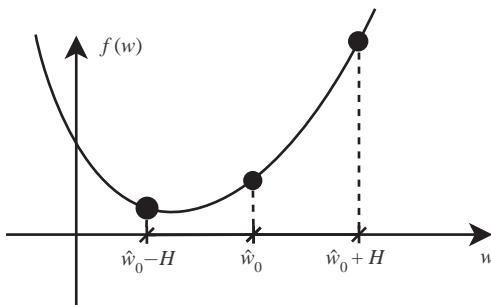

Let us consider first a one-dimensional quadratic problem

$$\min_w \left\{ f(w) = \frac{1}{2}aw^2 - bw + c \right\},$$

where  $a > 0$ ,  $b$ , and  $c$  are constants. Assume in addition that you want to implement your algorithm in hardware, using fixed-point arithmetic.

In order to solve this problem, you could proceed as follows. Assume you have an initial approximation  $\hat{w}(0)$ . Choose a step-size  $H > 0$  and compute

$$\Delta f_+ = f(\hat{w}(0) + H) - f(\hat{w}(0)), \quad \Delta f_- = f(\hat{w}(0) - H) - f(\hat{w}(0)).$$

**FIGURE 12.34**

DCD applied to one-dimensional minimization.

Then, if  $\Delta f_+ < 0$ , choose  $\hat{w}(1) = \hat{w}(0) + H$ , and if  $\Delta f_- < 0$ , choose  $\hat{w}(1) = \hat{w}(0) - H$ . If both are positive, choose  $\hat{w}(1) = \hat{w}(0)$  and reduce the step-size  $H \leftarrow H/2$  (note that if  $f(\cdot)$  is convex, the case of both  $\Delta f_+ < 0$  and  $\Delta f_- < 0$  can never occur). With the new estimate  $\hat{w}(1)$ , the procedure can be repeated to find a new improved estimate  $\hat{w}(2)$ , and so on. It can be shown that this algorithm will converge to the minimum of  $f(\cdot)$  whenever  $f(\cdot)$  is a convex function—see Figure 12.34.

Although the description given so far explains the general working of the DCD algorithm, it does not show how it can be efficiently implemented, using as few operations as possible. We will turn to this point now, but already extending the algorithm to minimize a quadratic function of several variables. Consider then the problem of finding the solution  $\mathbf{w}_o$  to

$$\min_{\mathbf{w}} \left\{ f(\mathbf{w}) = \frac{1}{2} \mathbf{w}^T \mathbf{R} \mathbf{w} - \mathbf{b}^T \mathbf{w} + c \right\},$$

where  $\mathbf{R}$  is a positive-definite matrix,  $\mathbf{b}$  is a vector, and  $c$  is a constant (note that the minimum  $\mathbf{w}_o$  of  $f(\mathbf{w})$  is also the solution  $\mathbf{w}_o$  to  $\mathbf{R}\mathbf{w}_o = \mathbf{b}$ , that is, any algorithm to find  $\mathbf{w}_o$  can be also used to solve the normal equations (12.282)).

Assume that we have an initial approximation  $\hat{\mathbf{w}}(0)$  to the solution, and we want to find an improved approximation, changing one entry of  $\hat{\mathbf{w}}(0)$  at a time. In order to differentiate each new approximation, we use the following notation. Define  $\hat{\mathbf{w}}^{(0)}(0) = \hat{\mathbf{w}}(0)$ . We shall first seek an improved estimate to the first entry of  $\hat{\mathbf{w}}^{(0)}(0)$ . The resulting vector will be denoted by  $\hat{\mathbf{w}}^{(1)}(0)$ . Continuing, we find an improved estimate to the second entry of  $\hat{\mathbf{w}}^{(1)}(0)$ , resulting in vector  $\hat{\mathbf{w}}^{(2)}(0)$  and so on. After updating all entries of the initial estimate, we have  $\hat{\mathbf{w}}^{(M)}(0)$ . We then let  $\hat{\mathbf{w}}^{(0)}(1) = \hat{\mathbf{w}}^{(M)}(0)$ , and repeat the procedure.

Then we need to check if  $f(\hat{\mathbf{w}}^{(0)}(0) \pm H\mathbf{e}_1) < f(\hat{\mathbf{w}}(0))$  if we add or subtract  $H$  to the first entry of  $\hat{\mathbf{w}}^{(0)}(0)$  ( $\mathbf{e}_1$  is the vector  $[1 \ 0 \ \dots \ 0]^T$ ). The change  $\Delta f_+$  in the cost-function obtained by adding  $H$  to the first entry of  $\hat{\mathbf{w}}^{(0)}(0)$  is

$$\begin{aligned} \Delta f_+ &= \frac{1}{2} \left( \hat{\mathbf{w}}^{(0)}(0) + H\mathbf{e}_1 \right)^T \mathbf{R} \left( \hat{\mathbf{w}}^{(0)}(0) + H\mathbf{e}_1 \right) - \mathbf{b}^T \left( \hat{\mathbf{w}}^{(0)}(0) + H\mathbf{e}_1 \right) + c \quad (12.285) \\ &\quad - \left( \frac{1}{2} \hat{\mathbf{w}}^{(0)T}(0) \mathbf{R} \hat{\mathbf{w}}^{(0)}(0) - \mathbf{b}^T \hat{\mathbf{w}}^{(0)}(0) + c \right) \end{aligned}$$

$$= \mathbf{H}\mathbf{e}_1^T \mathbf{R}\hat{\mathbf{w}}^{(0)}(0) + \frac{1}{2}H^2\mathbf{e}_1^T \mathbf{R}\mathbf{e}_1 - H\mathbf{b}^T \mathbf{e}_1. \quad (12.286)$$

Similarly, the variation  $\Delta f_-$  obtained from subtracting  $H$  from the first entry of  $\hat{\mathbf{w}}(0)$  is

$$\Delta f_- = -\mathbf{H}\mathbf{e}_1^T \mathbf{R}\hat{\mathbf{w}}^{(0)}(0) + \frac{1}{2}H^2\mathbf{e}_1^T \mathbf{R}\mathbf{e}_1 + H\mathbf{b}^T \mathbf{e}_1. \quad (12.287)$$

Therefore, we should make

$$\hat{\mathbf{w}}^{(1)}(0) = \begin{cases} \hat{\mathbf{w}}^{(0)}(0) + H\mathbf{e}_1, & \text{if } \Delta f_+ < 0, \\ \hat{\mathbf{w}}^{(0)}(0) - H\mathbf{e}_1, & \text{if } \Delta f_- < 0, \\ \hat{\mathbf{w}}^{(0)}(0), & \text{otherwise.} \end{cases} \quad (12.288)$$

The same steps can be repeated for the second entry of  $\hat{\mathbf{w}}^{(1)}(0)$  and so on, that is, we can update the  $(m+1)$ th entry of  $\hat{\mathbf{w}}^{(m)}(0)$  to obtain a new approximation  $\hat{\mathbf{w}}^{(m+1)}(0)$  for  $m = 0, \dots, M-1$ . After obtaining  $\hat{\mathbf{w}}^{(M)}(0)$ , we have updated all entries of  $\hat{\mathbf{w}}(0)$ . We can then make  $\hat{\mathbf{w}}^{(0)}(1) = \hat{\mathbf{w}}^{(M)}(0)$  and repeat the procedure. However, if no update is made for  $m = 1, \dots, M$ , before repeating we decrease the step  $H$  by a factor of two (i.e.,  $H \leftarrow H/2$ ). By reducing  $H$  only when no update is necessary for any entry of the vector, we avoid problems that would appear if the initial value of  $H$  were too small.

Implemented as described so far, the algorithm has a high computational cost. For example, for the evaluation of  $\Delta f_+$  at each step we must

- Evaluate  $\mathbf{e}_m^T \mathbf{R}\hat{\mathbf{w}}^{(m-1)}(i)$ . This is equivalent to multiplying the  $m$ th row of  $\mathbf{R}$  by  $\hat{\mathbf{w}}^{(m-1)}(i)$ , involving  $M$  multiplications and  $M-1$  additions.
- Multiply  $-\mathbf{e}_m^T \mathbf{R}\hat{\mathbf{w}}^{(m-1)}(i) + \mathbf{b}^T \mathbf{e}_m$  by  $H$  and add the result to  $(H^2/2)R_{m,m}$  ( $R_{m,m}$  is the element  $(m, m)$  of  $\mathbf{R}$ ). This requires 2 multiplications and 2 additions, assuming  $H^2/2$  is pre-computed.

The same steps would be necessary for the computation of  $\Delta f_-$ . Note that all these computations would have to be repeated at each step, therefore the update of all entries of  $\hat{\mathbf{w}}^{(0)}(i)$  would require more than  $M^2$  multiplications.

However, the number of computations can be reduced substantially, if we take advantage of some properties of hardware implementations of arithmetic operations, as we describe next. Assume in the following that all variables are fixed-point binary numbers (see Box 8).

First, we can avoid the computation of  $\mathbf{R}\hat{\mathbf{w}}^{(m-1)}(i)$  by introducing a residue vector that is updated at each step. Let  $\mathbf{r}^{(0)}(0) = \mathbf{b} - \mathbf{R}\hat{\mathbf{w}}^{(0)}(0)$  be the initial residue vector. Note that this is the residue of solving  $\mathbf{R}\mathbf{w} = \mathbf{b}$  using  $\hat{\mathbf{w}}^{(0)}(0)$  as an approximation to the solution.

At the end of the first step,  $\hat{\mathbf{w}}^{(0)}(0)$  is updated as in (12.288). Since only one entry of  $\hat{\mathbf{w}}^{(0)}(0)$  is changed, the modification in the residue is simple to evaluate

$$\mathbf{r}^{(1)}(0) = \mathbf{b} - \mathbf{R}\hat{\mathbf{w}}^{(1)}(0) = \begin{cases} \mathbf{b} - \mathbf{R}(\hat{\mathbf{w}}^{(0)}(0) + H\mathbf{e}_1) = \mathbf{r}^{(0)}(0) - H\mathbf{R}\mathbf{e}_1, & \text{if } \Delta f_+ < 0, \\ \mathbf{b} - \mathbf{R}(\hat{\mathbf{w}}^{(0)}(0) - H\mathbf{e}_1) = \mathbf{r}^{(0)}(0) + H\mathbf{R}\mathbf{e}_1, & \text{if } \Delta f_- < 0, \\ \mathbf{r}^{(0)}(0), & \text{otherwise.} \end{cases} \quad (12.289)$$

This still requires  $M$  multiplications ( $H$  multiplied by the first column of  $\mathbf{R}$ ). However, if  $H$  is a power of two, that is, if  $H = 2^k$  for some integer  $k$ , then the computation of  $\mathbf{r}^{(1)}(0)$  in fixed-point

arithmetic requires only  $M$  shifts and  $M$  additions, which are much easier to implement in hardware than multiplications. Moreover, if both  $\Delta f_+$  and  $\Delta f_-$  are positive, no update is necessary.

Next, we note that it is not really necessary to compute both  $\Delta f_+$  and  $\Delta f_-$ : from (12.286) and (12.287), when updating the  $m$ th element of  $\hat{\mathbf{w}}^{(m-1)}(i)$  at step  $i$ , we have

$$\Delta f_+ = -H\mathbf{e}_m^T \mathbf{r}^{(m-1)}(i) + \frac{1}{2}H^2 \mathbf{e}_m^T R \mathbf{e}_m = -H r_m^{(m-1)}(i) + \frac{1}{2}H^2 R_{m,m}, \quad (12.290)$$

where  $r_m^{(m-1)}(i)$  is the  $m$ th entry of the residue vector  $\mathbf{r}^{(m-1)}(i)$ ,  $\mathbf{r}^{(0)}(i+1) \stackrel{\Delta}{=} \mathbf{r}^{(M)}(i)$ , and  $\mathbf{e}_m$  is the  $m$ th column of the  $M \times M$  identity matrix. Similarly,

$$\Delta f_- = H r_m^{(m-1)}(i) + \frac{1}{2}H^2 R_{m,m}. \quad (12.291)$$

Then, recalling that  $H$  and  $R_{m,m}$  are positive ( $R$  is positive-definite),  $\Delta f_+ < 0$  only if

$$r_m^{(m-1)}(i) > \frac{1}{2}H R_{m,m} \geq 0.$$

Repeating the arguments for  $\Delta f_-$ , we see that the  $m$ th entry of  $\hat{\mathbf{w}}^{(m-1)}(i)$  will be updated if and only if

$$|r_m^{(m-1)}(i)| > \frac{1}{2}H R_{m,m}, \quad (12.292)$$

with updates

$$\hat{\mathbf{w}}^{(m)}(i) = \hat{\mathbf{w}}^{(m-1)}(i) + H \text{sign}(r_m^{(m-1)}(i)) \mathbf{e}_m, \quad (12.293)$$

$$\mathbf{r}^{(m)}(i) = \mathbf{r}^{(m-1)}(i) - H \text{sign}(r_m^{(m-1)}(i)) R \mathbf{e}_m. \quad (12.294)$$

Equations 12.292–12.294 require one comparison,  $M + 1$  shifts, and  $M + 1$  additions. Table 12.10 summarizes the DCD algorithm for minimization of quadratic cost-functions. Note that the algorithm will update the entries of  $\hat{\mathbf{w}}(i)$  bit by bit. It therefore makes sense to choose the initial step-size  $H$  the power-of-two value represented by the most-significant bit in the fixed-point representation being used. The conditional jump in step 10 prevents problems in case  $H$  is chosen too small.

As seen in Table 12.10, the total number of operations never exceeds  $(2M + 2)(B - 1) + N_u(4M + 3)$  (note that here we are counting additions, comparisons and shifts as operations—the algorithm does not involve multiplications). In DCD-RLS, the maximum number of updates  $N_u$  can be chosen between 1 and 4 with good performance, while keeping the cost low.

When applied to RLS, one final simplification can be used when implementing DCD: instead of updating all entries of vector  $\hat{\mathbf{w}}(i)$ , we can only update the entry corresponding to the largest residue. As explained in [44], the resulting algorithm is still guaranteed to converge to the optimum solution.

### DCD-RLS

As we mentioned before, DCD-RLS uses the DCD algorithm just described to solve the normal equations as each new sample arrives. Since DCD is an iterative algorithm, we can use the current solution  $\mathbf{w}(n)$  as the initial value for computation of  $\mathbf{w}(n + 1)$ . In this way, the number of updates  $N_u$  of DCD can be

**Table 12.10** Summary of DCD Algorithm for Minimization of a Quadratic Cost-Function

Step	Initialization: Choose step $H = 2^k$ , number of bits $B$ , and maximum update count $N_u$ . Let $\hat{w} = 0$ , $r = b$ , $h = H$ , and $c = 0$ .	Number of	
		Additions, Shifts, Comparisons	Multiplications
1	for $b = 0 : B - 1$		
2	$h \leftarrow h/2$	1	0
3	flag $\leftarrow 0$	0	0
4	for $m = 1 : M$		
5	if $ r_m  > \frac{1}{2} h R_{m,m}$	2	0
6	$\hat{w}_m \leftarrow \hat{w}_m + h \text{sign}(r_m)$	1	0
7	$r \leftarrow r - h \text{sign}(r_m) R e_m$	$2M$	0
8	$c \leftarrow c + 1$ , flag $\leftarrow 1$	1	0
9	if $c > N_u$ , stop algorithm.	1	0
10	if flag = 1, go to step 2	1	0
Total: (worst case)		$\leq (2M + 2)(B - 1)$	0
		$N_u(2M + 3)$	

restricted to a small number (in many situations from 1 to 4 updates is enough for performance close to that of exact RLS). This further reduces the computational cost of the algorithm.

In the following, we will use  $w(n+1)$  to denote the exact solution of (12.282) (i.e., the exact RLS estimate), and  $\hat{w}(n+1)$  to denote the approximation computed by DCD-RLS (both would be equal if we let  $N_u \rightarrow \infty$ ). Assume that at time instant  $n$ , we have available both  $\hat{w}(n)$  and the residue

$$r(n) = \hat{r}_{d\phi}(n-1) - \hat{R}_\phi(n-1)\hat{w}(n), \quad (12.295)$$

In order to apply the DCD algorithm to solve for  $\hat{w}(n+1)$ , it is convenient to update the difference

$$\Delta w(n+1) = w(n+1) - \hat{w}(n). \quad (12.296)$$

Define also

$$\Delta \hat{R}_\phi(n) = \hat{R}_\phi(n) - \hat{R}_\phi(n-1), \quad (12.297)$$

$$\Delta \hat{r}_{d\phi}(n) = \hat{r}_{d\phi}(n) - \hat{r}_{d\phi}(n-1). \quad (12.298)$$

The normal Eq. (12.282) then become

$$\hat{R}_\phi(n) [\hat{w}(n) + \Delta w(n+1)] = \hat{r}_{d\phi}(n),$$

and thus

$$\begin{aligned} \hat{R}_\phi(n) \Delta w(n+1) &= \hat{r}_{d\phi}(n-1) + \Delta \hat{r}_{d\phi}(n) - \hat{R}_\phi(n-1)\hat{w}(n) - \Delta \hat{R}_\phi(n)\hat{w}(n) \\ &= r(n) + \Delta \hat{r}_{d\phi}(n) - \Delta \hat{R}_\phi(n)\hat{w}(n) \stackrel{\Delta}{=} \beta(n). \end{aligned} \quad (12.299)$$

Given an approximate solution  $\Delta\hat{\mathbf{w}}(n+1)$  to these equations, we obtain an updated approximate solution  $\hat{\mathbf{w}}(n+1) = \hat{\mathbf{w}}(n) + \Delta\hat{\mathbf{w}}(n+1)$ . Note that the residue of solving (12.282) using  $\hat{\mathbf{w}}(n+1)$ ,

$$\begin{aligned}\mathbf{r}(n+1) &= \hat{\mathbf{r}}_{d\phi}(n) - \hat{\mathbf{R}}_\phi(n)\hat{\mathbf{w}}(n+1) \\ &= \hat{\mathbf{r}}_{d\phi}(n-1) + \Delta\hat{\mathbf{r}}_{d\phi}(n) - \hat{\mathbf{R}}_\phi(n)[\hat{\mathbf{w}}(n) + \Delta\hat{\mathbf{w}}(n+1)] \\ &= \hat{\mathbf{r}}_{d\phi}(n-1) + \Delta\hat{\mathbf{r}}_{d\phi}(n) - \hat{\mathbf{R}}_\phi(n)\Delta\hat{\mathbf{w}}(n+1) - [\hat{\mathbf{R}}_\phi(n-1) + \Delta\hat{\mathbf{R}}_\phi(n)]\hat{\mathbf{w}}(n) \\ &= \mathbf{r}(n) + \Delta\hat{\mathbf{r}}_{d\phi}(n) - \hat{\mathbf{R}}_\phi(n)\Delta\hat{\mathbf{w}}(n+1) - \Delta\hat{\mathbf{R}}_\phi(n)\hat{\mathbf{w}}(n) \\ &= \boldsymbol{\beta}(n) - \hat{\mathbf{R}}_\phi(n)\Delta\hat{\mathbf{w}}(n+1),\end{aligned}\tag{12.300}$$

is exactly the residue of approximately solving (12.299) by  $\Delta\hat{\mathbf{w}}(n+1)$ .

To complete, we only need to evaluate  $\Delta\hat{\mathbf{R}}_\phi(n)$  and  $\Delta\hat{\mathbf{r}}_{d\phi}(n)$ . From (12.297), (12.298), (12.283) and (12.284), we obtain

$$\Delta\hat{\mathbf{R}}_\phi(n) = (\lambda - 1)\hat{\mathbf{R}}_\phi(n-1) + \boldsymbol{\phi}(n)\boldsymbol{\phi}^T(n),\tag{12.301}$$

$$\Delta\hat{\mathbf{r}}_{d\phi}(n) = (\lambda - 1)\hat{\mathbf{d}}_{d\phi}(n-1) + d(n)\boldsymbol{\phi}(n).\tag{12.302}$$

Substituting these results in the definition of  $\boldsymbol{\beta}(n)$ , we obtain

$$\begin{aligned}\boldsymbol{\beta}(n) &= \mathbf{r}(n) + (\lambda - 1)\hat{\mathbf{r}}_{d\phi}(n-1) + d(n)\boldsymbol{\phi}(n) - [(\lambda - 1)\hat{\mathbf{R}}_\phi(n-1) + \boldsymbol{\phi}(n)\boldsymbol{\phi}^T(n)]\hat{\mathbf{w}}(n) \\ &= \mathbf{r}(n) + (\lambda - 1)\mathbf{r}(n) + e(n)\boldsymbol{\phi}(n) = \lambda\mathbf{r}(n) + e(n)\boldsymbol{\phi}(n).\end{aligned}\tag{12.303}$$

We can therefore use the DCD algorithm to compute an approximate solution to (12.299) and update the residue defined by (12.300), as described in Table 12.11.

As we mentioned before, the number of operations of the DCD algorithm can be reduced if we modify the algorithm in Table 12.10 to update only the entries of the weight vector corresponding to the largest residue entry, as described in Table 12.12.

The total number of operations of DCD-RLS as described in Tables 12.11 and 12.12 is  $M^2 + 4M$  multiplications and  $M^2/2 + 3.5M + (2M + 1)N_u + B$  additions. Most of these operations are due to the updating of  $\hat{\mathbf{R}}_\phi$  in Table 12.11, which is responsible for the terms in  $M^2$ . While this cannot be helped for general regressors  $\boldsymbol{\phi}(n)$ , the operation count can be substantially reduced when our filter is modeling an FIR relation as in (12.41) (i.e.,  $\boldsymbol{\phi}(n)$  is a tap-delay line), as we show next.

If

$$\boldsymbol{\phi}(n) = [x(n) \ x(n-1) \ \dots \ x(n-M+1)]^T,\tag{12.304}$$

**Table 12.11** Summary of the DCD RLS Algorithm for General Regressors

Initialization:

$$\hat{\mathbf{w}}(0) = \mathbf{0}, \mathbf{r}(0) = \mathbf{0}, \hat{\mathbf{R}}_\phi(-1) = \Pi > 0$$

for  $n = 0, 1, 2, \dots$

$$\hat{\mathbf{R}}_\phi(n) = \lambda \hat{\mathbf{R}}(n-1) + \phi(n)\phi^T(n) \text{ (use (12.306) for tap-delay lines)}$$

$$\hat{y}(n) = \hat{\mathbf{w}}^T(n)\phi(n),$$

$$\mathbf{e}(n) = d(n) - \hat{y}(n),$$

$$\beta(n) = \lambda \mathbf{r}(n) + \mathbf{e}(n)\phi(n),$$

Use DCD algorithm to compute new  $\Delta \hat{\mathbf{w}}(n+1)$  and  $\mathbf{r}(n+1)$  from  $\hat{\mathbf{R}}_\phi(n)\Delta \hat{\mathbf{w}}(n+1) = \beta(n)$ ,

$$\hat{\mathbf{w}}(n+1) = \hat{\mathbf{w}}(n) + \Delta \hat{\mathbf{w}}(n+1).$$

**Table 12.12** Summary of Leading-Element DCD Algorithm for Use in DCD-RLS, from [44]

Step	<b>Initialization: Choose initial condition step <math>H = 2^k</math>, number of bits <math>B</math>, and maximum update count <math>N_u</math>. Let <math>\Delta \hat{\mathbf{w}} = \mathbf{0}</math>, <math>\mathbf{r} = \beta(n)</math>, <math>h = H/2</math>, <math>b = 1</math>.</b>
	for $k = 1 : N_u$
1	$p = \arg \max_{1 \leq m \leq M} \{ r_m \}$ , go to step 4
2	$b \leftarrow b + 1, h \leftarrow h/2$
3	Stop if $b > B$
4	Go to step 2 if $ r_p  \leq (h/2)R_{p,p}$
5	$\Delta \hat{\mathbf{w}}_p = \Delta \hat{\mathbf{w}}_p + \text{sign}(r_p)h$
6	$\mathbf{r} = \mathbf{r} - \text{sign}(r_p)h\hat{\mathbf{R}}_\phi \mathbf{e}_p$

then  $\hat{\mathbf{R}}(n)$  and  $\hat{\mathbf{R}}(n-1)$  share a common structure. Assume that the initial condition  $\hat{\mathbf{R}}(-1) = \Pi = \text{diag}(\lambda^{M-1}, \lambda^{M-2}, \dots, 1)$ . Then

$$\begin{aligned} \hat{\mathbf{R}}(0) &= \lambda \begin{bmatrix} \lambda^{M-1} & 0 & \dots & 0 \\ 0 & \lambda^{M-2} & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & 1 \end{bmatrix} + \begin{bmatrix} x(0) \\ 0 \\ \vdots \\ 0 \end{bmatrix} \begin{bmatrix} x(0) & 0 & \dots & 0 \end{bmatrix}^T \\ &= \begin{bmatrix} \lambda^M + x^2(0) & 0 & \dots & 0 \\ 0 & \lambda^{M-1} & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & \lambda \end{bmatrix} = \begin{bmatrix} \lambda^M + x^2(0) & \mathbf{0}^T \\ \mathbf{0} & [\hat{\mathbf{R}}_\phi(-1)]_{1:M-1, 1:M-1} \end{bmatrix}, \end{aligned}$$

where  $[\hat{\mathbf{R}}_\phi(-1)]_{1:M-1, 1:M-1}$  denotes the top-left  $(M-1) \times (M-1)$  block of  $\hat{\mathbf{R}}_\phi(-1)$ . We note that, except for its first row and column,  $\hat{\mathbf{R}}(0)$  can be obtained directly from  $\hat{\mathbf{R}}(-1)$ .

Following this observation, we claim that for tapped-delay line regressors, the computation of  $\widehat{\mathbf{R}}_\phi(n)$  in Table 12.11 can be replaced by an update of only its first column  $[\widehat{\mathbf{R}}_\phi(n)]_1$ , that is,

$$[\widehat{\mathbf{R}}_\phi(n)]_1 = \lambda[\widehat{\mathbf{R}}_\phi(n-1)]_1 + x(n)\phi(n). \quad (12.305)$$

Since  $\widehat{\mathbf{R}}_\phi(n)$  is symmetric, its first row is the transpose of (12.306), and does not need to be evaluated again.

We show next by induction that this pattern holds for all  $n$ . We just showed that it is true for  $n = 0$ . Assume then that for a certain  $n$ , it holds that

$$\widehat{\mathbf{R}}_\phi(n) = \left[ \begin{array}{c|c} \lambda[\widehat{\mathbf{R}}_\phi(n-1)]_1 + x(n)\phi(n) & (\cdot)^T \\ \hline [\widehat{\mathbf{R}}_\phi(n-1)]_{1:M-1,1:M-1} \end{array} \right], \quad (12.306)$$

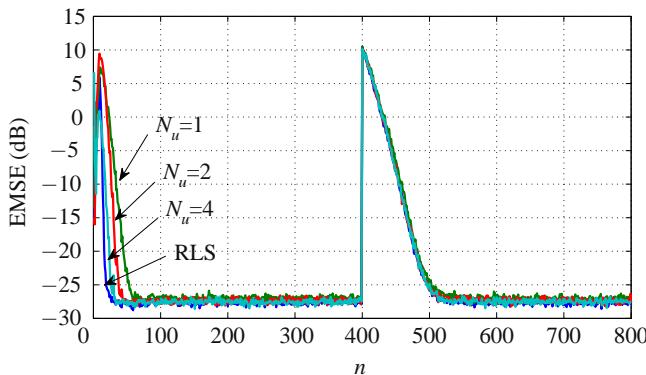

where we use  $(\cdot)^T$  to indicate that the entries of the first row are the same as the entries of the first column. We show next that  $\widehat{\mathbf{R}}_\phi(n+1)$  must follow the same pattern. Indeed,

$$\begin{aligned} \widehat{\mathbf{R}}_\phi(n+1) &= \lambda\widehat{\mathbf{R}}_\phi(n) + \begin{bmatrix} x(n+1) \\ x(n) \\ \vdots \\ n(n-M+2) \end{bmatrix} \begin{bmatrix} x(n+1) & x(n) & \dots & x(n-M+2) \end{bmatrix}^T \\ &= \left[ \begin{array}{c|c} \lambda[\widehat{\mathbf{R}}_\phi(n)]_1 & (\cdot)^T \\ \hline \lambda[\widehat{\mathbf{R}}_\phi(n-1)]_{1:M-1,1:M-1} \end{array} \right] \\ &\quad + \begin{bmatrix} x(n+1)\phi(n+1) \\ \begin{bmatrix} x^2(n) & \dots & x(n)x(n-M+2) \\ \vdots & \ddots & \vdots \\ x(n)x(n-M+2) & \dots & x^2(n-m+2) \end{bmatrix}^T \end{bmatrix} \\ &= \left[ \begin{array}{c|c} \lambda[\widehat{\mathbf{R}}_\phi(n)]_1 + x(n+1)\phi(n+1) & (\cdot)^T \\ \hline [\widehat{\mathbf{R}}_\phi(n)]_{1:M-1,1:M-1} \end{array} \right], \end{aligned}$$

where in the last step we identified the  $(2, 2)$  block of the intermediate result with the first  $M - 1$  rows and columns of  $\widehat{\mathbf{R}}_\phi(n)$ , from (12.283).

Note that in practice we should not actually move the entries of  $\widehat{\mathbf{R}}_\phi(n-1)$  to their new position; rather, we should use an indexing system to access the entries of  $\widehat{\mathbf{R}}_\phi(n)$  to avoid this costly moving operation. The total number of operations of DCD-RLS using (12.306) is  $3M$  multiplications and  $2MN_u + 6M$  additions. This is not much larger than the complexity of NLMS. The DCD-RLS algorithm has been implemented in FPGAs and run for long periods of time without observation of divergence [44].

Figure 12.35 shows a comparison of RLS and DCD-RLS in a system identification problem. We are trying to identify an  $M = 10$  FIR filter, so we use (12.306) to update  $\widehat{\mathbf{R}}_\phi(n)$  with lower cost. The input

**FIGURE 12.35**

EMSE for RLS and DCD-RLS for different values of  $N_u$ , with  $\lambda = 0.95$ ,  $M = 10$ , and for DCD,  $H = 2$  and  $B = 16$ . Average of  $L = 500$  realizations.

signal  $x(n)$  is white Gaussian noise with zero mean and unit variance. The optimum coefficient vector  $\mathbf{w}_o(n)$  follows a random-walk model as in (12.182) with  $\mathbf{Q} = 10^{-5} \mathbf{I}$  (the initial value,  $\mathbf{w}_o(0)$  is random, taken from a Gaussian distribution with covariance matrix equal to  $\mathbf{I}$ ). Both RLS and RLS-DCD use a forgetting factor of  $\lambda = 0.95$ . RLS-DCD is implemented with leading DCD (Table 12.12),  $B = 16$  and  $H = 2$ . The maximum number of updates  $N_u$  is varied from 1 to 8. The optimum vector  $\mathbf{w}_o(n)$  suffers an abrupt change at  $n = 400$ . The learning curves were obtained from the average of  $L = 500$  realizations. As the figure shows, even for  $N_u = 1$ , the performance of RLS-DCD is very close to that of RLS. The only difference is a smaller convergence rate at the start of the algorithm. However, after the abrupt modification of  $\mathbf{w}_o(n)$  at instant  $n = 400$ , all filters converge equally quickly to the new vector. This shows that RLS-DCD does not lose in tracking capability when compared to standard RLS.

### 1.12.5.2 Regularization

There are applications in which the autocorrelation matrix  $\mathbf{R}_\phi$  may become very ill-conditioned (i.e., nearly singular). In these cases, it can be shown that the LMS weight estimates may slowly drift to quite large values, even though the error remains small. The problem arises when the filter is implemented in finite-precision arithmetic, because the variables holding the filter weights may overflow, thereby making the error grow suddenly very large.

This can happen, for example, for certain kinds of equalizers in communications [87, 92, 93]. The mechanism through which the LMS coefficients may slowly drift is explained in [94, 136].

The usual solution to this problem is to modify the cost function to add a term proportional to  $\|\mathbf{w}\|^2$ , so that large values of the weight vector are penalized:

$$J_{\text{leaky}} = E \left\{ |d(n) - \mathbf{w}^H \boldsymbol{\phi}(n)|^2 \right\} + \alpha \|\mathbf{w}\|^2, \quad (12.307)$$

where  $\|\cdot\|$  is the Euclidean norm and  $\alpha > 0$  is a small constant. With this cost function, the corresponding algorithm is

$$\mathbf{w}(n+1) = (1 - \mu\alpha)\mathbf{w}(n) + \mu e^*(n)\boldsymbol{\phi}(n). \quad (12.308)$$

This is known as *leaky-LMS* algorithm [4]. It can be shown that the introduction of leakage will bias the solution away from the Wiener solution, but will prevent any excessive growth of the weight coefficients. A detailed analysis of the leaky-LMS algorithm is available in [137]. Reference [94] proposes a modified version of the algorithm without the bias.

Difficulties with singular or near-singular autocorrelation matrices also appears with RLS. For example, if the input is a periodic signal with little noise, the autocorrelation matrix will become nearly singular, and matrix  $\mathbf{P}(n)$  in RLS will diverge. This problem, as well as a solution to it using variable forgetting-factor, is described in [138]. A constant regularization method based on DCD can be found in [139]. Another approach, valid only for short filters, but which allows constant regularization, is described in [140].

The leaky-LMS algorithm has found other important applications, most particularly in beamforming, in which it is used to turn the beamformer robust against array imperfections [141]. The algorithms used in beamforming are examples of constrained adaptive filters, in which the cost function incorporates equality conditions that must be satisfied at all times—see Section 1.12.5.11.

Another algorithm closely related to leaky-LMS, in which the extra term in the cost function penalizes large values of the filter output (that is,  $\alpha|\mathbf{w}^H(n)\boldsymbol{\phi}(n)|^2$  instead of  $\alpha\|\mathbf{w}(n)\|^2$  in (12.307)), was recently employed to improve the performance of FIR adaptive filters in the presence of saturation nonlinearities [142].

More recent applications of regularization involve the use of the  $\ell_1$ -norm,

$$\|\mathbf{w}\|_1 = |w_0| + |w_1| + \dots + |w_{M-1}|,$$

instead of the Euclidean norm. This is because the  $\ell_1$  norm promotes solutions that are sparse, that is, a filter that minimizes the cost function

$$J_{\text{sparse}} = E \left\{ \left| d(n) - \mathbf{w}^H \boldsymbol{\phi}(n) \right|^2 \right\} + \alpha \|\mathbf{w}\|_1, \quad (12.309)$$

will favor solutions in which the vector  $\mathbf{w}$  has only a few nonzero entries (an intuitive explanation for this can be found in [143], which is a good introduction to compressive sensing). Algorithms for promoting sparsity have been receiving much attention lately, due to the interest in compressive sensing applications [144–148]. See also the references for the proportionate NLMS (PNLMS) algorithm in Section 1.12.5.3.

### 1.12.5.3 Variable step-size

The steady-state analysis of Section 1.12.4.4 shows that the step-size  $\mu$  plays an import role in controlling the performance of the LMS algorithm since it is one of the main factors affecting the convergence rate and the misadjustment. To obtain a better tradeoff between convergence speed and steady-sate EMSE, several authors proposed different forms of adjusting the step-size of LMS. Variable step-size algorithms allow the filters to dynamically adjust their performance in response to conditions in the input data and error signals.

In this context, one of the most popular algorithms is the variable step-size LMS (VSLMS) proposed in [149]. In the VSLMS algorithm, each coefficient  $w_k(n)$ ,  $k = 0, \dots, M - 1$  is updated with a time-varying step-size  $\mu_k(n)$ , whose adjustment is given by

$$\mu_k(n) = \mu_k(n - 1) + \rho \text{sign}[e(n)\phi_k(n)] \text{sign}[e(n - 1)\phi_k(n - 1)], \quad (12.310)$$

where  $\rho$  is a small positive constant. This algorithm operates in a very intuitive way. When the algorithm has not yet converged, the gradient term  $e(n)\phi_k(n)$  shows a positive or negative direction in successive iterations and the step-size  $\mu_k(n)$  increases up to an allowed maximum value. On the other hand, near steady-state  $e(n)\phi_k(n)$  approaches zero and its sign changes in successive iterations, which reduces  $\mu_k(n)$  (the step-size is lower-bounded by a small minimum value). Therefore, during the initial convergence VSLMS uses a large step-size, which leads to a high convergence rate. When its coefficients are close to the optimum solution, the algorithm is updated with a small step-size, which allows VSLMS to achieve a small EMSE. A variant of this algorithm is obtained by dropping the sign functions in (12.310), i.e.,

$$\mu_k(n) = \mu_k(n - 1) + \rho e(n)e(n - 1)\phi_k(n)\phi_k(n - 1). \quad (12.311)$$

The choice between (12.310) and (12.311) depends on the application [150].

The NLMS algorithm, proposed independently by Nagumo and Noda [151] and Albert and Gardner [152], can be interpreted a variable step-size LMS with a particular choice for  $\mu(n)$  (see Section 1.12.3.2). An important variant of NLMS is the so-called *power-normalized* LMS (PN-LMS) algorithm, which uses the following variable step-size

$$\mu(n) = \frac{\tilde{\mu}}{\varepsilon + p(n)}, \quad (12.312)$$

where

$$p(n) = \gamma p(n - 1) + (1 - \gamma)|\phi_0(n)|^2, \quad (12.313)$$

with  $p(-1) = 0$  and  $\gamma$  being a positive scalar chosen from within the interval  $0 < \gamma \leq 1$ . This algorithm is useful when the regressor is a tapped-delay line, that is, when  $\phi_i(n) = x(n - i)$ , so that the scalar  $p(n)$  is an estimate for the power of the input sequence  $\{x(n)\}$ . The range of  $\tilde{\mu}$  in (12.312) is  $0 \leq \tilde{\mu} \leq \frac{2}{M}$  [3].

Over the years, several variable step-size algorithms were proposed in the literature. Some of these algorithms are in the papers [153–167] and in their references. Besides the variable step-size approaches, an alternative scheme to improve the tradeoff between convergence speed and steady-state EMSE is constituted by combinations of adaptive algorithms, described in Section 1.12.5.8.1.

Another class of variable step-size algorithms was developed specifically to accelerate the convergence of filters whose optimum weight vector  $\mathbf{w}_o$  is sparse, that is, has only a small fraction of nonzero elements. The primary application for this is echo cancellation, mainly for echo due to reflections in the telephone connection. The algorithms are known as *proportionate* NLMS (PNLMS) algorithms, and have usually very good performance for approximating sparse weight vectors [168–172].

**Table 12.13** Fourth- and Sixth-Order Moments of Different Distributions

Distribution	$\frac{E\{(x-\mu_x)^4\}}{\sigma_x^4}$	$\frac{E\{(x-\mu_x)^6\}}{\sigma_x^6}$
Binary	1	1
Uniform	9/5	27/7
Gaussian	3	15
Exponential	6	90

#### 1.12.5.4 Non-Gaussian noise and robust filters

Consider a problem in which we know that the regressor  $\phi(n)$  and the desired signal  $d(n)$  are related through a model (we assume for simplicity that all variables are real)

$$d(n) = \mathbf{w}_o^T \phi(n) + v(n), \quad (12.314)$$

in which  $v(n)$  is independent of  $\phi(n)$ . It is shown in [173] that minimization of the *fourth* power of the error may lead to an adaptive filter with better compromise between convergence rate and excess mean-square error than LMS, if  $v(n)$  is *sub-Gaussian*. Let us explain what this means.

Recall that for any random variable  $x$ , it holds that  $0 \leq \sigma_x^2 = E\{x^2\} - (E\{x\})^2$ . Similarly, if we define  $\mu_x = E\{x\}$ ,

$$E\{(x - \mu_x)^4\} \geq \left(E\{(x - \mu_x)^2\}\right)^2 = \sigma_x^4, \quad E\{(x - \mu_x)^6\} \geq \left(E\{(x - \mu_x)^2\}\right)^3 = \sigma_x^6.$$

In general, we can write  $E\{(x - \mu_x)^4\} = \alpha \sigma_x^4$ , with  $\alpha \geq 1$ . For example, consider the distributions in Table 12.13. Distributions for which  $\frac{E\{(x - \mu_x)^4\}}{\sigma_x^4} < 3$ , such as binary and uniform, are called *sub-Gaussian*, and those for which  $\frac{E\{x^4\}}{(E\{(x - \mu_x)^2\})^2} > 3$ , such as the exponential, are called *super-Gaussian*. These relations are usually given in terms of the *kurtosis*  $\gamma_4$  of a distribution

$$\gamma_4 = \frac{E\{(x - \mu_x)^4\}}{\sigma_x^4} - 3.$$

Therefore, a distribution is sub-Gaussian if its kurtosis is negative, and super-Gaussian if its kurtosis is positive. A distribution with positive kurtosis is such that its probability density function (pdf)  $f(x)$  decays more slowly than the Gaussian as  $|x| \rightarrow \infty$ .

The authors of [173] show that when the noise  $v(n)$  is sub-Gaussian, an algorithm based on the minimization of

$$J_{LMP} = E\{|e(n)|^p\}, \quad (12.315)$$

with  $p > 2$  results in lower steady-state excess mean-square error (EMSE) than LMS. They study particularly the case  $p = 4$ , for which the stochastic gradient algorithm is of the form

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \mu e^3(n) \phi(n). \quad (12.316)$$

This algorithm is known as *least-mean fourth (LMF)* algorithm. Analyses of general algorithms with error nonlinearities can be found in [174], and a unified analysis is available in [175].

The LMF algorithm can be understood intuitively as a variable-step version of LMS:

$$\mathbf{w}(n+1) = \mathbf{w}(n) + (\mu e^2(n)) e(n) \phi(n).$$

When the error is large, the “equivalent” step-size  $\mu e^2(n)$  is large, and the filter converges quickly. On the other hand, when the error is small, the “equivalent” step-size is reduced, which consequently reduces the EMSE.

This idea works well if the distributions of  $\phi(n)$  and  $v(n)$  are indeed sub-Gaussian, but it was soon noticed that the algorithm becomes sensitive to outliers (large but rare values of the input signals). This is also easy to understand: if the error is too large, the “equivalent” step-size may be such that the recursion becomes unstable. References [176, 177] proposed changing the cost function to a mixture of quadratic and quartic, in an attempt to reduce this sensitivity. In [178, p. 313], a different modification of the cost function is proposed, with the same purpose. The new cost function is the following

$$J_{\text{LMF, mod}} = E \{ f(e(n)) \}, \quad f(e) = \begin{cases} e^4, & \text{if } |e| \leq \gamma, \\ e^2, & \text{if } |e| > \gamma, \end{cases} \quad (12.317)$$

in which  $\gamma$  is a constant. References [45, 59] show that when the regressor is Gaussian, LMF has a non-zero probability of diverging. From these results one can see that the solution proposed in [178] indeed stabilizes the algorithm.

Since the LMF recursion contains a cubic nonlinearity, it can be used as a simpler platform to understand the behavior of blind-equalization algorithms such as CMA (see Section 1.12.5.5), which also contains a cubic nonlinearity.

*Set-membership* algorithms [1], which are explained in more detail in Section 1.12.5.10, can be seen as an extreme version of (12.317), in which  $f(e)$  is reduced to simply 0 when  $|e| \leq \gamma$ . The corresponding cost function is

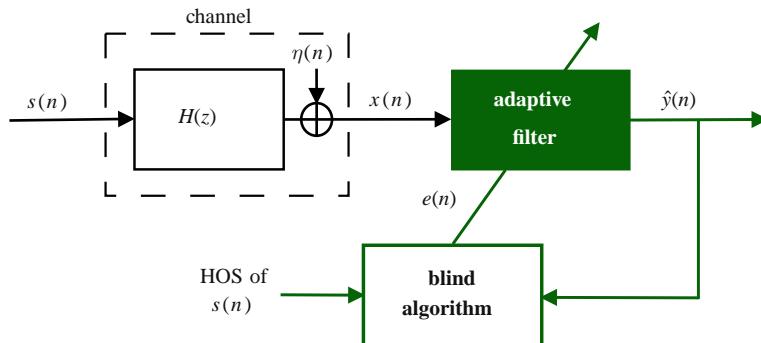

$$J_{\text{SM}} = E \{ f(e(n)) \}, \quad f(e) = \begin{cases} 0, & \text{if } |e| \leq \gamma, \\ e^2, & \text{if } |e| > \gamma. \end{cases} \quad (12.318)$$

Set-membership algorithms are particularly well-suited to bounded noise, i.e., to the case in which one knows that  $|v| \leq \gamma$ .

All these methods are suited to the case in which the noise  $v(n)$  is sub-Gaussian. When the noise is super-Gaussian, there is a small but significant probability that  $v(n)$  will assume a very large value. This may make the performance of even LMS become poor. The solution is to give less weight to large errors, and one choice is to use  $p < 2$  in (12.315). This will give rise to several *robust* adaptive filters, that is, algorithms that are insensitive to outliers. It should be noticed that LMS itself is quite robust in terms of energy (quadratic) relations: in fact, [179] shows that LMS is optimal in the  $\mathcal{H}_\infty$  sense (see also [178, ch. 17]). However, for noise distributions with higher kurtosis, it is convenient to use a smaller value of  $p$  [180–183].

One important algorithm of this class is the *sign-LMS* algorithm [98, 184], which is obtained from (12.315) with  $p = 1$ , and which we already saw in Section 1.12.5.1.1.

For very impulsive signals, methods based on *order statistics* (such as the median, for example), may produce better results, although their complexity tends to be higher [185].

**FIGURE 12.36**

Simplified communications system with a blind adaptive equalizer.

### 1.12.5.5 Blind equalization

As described in Section 1.12.1.3, the objective of equalization is to mitigate the intersymbol interference (ISI) introduced by dispersive channels in order to recover the transmitted sequence. Assuming that the equalizer is an adaptive FIR filter, its coefficients may be updated in two different ways:

- i. using a supervised algorithm in the training and decision-directed modes, as explained in Section 1.12.1.3; or
- ii. using a blind equalization algorithm, which uses higher-order statistics (HOS) of the transmitted signal instead of a training sequence, as shown in Figure 12.36. In this case, the available bandwidth is used in a more efficient manner due to the absence of a training sequence.

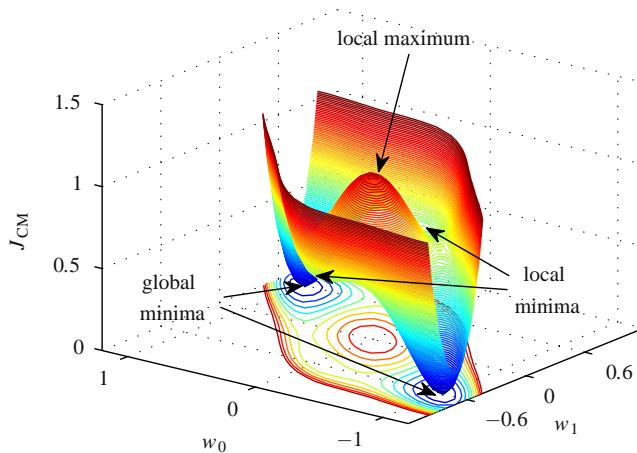

The literature contains many blind equalization algorithms based on HOS, but the most popular is the constant modulus algorithm (CMA), proposed independently by Godard [186] and Treichler and Agee [187] in the 1980s. CMA seeks to minimize the constant-modulus cost function defined as

$$J_{CM} = E \left\{ (r - |\hat{y}(n)|^2)^2 \right\}, \quad (12.319)$$

where  $r = E\{|s(n)|^4\}/E\{|s(n)|^2\}$  is a dispersion constant, which contains information about higher-order statistics of the transmitted signal  $s(n)$  and  $\hat{y}(n) = \mathbf{w}^H \mathbf{x}(n)$  is the equalizer output. This function penalizes deviations in the modulus of the equalized signal away from the dispersion constant  $r$ . Different from the mean-square-error cost function used in supervised adaptive filtering,  $J_{CM}$  is not convex in relation to the coefficients of the equalizer (see the definition of convex functions in Box 5). It has local minima, and constant-modulus-based algorithms can get stuck at these suboptimal solutions.

CMA is obtained from an instantaneous approximation for the gradient of  $J_{CM}$  in relation to  $\mathbf{w}$ . Defining the estimation error

$$e(n) = (r - |\hat{y}(n)|^2)\hat{y}(n), \quad (12.320)$$

**FIGURE 12.37**

Constant-modulus cost function as a function of the equalizer weights.

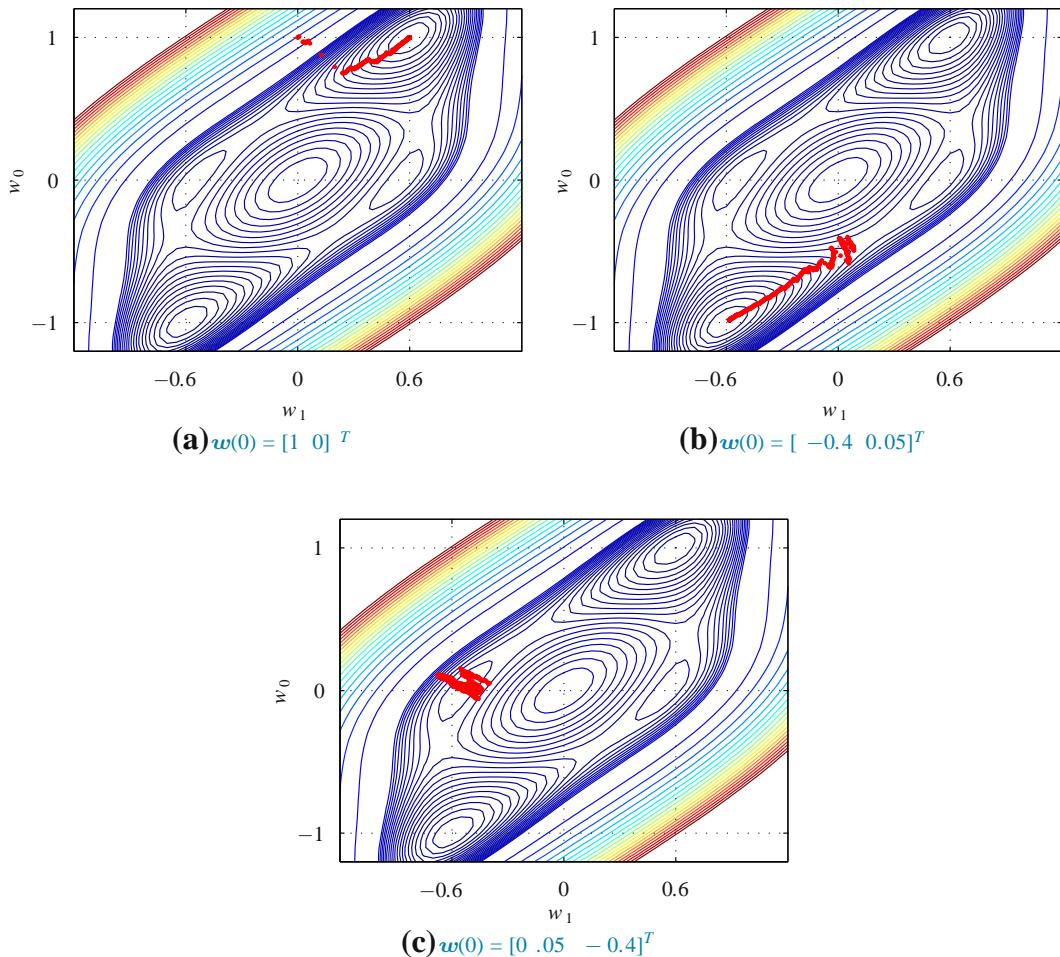

the update equation of CMA can be written as

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \mu e^*(n) \mathbf{x}(n), \quad (12.321)$$

where  $\mu$  stands for a step-size. Since CMA is a stochastic-gradient type algorithm, the similarity of (12.321) to the LMS update equation is not surprising. Due to this similarity, CMA is sometimes interpreted as a blind version of the LMS algorithm [188]. Thus, as in LMS, small step-sizes lead to a small misadjustment and slow convergence. However, the similarity to LMS stops here. The multimodality of the CM cost function makes the prediction of the behavior of CMA a hard task.

To illustrate the constant-modulus cost function, we assume the transmission of a binary signal  $\{-1, +1\}$  through the IIR channel  $H(z) = 1/(1 + 0.6z^{-1})$  in the absence of noise [189]. Considering an FIR equalizer with  $M = 2$  coefficients, we can obtain a 3-D plot of  $J_{CM}$  as a function of  $w_0$  and  $w_1$  as shown in Figure 12.37. As indicated in the figure,  $J_{CM}$  contains two global minima at  $\pm[1 \ 0.6]^T$  and two local minima. Note that if  $\mathbf{w}$  converges to one of the global minima, the transmitted sequence or its inverse will be recovered. These two possibilities occur due to the fact that CMA seeks to recover only the modulus of the transmitted signal and does not solve phase ambiguities introduced by the channel. The phase ambiguities can be corrected by using differential code, which is based on the change of sign between two successive samples.

The animations in Figure 12.38 illustrate the behavior of CMA initialized at the different points. Initializing at  $\mathbf{w}(0) = [1 \ 0]^T$ , the weight vector converges to  $[+1 \ +0.6]^T$ . Now, considering  $\mathbf{w}(0) = [-0.4 \ 0.05]^T$ , we get  $\mathbf{w}(n) \approx [-1 \ -0.6]^T$  at the steady-state. On the other hand, if CMA is initialized at  $[0.05 \ -0.4]^T$ , the algorithm gets stuck at a local minimum. We should notice that in the presence of noise or depending on the step-size, CMA also can escape from a minimum and drift to another solution.

**FIGURE 12.38**

CMA initialized at different points,  $\mu = 0.016$ , channel  $H(z) = 1/(1 + 0.6z^{-1})$  in the absence of noise.  
[Click](#) on each caption to see animations on your browser.

Despite the name of the algorithm, CMA also works for non-constant modulus signals. However, as shown analytically in [80, 190], its best performance occurs for constant-modulus signals since the variability in the transmitted signal modulus plays a role similar to the measurement noise in supervised algorithms.

The stochastic analysis of constant-modulus based algorithms is a hard task. Due to the nonlinearity and multimodality of the CM cost function, additional assumptions are necessary. A good review of the main results in the analysis of CMA can be found in [191], but many results were obtained after its

publication. These results address different issues of constant-modulus based algorithms as the steady-state and transient behavior [77, 80, 190, 192–196], convergence and stability [58, 60, 197–200], phase rotation [201–203], solutions for non-constant modulus signals [204–207], among others.

### 1.12.5.6 Subband and transform-domain adaptive filters

In transform-domain adaptive filters, the input signals are transformed (using the FFT, the DCT or other convenient transform), and the adaptation is performed in the transform domain. The gains are twofold: first, using block processing, one can obtain large reductions in computational cost. Second, by using the decorrelation properties of the transforms, it is possible to use different step-sizes for each tap in the transformed domain, thereby reducing the equivalent eigenvalue spread and increasing the convergence rate [208–216].

A related approach is that of subband adaptive filters, which are also useful to both reduce the computational cost and increase the convergence speed of long filters, in particular for acoustic echo. The main idea is to split the input signal in several parts using an *analysis filter bank*. Each part, relative to a particular band of the full spectrum, is processed separately, and finally all parts are joined together again by a *synthesis filter bank* [217]. Since each subsignal has a smaller bandwidth, the sampling rate can be reduced. The whole process must be made carefully to avoid as much as possible a deterioration of the signals due to aliasing, while still gaining in computational cost, in comparison with standard full-band filters [218–224]. It is important to point out that it is possible to avoid the introduction of extra delay (compared with a full-band filter) [225–228].

Good introductions to the subject can be found in [1, 3, 150].

### 1.12.5.7 Affine projections algorithm

The *affine projections* algorithm (APA) is an extension of NLMS, designed to obtain a convergence rate closer to that of RLS, but with a low computational cost, as close as possible to that of NLMS. We saw in Section 1.12.3.2 that NLMS can be derived as a method for choosing the step-size so that the current a posteriori estimation error is zeroed (12.130). The APA extends this idea, by canceling a vector of a posteriori errors, obtained from data from times  $n - K$  to  $n$ , and the weight vector at time  $n + 1$ :

$$\xi(n) = \mathbf{d}(n) - \Phi(n)\mathbf{w}^*(n+1), \quad (12.322)$$

in which

$$\mathbf{d}(n) = \begin{bmatrix} d(n) \\ d(n-1) \\ \vdots \\ d(n-K-1) \end{bmatrix}, \quad \Phi(n) = \begin{bmatrix} \phi^T(n) \\ \phi^T(n-1) \\ \vdots \\ \phi^T(n-K-1) \end{bmatrix}. \quad (12.323)$$

The affine projections algorithm chooses as next weight estimate the vector  $\mathbf{w}(n+1)$  closest to the current estimate  $\mathbf{w}(n)$  such that  $\xi(n) = \mathbf{0}$  [229–234]:

$$\mathbf{w}(n+1) = \arg \min_{\substack{\mathbf{w} \\ \text{s.t. } \xi(n)=\mathbf{0}}} |\mathbf{w} - \mathbf{w}(n)|^2. \quad (12.324)$$

The solution to this problem is a recursion

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \Phi^T(n) \left( \Phi^*(n) \Phi^T(n) \right)^{-1} \mathbf{e}(n), \quad (12.325)$$

where

$$\mathbf{e}(n) = \mathbf{d}(n) - \Phi(n) \mathbf{w}^*(n). \quad (12.326)$$

Note that (12.325) reduces to NLMS when  $K = 1$ . Similarly to what is done for NLMS, it is convenient to introduce a regularization term  $\varepsilon \mathbf{I}$ , with  $\varepsilon > 0$  and a step-size  $0 < \mu \leq 1$  in (12.325), leading to

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \mu \Phi^T(n) \left( \varepsilon \mathbf{I} + \Phi^*(n) \Phi^T(n) \right)^{-1} \mathbf{e}(n). \quad (12.327)$$

The advantage of this algorithm is that  $\Phi^*(n) \Phi^T(n)$  is  $K \times K$  (as opposed to the  $M \times M$  matrix that must be recursively inverted for RLS), and the value of  $K$  does not need to be large, which keeps the computational cost low. In general, a value of two or three already gives a good improvement to the convergence rate even for regressors whose covariance matrix has large spreading factor.

In order to implement (12.327), it is useful to remember that computing the inverse explicitly is never a good idea: it is much better to solve the linear system

$$\left( \varepsilon \mathbf{I} + \Phi^*(n) \Phi^T(n) \right) \mathbf{a} = \mathbf{e}(n), \quad (12.328)$$

and then compute  $\Phi^T(n) \mathbf{a}$ . From a numerical point of view, the best option would be to use the QR decomposition of  $\Phi(n)$  and avoid forming  $\Phi^*(n) \Phi^T(n)$ , but the computational cost would be larger. When the regressor is a tapped-delay line and  $K$  is large, one can use a fast version of APA, in which the solution of (12.328) is obtained in  $\mathcal{O}(K)$  operations, instead of the usual  $\mathcal{O}(K^3)$  [235–237].

Recent works focusing in the analysis of the APA are [238–241]. The problem of regularization (choice of  $\varepsilon$ ) is considered in [242, 243]. Applications to echo cancellation can be found in [244, 245].

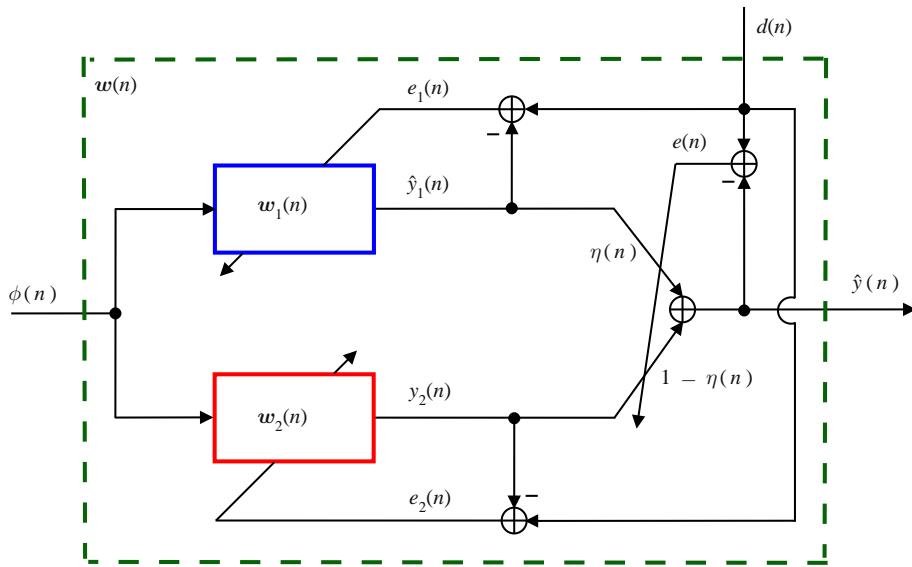

A related approach is the sliding-window RLS algorithm, a version of RLS in which only a finite memory is considered, instead of a forgetting factor as used in Section 1.12.3.3 [246, 247].

### 1.12.5.8 Cooperative estimation

In this section, we briefly describe important advances in adaptive filtering through cooperative estimation. We first describe combinations of adaptive filters and in the sequel, we focus on distributed adaptive filtering.

#### 1.12.5.8.1 Combinations of adaptive filters

Combinations of adaptive filters have received considerable attention lately, since they decrease the sensitivity of the filter to choices of parameters such as the step-size, forgetting factor or filter length. The idea is to combine the outputs of two (or several) different independently-run adaptive algorithms to achieve better performance than that of a single filter. In general, this approach is more robust than variable parameter schemes [190].

**FIGURE 12.39**

Convex combination of two transversal adaptive filters.

The first combined scheme that attracted attention was the convex combination of adaptive filters due to its relative simplicity and the proof that the optimum combination is universal, i.e., the combined estimate is at least as good as the best of the component filters in steady-state, for stationary inputs [248]. This scheme was proposed in [249] and further extended and analyzed in [248, 250]. The original idea was to combine one fast and one slow LMS filter to obtain an overall filter with fast convergence and low misadjustment, but it was extended to other algorithms to take advantages of different characteristics, as explained below.

Figure 12.39 shows the convex combination of two adaptive filters, in which the output of the overall filter is computed as

$$\hat{y}(n) = \eta(n)\hat{y}_1(n) + [1 - \eta(n)]\hat{y}_2(n), \quad (12.329)$$

where  $\eta(n) \in [0, 1]$  is the mixing parameter,  $\hat{y}_i(n) = \mathbf{w}_i^H(n)\phi(n)$ ,  $i = 1, 2$ , are the outputs of the transversal filters,  $\phi(n)$  is the common regressor vector, and  $\mathbf{w}_i(n)$  are the weight vectors of the component filters. Note that the weight vector and the estimation error of the overall filter are given respectively by

$$\mathbf{w}(n) = \eta(n)\mathbf{w}_1(n) + [1 - \eta(n)]\mathbf{w}_2(n) \quad (12.330)$$

and

$$e(n) = d(n) - \hat{y}(n) = \eta(n)e_1(n) + [1 - \eta(n)]e_2(n), \quad (12.331)$$

where  $e_i(n) = d(n) - \hat{y}_i(n)$  are the estimation errors of each component filter.

In order to restrict the mixing parameter to the interval  $[0, 1]$  and to reduce gradient noise when  $\eta(n) \approx 0$  or  $\eta(n) \approx 1$ , a nonlinear transformation and an auxiliary variable  $a(n)$  are used, i.e.,

$$\eta(n) = \text{sgm}[a(n)] \triangleq \frac{1}{1 + e^{-a(n)}}, \quad (12.332)$$

where  $a(n)$  is updated to minimize the overall squared error  $e^2(n)$ , i.e.,

$$a(n+1) = a(n) - \frac{\mu_a}{2} \nabla_a e^2(n) = a(n) + \mu_a [\hat{y}_1(n) - \hat{y}_2(n)] e(n) \eta(n) [1 - \eta(n)]. \quad (12.333)$$

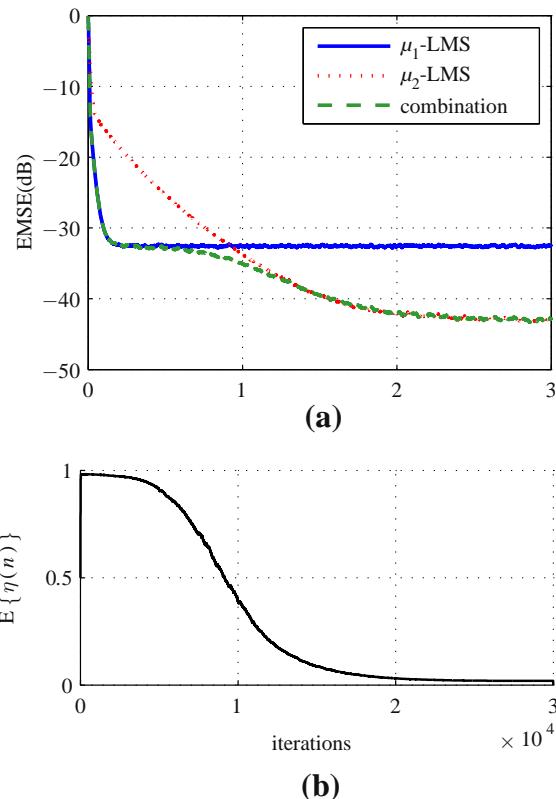

In practice,  $a(n)$  must be restricted by saturation of (12.333) to an interval  $[-a_+, a_+]$ , since the factor  $\eta(n)[1 - \eta(n)]$  would virtually stop adaptation if  $a(n)$  were allowed to grow too much. The correct adjustment of the step-size  $\mu_a$  depends on the input signal and additive noise powers and also on the step-sizes of the component filters. To make the choice of  $\mu_a$  independent of the filtering scenario, a normalized scheme was proposed in [251].

The combination of one fast and one slow LMS (with  $\mu_1 > \mu_2$ ) operates in a very intuitive way. When fast changes appear, the fast filter outperforms the slow one, making  $\eta(n) \approx 1$ . In stationary situations, the slow filter gets a lower quadratic error and  $\eta(n) \approx 0$ , which allows the overall filter to achieve the misadjustment of the slow LMS filter. There are situations in which the combination outperforms each component filter and in these cases,  $0 < \eta(n) < 1$ . This behavior can be observed in the simulation results shown in Figure 12.40, where the convex combination of two LMS filters with different step-sizes ( $\mu_1 = 0.1$  and  $\mu_2 = 0.01$ ) was used to identify the system (from [248])

$$[0.9003 \ -0.5377 \ 0.2137 \ -0.0280 \ 0.7826 \ 0.5242 \ -0.0871].$$

The regressor  $\phi(n)$  is obtained from a process  $x(n)$  generated with a first-order autoregressive model, whose transfer function is  $\sqrt{1 - b^2}/(1 - bz^{-1})$ . This model is fed with an iid Gaussian random process, whose variance is such that  $\text{Tr}(\mathbf{R}_\phi) = 1$ . Moreover, additive iid noise  $v(n)$  with variance  $\sigma_v^2 = 0.01$  is added to form the desired signal. Figure 12.40a shows the EMSE curves estimated from the ensemble-average of 500 independent runs and filtered by a moving-average filter with 128 coefficients to facilitate the visualization. The combined filter acquires the faster convergence of  $\mu_1$ -LMS and attains the EMSE of  $\mu_2$ -LMS. Figure 12.40b shows the time evolution of the mixing parameter. We can observe that it rapidly changes toward  $\text{sgm}[a_+]$  during the initial convergence, while its steady-state value is  $1 - \text{sgm}[a_+]$ .

After the publication of [249], many papers on combinations of adaptive filters appeared in the literature. Apparently, the idea of combining the outputs of several different independently-run adaptive algorithms was first proposed in [252], and later improved in [253, 254]. The algorithms proposed in [252–254] are based on a Bayesian argument, and construct an overall (combined) filter through a linear combination of the outputs of several independent adaptive filters. The weights are the *a posteriori* probabilities that the underlying models used to describe each individual algorithm are “true.” Since the weights add up to one, in a sense these first papers also proposed “convex” combinations of algorithms. Unconstrained linear combinations of adaptive filters were also proposed in [255]. However, the method of [248, 249] has received more attention due to its relative simplicity and the proof that the optimum combination is universal. By this, we mean that if the combination uses at every instant the optimum

**FIGURE 12.40**

(a) EMSE for  $\mu_1$ -LMS,  $\mu_2$ -LMS, and their convex combination; (b) ensemble-average of  $\eta(n)$ ;  $\mu_1 = 0.1$ ,  $\mu_2 = 0.01$ ,  $\mu_a = 100$ ,  $a^+ = 4$ ,  $b = 0.8$ ; mean of 500 independent runs.

value of  $\eta$ , then the combined filter is always at least as good as the best component filter. However, in practice  $\eta$  must also be estimated, so the performance of the combination may be slightly worse than that of the best filter.

In the sequel, we briefly describe some of the most important recent contributions in this area.

In [250], the convergence of the overall filter is greatly improved by transferring a part of the fast filter  $\mathbf{w}_1$  to the slow filter  $\mathbf{w}_2$  when  $\lambda(n) \geq \gamma$ , that is,

$$\mathbf{w}_2(n+1) = \alpha [\mathbf{w}_2(n) + \mu_2 e_2(n) \mathbf{x}(n)] + (1 - \alpha) \mathbf{w}_1(n), \quad (12.334)$$

where  $\alpha$  is a parameter close to 1 and  $\gamma$  is a threshold close to the maximum value that can be reached by  $\lambda(n)$ .

A steady-state analysis of the combined filter was presented in [248]. This analysis shows that the convex combination is universal if the optimum  $\eta$  is used, a property that was exploited to design filters

with improved tracking performance. Due to the nonlinear function (12.332), a transient analysis of the convex combination needs additional simplifications. This issue was addressed in [256] and [257], which provide models for the transient of the convex combination based on first and second-order Taylor series approximations.

The convex combination was used in [258] to improve the performance of a variable tap-length LMS algorithm in a low signal-to-noise environment ( $\text{SNR} \leq 0$  dB). The adaptation of the tap-length in the variable tap-length LMS algorithm is highly affected by the parameter choice and the noise level. Combination approaches improve such adaptation by exploiting advantages of parallel adaptive filters with different parameters.

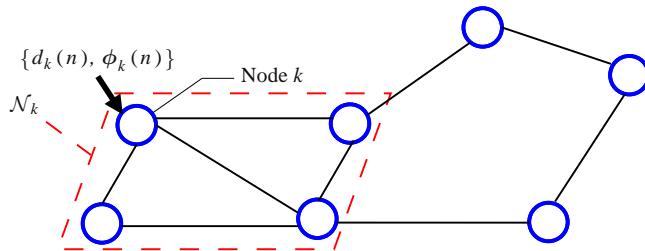

The convex combination was exploited in [190] to improve the tracking performance of adaptive filters by combining filters with different tracking capabilities, as are the cases of LMS and RLS (see Section 1.12.4.4). The combination of algorithms of different families was also addressed in [259], where it was shown that a combination of two filters from the same family (i.e., two LMS or two RLS filters) cannot improve the performance over that of a single filter of the same type with optimal selection of the step-size (or forgetting factor). However, combining LMS and RLS filters, it is possible to simultaneously outperform the optimum LMS and RLS filters. In other words, combination schemes can achieve smaller errors than optimally adjusted individual filters.

Convex combinations were used for sparse echo cancellation in [260], considering the combination of two improved proportionate normalized least-mean-square (IPNLMS) filters. The combined scheme increases the IPNLMS robustness to channels with different degrees of sparsity and also alleviates the tradeoff between rate of convergence versus steady-state misadjustment imposed by the selection of the step-size. Still considering the echo cancellation application, [261] proposes a combination of adaptive Volterra kernels that presents a similar behavior to that of the complete Volterra filters, but with a reduction in the computational load. This scheme is robust regardless of the level of nonlinear distortion, which is a desired property for nonlinear echo cancellation.

In [262], the convex combination was also used as a scheme for adaptively biasing the weights of adaptive filters using an output multiplicative factor. Interpreting the biased estimator as the combination of the original filter and a filter with constant output equal to zero, practical schemes to adaptively adjust the multiplicative factor were proposed. This scheme provides a convenient bias versus variance tradeoff, leading to reductions in the filter mean-square error, especially in situations with a low signal-to-noise ratio.

Extending [248], the authors of [263] proposed an affine combination of two LMS algorithms, where the condition on the mixing parameter is relaxed, allowing it to be negative. Thus, this scheme can be interpreted as a generalization of the convex combination since the mixing parameter is not restricted to the interval  $[0, 1]$ . This approach allows for smaller EMSE in theory, but suffers from larger gradient noise in some situations. Under certain conditions, the optimum mixing parameter was proved to be negative in steady-state. Although the optimal linear combiner is unrealizable, two realizable algorithms were introduced. One is based on a stochastic gradient search and the other is based on the ratio of the average error powers from each individual adaptive filter. Under some circumstances, both algorithms present performance close to the optimum.

Similarly to the convex combination, the correct adjustment of the step-size for the updating of the mixing parameter in the affine combination (using the stochastic algorithm of [263]) depends on characteristics of the filtering scenario. This issue was addressed in [193], where a transient analysis for

**FIGURE 12.41**

Diffusion network with  $N = 7$  nodes: at time  $n$ , every node  $k$  takes a measurement  $\{d_k(n), \phi_k(n)\}$ .

the affine combination of two adaptive filters was presented. The results of this analysis were used to facilitate the adjustment of the free parameters of the scheme and to propose two normalized algorithms to update the mixing parameter. Recently, the scheme based on the ratio of error powers of the two filters proposed in [263] to update the mixing parameter was analyzed in [264].

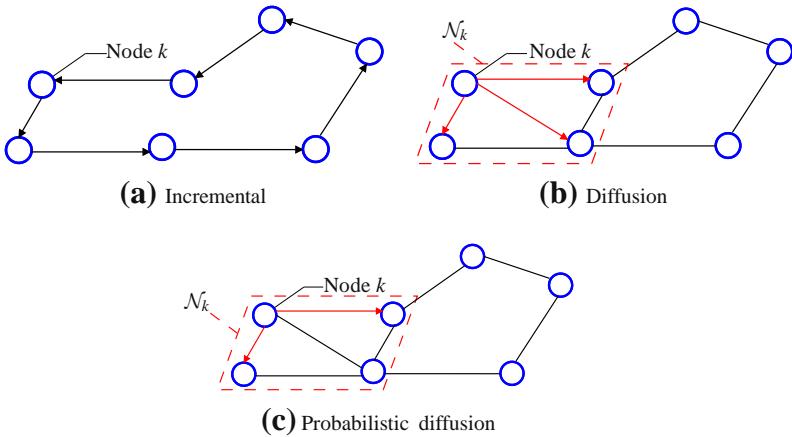

Finally, Kozat et al. [265] studied different mixing strategies in which the overall output is formed as the weighted linear combination (not necessarily constrained to convex or affine, as before) of the outputs of several component algorithms for stationary and certain nonstationary data.

### 1.12.5.8.2 Distributed adaptive filtering

Adaptive networks use the information from data collected at nodes distributed over a certain region. Each node collects noisy observations related to a parameter of interest and interacts with its neighbors considering a certain network topology. The objective is to obtain an estimate of the parameter of interest as accurate as the one that would be obtained if each node had access to the information across the entire network [266, 267]. Distributed estimation algorithms are useful in several contexts, including wireless and sensor networks, where scalability, robustness, and low power consumption are desirable. They also find applications in precision agriculture and environmental monitoring and transportation [268].

Figure 12.41 shows a network composed by  $N$  nodes distributed over some geographical area. At time instant  $n$ , every node  $k$  takes a measurement  $\{d_k(n), \phi_k(n)\}$  to estimate some parameter vector  $\mathbf{w}_o$ . The scalar measurement  $d_k(n)$  represents the desired signal and  $\phi_k(n)$  denotes the length- $M$  input regressor vector for node  $k$ . There are different solutions to the problem of estimating  $\mathbf{w}_o$ . In the *centralized* solution, every node transmits its data  $\{d_k(n), \phi_k(n)\}$  to a fusion center for processing. This solution is non-robust to failure in the fusion center. In *distributed* solutions, every node exchanges information with a subset of its neighboring nodes, and the processing is distributed among all nodes in the network. The set of nodes connected to node  $k$  (including  $k$  itself) is denoted by  $\mathcal{N}_k$  and is called the neighborhood of node  $k$ .

There are three main network topologies used in distributed estimation: incremental, diffusion, and probabilistic diffusion [267]. In incremental networks, the nodes are connected so that information flows sequentially from node to node, in a cyclic manner (Figure 12.42a). In diffusion networks, each node communicates with its entire neighborhood at each instant (Figure 12.42b). Finally, in probabilistic

**FIGURE 12.42**

## Different network topologies.

diffusion networks each node communicates with a (possibly random) subset of its neighbors at each instant (Figure 12.42c).

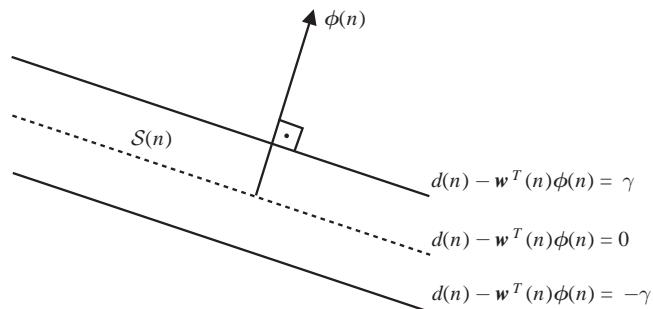

Several estimation algorithms have been proposed in the context of distributed adaptive filtering, such as incremental LMS, incremental RLS, diffusion LMS, diffusion RLS, diffusion Kalman filtering, and smoothing algorithms. In these algorithms, the nodes share information with their neighbors, and perform local adaptation and merging of information using convex combinations of available estimates. Distributed algorithms only require local communications between neighboring nodes, and can attain good estimation performance compared to centralized solutions. This is a current area of intense research [268–280].

Recently, adaptive distributed algorithms have also been used to model biological systems due to their self-organization property. Examples include fish joining together in schools, bacterial motility, and bird flight formations [281–286].

### 1.12.5.9 Adaptive IIR filters

Adaptive infinite impulse response (IIR) filters represent an advantageous alternative in relation to adaptive FIR filters, due to their capacity of providing long impulse responses with a small number of coefficients. Their use may be desirable in applications requiring hundreds or thousands of taps, such as satellite-channel and mobile-radio equalizers. The advantages of adaptive IIR filters have a price: slow convergence, possible instability, error surface with local minima or biased global minimum [1,287–290]. In addition, not all long impulse responses will necessarily be well approximated by an IIR filter with low order.

The nonlinear relation between the adaptive-filter coefficients and the internal signals makes the gradient computation and convergence analysis more complicated than those of adaptive FIR filters [1]. Over the years, problems related to local minima, stability, and the effect of poles close to the unit

**FIGURE 12.43**

Constraint imposed by data at time  $n$ .

circle have been addressed by several authors leading to different adaptive algorithms and realization structures [291–300].

Another difficulty with adaptive IIR filters is that the performance of simple constant-gain algorithms may rapidly degrade as the order of the filter grows. Even in the absence of local minima, the adaptation of filters with order greater than two can remain almost stopped in regions where the mean square error is relatively high. This issue was addressed in [287], which was able to obtain a large acceleration in the convergence rate of IIR filters.

### 1.12.5.10 Set-membership and projections on convex sets

When the desired signal and the regressor are related as

$$d(n) = \mathbf{w}_o^H \boldsymbol{\phi}(n) + v(n),$$

where  $v(n)$  is *bounded*, that is,  $|v(n)| \leq \gamma$  for all  $n$ , it is natural to consider that each pair  $(d(n), \boldsymbol{\phi}(n))$  defines a region in which the true solution  $\mathbf{w}_*$  must lie:

$$\mathbf{w}_o \in \mathcal{S}(n) = \left\{ \mathbf{w} \in \mathcal{C}^M : |d(n) - \mathbf{w}^H \boldsymbol{\phi}(n)| \leq \gamma \right\}. \quad (12.335)$$

For example, if all vectors are two-dimensional and real, the region  $\mathcal{S}(n)$  would be as in Figure 12.43. *Set-membership* algorithms aim to find the set of possible solutions, by tracking the intersection

$$\mathcal{T}(n) = \bigcap_{k=0}^n \mathcal{S}(k) \quad (12.336)$$

of all  $\mathcal{S}(n)$  [301]. In the control literature and earlier algorithms, this is made by approximating  $\mathcal{T}(n)$  by ellipsoids [301–303]. However, very good performance is obtained if one uses just any point contained in  $\mathcal{T}(n)$  as a point estimate of  $\mathbf{w}_o$  at each instant. In fact, it is more interesting to restrict the memory,

so that the filter can track variations of  $\mathbf{w}_o$ . In this case, only the last  $K$  constraint sets  $\mathcal{S}(n)$  are used:

$$\mathcal{T}_K(n) = \bigcap_{k=n-K+1}^n \mathcal{S}(k). \quad (12.337)$$

This approach has a very nice property: close to steady-state, if the weight estimates are already inside  $\mathcal{T}_K(n)$ , it is not necessary to perform any update. This may reduce considerably the average complexity of the filter [304–310].

More recently, the approach has been extended to a more general setting, using projections onto convex sets and subgradients. This allows the extension of the results to non-differentiable cost functions, with different descriptions for the constraints (not restricted to (12.335)), also allowing the design of kernel adaptive filters [6,311–313] (an introduction to kernel adaptive filters can be found in [314]).

### 1.12.5.11 Adaptive filters with constraints

In some applications, one wishes to minimize a cost function given certain constraints: a typical case is beamforming. In the simplest example, an array of antennas or microphones receives a signal coming from a certain (known) direction, and interference from other (unknown) directions. The output of the array is a linear combination of the signals  $\phi_i(n)$  received at each antenna, e.g.,

$$\hat{y}(n) = w_0^* \phi_0(n) + w_1^* \phi_1(n) + \cdots + w_{M-1}^* \phi_{M-1}(n).$$

One way of improving the signal-to-noise ratio at the output is to minimize the output power, under the restriction that the gain of the array in the direction of the desired signal is one. This is described by a constraint of the kind

$$\mathbf{c}^H \mathbf{w} = 1,$$

where  $\mathbf{w} = [w_0 \dots w_{M-1}]$  is the weight vector, and  $\mathbf{c} \in \mathcal{C}^M$  is a vector describing the constraint. The goal of the filter would then be to find the optimum  $\mathbf{w}_o$  that is the solution of

$$\mathbf{w}_o = \arg \min_{\substack{\mathbf{w} \\ \text{s.t. } \mathbf{c}^H \mathbf{w} = 1}} |\hat{y}(n)|^2.$$

This solution is known as *minimum-variance distortionless response* (MVDR), or Capon beamformer, since it was originally proposed in [315]. There is an extensive literature on this subject [312,316–325]. Introductions to the topic can be found in [326–328].

### 1.12.5.12 Reduced-rank adaptive filters

In applications in which large filters are necessary, such as acoustic echo cancellation and nonlinear models using Volterra expansions, it may be useful to reduce the order of the problem, by working in a smaller subspace of the original problem. This reduces the number of parameters to be estimated, increasing the convergence speed and reducing the excess mean-square error [329]. Several methods have been proposed, such as [330,331], based on eigen-decompositions, the multi-stage Wiener filter of [332–334], the auxiliary vector filtering algorithm [335], and the joint iterative optimization method of [336–339]. This last method has the advantage of having low computational cost.

---

## Box 8: [Fixed-point arithmetic]

---

In fixed-point arithmetic, all variables are restricted to lie in a fixed interval  $[-a, a)$ , and are stored as a sequence of  $B$  bits  $b_0 b_1 \dots b_{B-1}$ . Assuming that two's complement arithmetic is used and that  $a = 1$ , then  $b_0$  represents the signal of the variable and the sequence of bits represents the number

$$-b_0 + \sum_{m=1}^{B-1} b_m 2^{-m}.$$

## 1.13.1 Scope and context

Classically, within the signal processing community, linear parametric models have been a method of first choice in several applications. Historically, many computationally efficient algorithms have been developed for on-line and adaptive signal processing with e.g., LMS, recursive least squares and Kalman filtering type algorithms [1]. However, more recently considerable progress has been made also on the use of flexible nonlinear models, e.g., related to kernel methods, support vector machines [2–10] and probabilistic models [11–16], and the importance of regularization techniques has been realized both in the context of parametric models and non-parametric models. This is witnessed also by the progress in the area of compressed sensing and sparse models [17–22]. Moreover, many emerging applications in e.g., big data, networks applications, bioinformatics, brain-machine interfaces, are posing new challenges for predictive models towards handling large amounts of data in high dimensional input spaces. In this Machine Learning Section we therefore take a broad view on the subject of signal processing and machine learning in connection also to other related areas as pattern recognition and neural networks [23–25], mathematics and statistics [3,26,27], optimization [28,29], and information theory [30] (Figure 13.1).

In general one distinguishes between different types of learning models, such as supervised, unsupervised and semi-supervised learning [9,31,32], various tasks such as e.g., classification, regression, clustering and different types of models, including e.g., linear and nonlinear parametric models, kernel-based models, and probabilistic models (Figure 13.2). For many of the successful methods it is interesting to trace back to the original roots. For on-line learning of linear models in classification problems, the perceptron has originally served as a paradigm. However, soon one has encountered its limitations. In the neural networks area this led to introducing one or more hidden layers with multilayer perceptron neural networks. Backpropagation as the original learning algorithm for such feedforward networks, in its on-line learning form, could be interpreted as an extension of the LMS algorithm as used in adaptive signal processing [33]. On a different track, the perceptron has also been studied within the context of statistical learning theory [9,34,35]. Here one is interested in characterizing the generalization error of the model, which is typically expressed in terms of the error on the training data and a complexity term.

Multilayer perceptrons are universal approximators [36] which make them powerful tools to parameterize nonlinear functions. In order to overcome the problem of overfitting with flexible nonlinear models, an important technique to use is regularization [15,23]. In the objective function one not only

**FIGURE 13.1**

Signal processing and machine learning and several related areas.

minimizes then the error on the training data but one also keeps the estimated parameter values small. This leads to the notion of effective number of parameters which is relevant then to characterize the model complexity, instead of the number of parameters. The flexibility of the model is controlled by the regularization term. In a Bayesian inference and probabilistic modeling picture the regularization term corresponds then to the prior distribution on the unknown parameters. Classical regularization schemes minimize the  $\ell_2$  norm on the unknown parameters, which is known as ridge regression in statistics

Learning modes	Tasks	Models
supervised learning	regression	linear parametric
unsupervised learning	classification	non-linear parametric
semi-supervised learning	clustering	polynomial model
reinforcement learning	density estimation	multilayer perceptron
inductive learning	component analysis	radial basis function network
transductive learning	dimensionality reduction	splines
ensemble learning	data visualization	kernel-based model
transfer learning	manifold learning	support vector machines
	structure/feature selection	graphical models
	multi-task learning	probabilistic models
	dynamical systems modelling	
	time-series analysis	mixture models

**FIGURE 13.2**

Learning modes, learning tasks and examples of different possible models.

and dates back also to ill-posed problems and Tikhonov regularization [37]. In recent years there has been considerable interest in alternative regularization schemes based on  $\ell_0$ ,  $\ell_1$ , and  $\ell_p$  regularization to achieve sparsity in the solution vector (Figure 13.3), in connection also to compressed sensing [17–20,22].

Regularization also plays an important role in non-parametric and kernel-based models. The use of positive definite kernels and reproducing kernels dates back to the early work of Mercer [38], Moore [39], Aronszajn [40] and are key ingredients within methods of function estimation in reproducing kernel Hilbert spaces, the theory of splines and radial basis function networks [10,41]. Early use of reproducing kernel Hilbert spaces in signal processing is e.g., [42–44]. In Gaussian processes the kernel function relates to the correlation function [14,16]. An increasing and renewed interest in kernel-based methods appeared with the introduction of nonlinear support vector machines for classification and regression [9]. The use of a positive definite kernel is viewed here in connection to a feature map (often called the kernel trick, which relates to the Mercer theorem), where in the primal a constrained optimization problem formulation is given on the model that is expressed in terms of the feature map. The Lagrange dual problem results then into a kernel-based model representation. In standard support

Regularization	
Parametric	Kernel-based
$\ell_2$ , ridge regression	RKHS function estimation
$\ell_1$ , LASSO	splines
$\ell_p$ ( $0 < p \leq 1$ )	regularization networks
group LASSO	Gaussian processes
elastic net	support vector machines
spectral regularization	LS-SVMs
nuclear norm	

**FIGURE 13.3**

Regularization and its role in parametric and non-parametric modeling approaches.

vector machines a sparse kernel-based model is then achieved through the choice of the loss function, typically the hinge loss in classification and the epsilon-insensitive loss function in function estimation.

The kernel trick on its own has also been frequently employed to obtain nonlinear kernel versions of classically known linear estimation schemes, e.g., kernel principal component analysis [45] as an extension to the classical linear principal component analysis [46]. Special kernel functions have also been designed to handle specific data types or in specific applications area such as e.g., text mining or bioinformatics [5,6,47]. It is also possible to relate kernel functions to probabilistic graphical models and graphs. In least squares support vector machines one works with simple core models within the primal-dual setting for a wide range of problems in supervised and unsupervised learning and beyond [8,48]. The primal representation relates then to parametric picture, while the dual representation to a non-parametric. Depending on the nature of the given problem (large number of data versus dimensionality of the input space) this choice in representation can be exploited for developing efficient large scale algorithms [8,48].

An advantage of support vector machines for classification and regression is that the problem is recasted as a convex optimization problem, up to a small amount of tuning parameters of regularization constant(s) and kernel parameter(s). This has been viewed as a considerable advantage over other

nonlinear models such as multilayer perceptrons which suffer from the existence of many local minima solutions. Also towards sparse models and compressed sensing, convex optimization is playing an important role [29] (Figure 13.3). In many emerging applications one often has to cope with large amounts of data in often high-dimensional input spaces. This is posing new challenges for scalable optimization algorithms. In this direction efficient first order methods, on-line optimization, stochastic optimization or distributed optimization are suitable possible algorithms [49,50].

In the next section a brief overview is given on the chapter contributions that present introductory and tutorial contributions related to Signal Processing and Machine Learning.

### 1.13.2 Contributions

In [51] the authors present an overview of learning theory including statistical and computational aspects, with emphasis on classification and regression problems. Empirical risk minimization is discussed and concepts for characterizing the generalization performance of the model such as Rademacher complexity, covering numbers, Vapnik-Chervonenkis and fat shattering dimension. In connection to this, the problem of model selection is addressed.

In [52] an overview is presented on different types of neural networks for supervised and unsupervised learning. Starting from the perceptron, feedforward networks and backpropagation is explained. Next recurrent neural networks and recursive structure processing are discussed. Neural architectures for principal component analysis and topographic mapping for data mining and data visualization is outlined.

In [53] the authors give an introduction to the foundations and implementations of kernel methods, computational issues and recent developments. This includes the kernel trick, properties and types of kernels, kernel principal component analysis, kernel canonical correlation analysis, kernel Fisher discriminant analysis, support vector machines for classification and regression, and Gaussian processes.

In [54] on-line learning in reproducing kernel Hilbert spaces is presented. First parameter estimation is discussed in regression and classification tasks and how to overcome overfitting by applying regularization. It is explained how a nonlinear task can be mapped to a linear task. In this way kernel LMS and complex kernel LMS are extended to kernel versions of the well-known LMS algorithm in signal processing. For least squares learning algorithms extensions to kernel recursive least squares are discussed. Finally, convex analysis concepts for online learning are provided.

In [55] an introduction to probabilistic graphical models is given. It includes three representations of probabilistic graphical models: Markov networks (or undirected graphical models), Bayesian networks (or directed graphical models) and factor graphs. An overview about structure and parameter learning techniques is given on maximum likelihood and Bayesian learning, and generative and discriminative learning. Exact inference methods and approximate inference techniques are addressed. Applications for each of the three representations are given: Bayesian networks for expert systems, dynamic Bayesian networks for speech processing, Markov random fields for image processing, and factor graphs for decoding error-correcting codes.

In [56] a tutorial introduction to Monte Carlo Methods, Markov Chain Monte Carlo and Particle Filtering is given. Starting from the Monte Carlo principle and basic techniques for simulating and transforming random variables, Markov Chain Monte Carlo is explained. Other topics that are addressed are

rejection sampling, detailed balance, the Gibbs sampler, sequential Monte Carlo, importance sampling, resampling, and advanced Monte Carlo methods.

In [57] an introduction to clustering is given. Different clustering algorithms are discussed including hierarchical clustering, the K-means algorithm, fuzzy C-means algorithm, mixture density-based clustering, neural network-based clustering based on adaptive resonance theory, spectral clustering, subspace clustering and biclustering, and deep learning clustering.

In [58] unsupervised learning algorithms and latent variable models are presented. Basic linear and multilinear models for matrix and tensor factorizations and decompositions are discussed. Constrained matrix and tensor decompositions for sparse representation of data and their extensions are addressed. Various constraints such as orthogonality, statistical independence, nonnegativity, and/or sparsity are explained. The importance of matrix/tensor decompositions is given for blind source separation, dimensionality reduction, pattern recognition, object detection, classification, multiway clustering, sparse representation and coding, and data fusion.

In [59] an introduction is presented on semi-supervised learning. Discussed topics include transductive support vector machine and low density separation, co-training and multi-view, co-regularization and expectation-maximization for mixture models. Finally graph-based semi-supervised learning is addressed with graph Laplacian regularization, manifold regularization, measure-based regularization, and semi-supervised learning for structured outputs.

In [60] an overview is given on sparsity-aware learning and compressed sensing. The Least Absolute Shrinkage and Selection Operator (LASSO), sparse signal representation,  $\ell_2$ ,  $\ell_0$ ,  $\ell_1$  norm minimizers and their geometric interpretation are discussed. In view of conditions for equivalence of the  $\ell_0$  and  $\ell_1$  minimizer, mutual coherence and the Restricted Isometry Property (RIP) is explained. Robust sparse signal recovery from noisy measurements and compressed sensing is covered. Sparsity-promoting algorithms are discussed like Orthogonal Matching Pursuit, the Least Angle Regression (LARS) algorithm and Iterative Shrinkage Algorithms. A case study on time-frequency analysis is provided.

In [61] the authors present information based learning approaches. Starting from information theoretic descriptors as entropy, divergence and mutual information, a unifying information theoretic framework for machine learning is outlined. Filtering, classification, feature extraction and nonparametric information estimators are discussed. Next a reproducing kernel Hilbert space framework for information based learning is proposed. Illustrative examples are given on adaptive system training, classification, information cut for clustering, and independent component analysis.

In [62] model selection aspects are discussed. The Akaike information criterion and the Kullback information criterion are explained with linear regression as an example application. Then consistency and efficiency are addressed. Other topics that are included are Bayesian approaches to model selection, the Bayesian information criterion, Markov-Chain Monte-Carlo Bayesian methods, model selection by compression, minimum message length, model selection consistency, parameter estimation consistency, and sequential variants of minimum description length.

In [63] an overview is given on music mining. Topics that are addressed include ground truth acquisition and evaluation, audio feature extraction, extracting context information about music, content-based similarity retrieval, genre classification, emotion/mood classification, music clustering, automatic tag annotation, audio fingerprinting, and cover song detection.

## 1.14.1 Introduction

In a section on *Learning Machines* in one of his most famous papers [1], Turing wrote:

*Instead of trying to produce a programme to simulate the adult mind, why not rather try to produce one which simulates the child's? If this were then subjected to an appropriate course of education one would obtain the adult brain. Presumably the child brain is something like a notebook as one buys it from the stationer's. Rather little mechanism, and lots of blank sheets. (Mechanism and writing are from our point of view almost synonymous.) Our hope is that there is so little mechanism in the child brain that something like it can be easily programmed. The amount of work in the education we can assume, as a first approximation, to be much the same as for the human child.*

The year was 1950. Earlier, in 1943, McCulloch and Pitts [2] had already hit upon the idea that mind-like machines could be built by studying how biological nerve cells behave. This directly lead to neural networks. By the late 1950s, Samuels [3] had programmed a machine to play checkers and Rosenblatt [4] had proposed one of earliest models of a learning machine, the perceptron. The importance of the perceptron in the history of learning theory cannot be overemphasized. Vapnik says that the appearance of the perceptron was “when the mathematical analysis of learning processes truly began.” Novikoff’s perceptron theorem (we will prove it in Section 1.14.6.5.2) was also proved in 1962 [5].

Vapnik [6] points out the interesting fact that the 1960s saw four major developments that were to have lasting influence on learning theory. First, Tikhonov and other developed regularization theory for the solution of ill posed inverse problems. Regularization theory has had and continues to have tremendous impact on learning theory. Second, Rosenblatt, Parzen, and Chentsov pioneered nonparametric methods for density estimation. These beginnings were crucial for a distribution free theory of non-parametric classification and regression to emerge later. Third, Vapnik and Chervonenkis proved the uniform law of large numbers for indicators of sets. Fourth, Solomonoff, Kolmogorov, and Chaitin all independently discovered algorithmic complexity: the idea that the complexity of a string of 0's and 1's can be defined by the length of the shortest program that can generate that string. This later led Rissanen to propose his Minimum Description Length (MDL) principle.

In 1986, a major technique to learn weights in neural networks was discovered: backpropagation [7]. Around the same time, Valiant [8] published his paper introducing a computational model of learning that was to be called the PAC (probably approximately correct) model later. The 1990s saw the appearance of support vector machines [9] and AdaBoost [10]. This brings us to the brink of the second millennium which is where we end our short history tour.

As we can see, learning theory has absorbed influences from a variety of sources: cybernetics, neuroscience, nonparametric statistics, regularization theory of inverse problems, and the theory of computation and algorithms. Ongoing research is not only trying to overcome known limitations of classic models but is also grappling with new issues such as dealing with privacy and web-scale data.

Learning theory is a formal mathematical theory. Assumptions are made, beautiful lemmas are proved, and deep theorems are discovered. But developments in learning theory also lead to practical algorithms. SVMs and AdaBoost are prime examples of high impact learning algorithms evolving out of a principled and well-founded approach to learning. We remain hopeful that learning theory will help us discover even more exciting learning algorithms in the future.

Finally, a word about the mathematical background needed to read this overview of learning theory. Previous exposure to mathematical reasoning and proofs is a must. So is familiarity with probability theory. But measure theory is not needed as we will avoid all measure-theoretic details. It will also be helpful, but not essential, to be aware of the basics of computational complexity such as the notion of polynomial time computation and NP-completeness. Similarly, knowing a little bit of functional analysis will help.

### 1.14.2 Probabilistic formulation of learning problems

A basic problem in learning theory is that of learning a functional dependence  $f : \mathcal{X} \rightarrow \mathcal{Y}$  from some *input space*  $\mathcal{X}$  to some *output* or *label* space  $\mathcal{Y}$ . Some special choices for the output space deserve particular attention since they arise often in applications. In *multiclass classification*, we have  $\mathcal{Y} = \{1, \dots, K\}$  and the goal is to classify any input  $x \in \mathcal{X}$  into one of  $K$  given classes. A special case of this problem is when  $K = 2$ . Then, the problem is called *binary classification* and it is mathematically convenient to think of the output space as  $\mathcal{Y} = \{-1, +1\}$  rather than  $\mathcal{Y} = \{0, 1\}$ . In *regression*, the output space  $\mathcal{Y}$  is some subset of the set  $\mathbb{R}$  of real numbers. Usually  $\mathcal{Y}$  is assumed to be a bounded interval, say  $[-1, +1]$ .

We assume that there is an underlying distribution  $P$  over  $\mathcal{X} \times \mathcal{Y}$  and that the learner has access to  $n$  samples

$$(X_1, Y_1), \dots, (X_n, Y_n),$$

where the  $(X_i, Y_i)$  are independent and identically distributed (or *iid*) random variables with the same distribution  $P$ . Note that  $P$  itself is assumed to be unknown to the learner. A *learning rule* or *learning algorithm*  $\hat{f}_n$  is simply a mapping

$$\hat{f}_n : (\mathcal{X} \times \mathcal{Y})^n \times \mathcal{X} \rightarrow \mathcal{Y}.$$

That is, a learning rule maps the  $n$  samples to a function from  $\mathcal{X}$  to  $\mathcal{Y}$ . When the sample is clear from context, we will denote the function returned by a learning rule itself by  $\hat{f}_n$ .

### 1.14.2.1 Loss function and risk

In order to measure the predictive performance of a function  $f : \mathcal{X} \rightarrow \mathcal{Y}$ , we use a *loss function*. A loss function  $\ell : \mathcal{Y} \times \mathcal{Y} \rightarrow \mathbb{R}_+$  is a non-negative function that quantifies how bad the prediction  $f(x)$  is if the true label is  $y$ . We say that  $\ell(f(x), y)$  is the loss incurred by  $f$  on the pair  $(x, y)$ . In the classification case, binary or otherwise, a natural loss function is the 0–1 loss:

$$\ell(y', y) = \mathbf{1}[y' \neq y].$$

The 0–1 loss function, as the name suggests, is 1 if a misclassification happens and is 0 otherwise. For regression problems, some natural choices for the loss function are the *squared loss*:

$$\ell(y', y) = (y' - y)^2,$$

or the *absolute loss*:

$$\ell(y', y) = |y' - y|.$$

Given a loss function, we can define the *risk* of a function  $f : \mathcal{X} \rightarrow \mathcal{Y}$  as its expected loss under the true underlying distribution:

$$R(f) = \mathbb{E}_{(X, Y) \sim P}[\ell(f(X), Y)].$$

Note that the risk of any function  $f$  is not directly accessible to the learner who only sees the samples. But the samples can be used to calculate the *empirical risk* of  $f$ :

$$\widehat{R}(f) = \frac{1}{n} \sum_{i=1}^n [\ell(f(X_i), Y_i)].$$

Minimizing the empirical risk over a fixed class  $\mathcal{F} \subseteq \mathcal{Y}^{\mathcal{X}}$  of functions leads to a very important learning rule, namely *empirical risk minimization* (ERM):

$$\hat{f}_n = \operatorname{argmin}_{f \in \mathcal{F}} \widehat{R}(f).$$

Under appropriate conditions on  $\mathcal{X}$ ,  $\mathcal{Y}$ , and  $\mathcal{F}$ , an empirical risk minimizer is guaranteed to exist though it will not be unique in general. If we knew the distribution  $P$  then the best function from  $\mathcal{F}$  would be

$$f_{\mathcal{F}}^* = \operatorname{argmin}_{f \in \mathcal{F}} R(f),$$

as  $f_{\mathcal{F}}^*$  minimizes the expected loss on a random  $(X, Y)$  pair drawn from  $P$ . Without restricting ourselves to the class  $\mathcal{F}$ , the best possible function to use is

$$f^* = \operatorname{argmin}_f R(f),$$

where the infimum is with respect to all<sup>1</sup> functions.

---

<sup>1</sup>We should say “all measurable functions” here. We will, however, ignore measurability issues in this overview article.

For classification with 0–1 loss,  $f^*$  is called the *Bayes classifier* and is given simply by

$$f^*(x) = \operatorname{argmax}_{y \in \mathcal{Y}} P(Y = y | X = x).$$

Note that  $f^*$  depends on the underlying distribution  $P$ . If we knew  $P$ , we could achieve minimum misclassification probability by always predicting, for a given  $x$ , the label  $y$  with the highest conditional probability (ties can be broken arbitrarily). The following result bounds the *excess risk*  $R(f) - R(f^*)$  of any function  $f$  in the binary classification case.

**Theorem 1.** *For binary classification with 0–1 loss, we have*

$$R(f) - R(f^*) = \mathbb{E}[\mathbf{1}[f(X) \neq f^*(X)]|2\eta(X) - 1|],$$

where  $\eta(x) = P(Y = +1 | X = x)$ .

For the regression case with squared loss,  $f^*$  is called the *regression function* and is given simply by the conditional expectation of the label given  $x$ :

$$f^*(x) = \mathbb{E}[Y | X = x].$$

In this case, the excess risk takes a particularly nice form.

**Theorem 2.** *For regression with squared loss, we have*

$$R(f) - R(f^*) = \mathbb{E}[|f(X) - f^*(X)|^2].$$

### 1.14.2.2 Universal consistency

A particularly nice property for a learning rule  $\hat{f}_n$  to have is that its (expected) excess risk converges to zero as the sample size  $n$  goes to infinity. That is,

$$\mathbb{E}[R(\hat{f}_n)] - R(f^*) \rightarrow 0.$$

Note  $R(\hat{f}_n)$  is a random variable since  $\hat{f}_n$  depends on a randomly drawn sample. A rule  $\hat{f}_n$  is said to be *universally consistent* if the above convergence holds irrespective of the true underlying distribution  $P$ . This notion of consistency is also sometimes called *weak universal consistency* in order to distinguish it from *strong universal consistency* that demands

$$R(\hat{f}_n) - R(f^*) \rightarrow 0$$

with probability 1.

The existence of universally consistent learning rules for classification and regression is a highly non-trivial fact which has been known since Stone's work in the 1970s [11]. Proving universal consistency typically requires addressing the *estimation error* versus *approximation error* trade-off. For instance, often the function  $\hat{f}_n$  is guaranteed to lie in a function class  $\mathcal{F}_n$  that does not depend on the sample. The classes  $\mathcal{F}_n$  typically grow with  $n$ . Then we can decompose the excess risk of  $\hat{f}_n$  as

$$R(\hat{f}_n) - R(f^*) = \underbrace{R(\hat{f}_n) - R(f_{\mathcal{F}_n}^*)}_{\text{estimation error}} + \underbrace{R(f_{\mathcal{F}_n}^*) - R(f^*)}_{\text{approximation error}}.$$

This decomposition is useful as the estimation error is the only random part. The approximation error depends on how rich the function class  $\mathcal{F}_n$  is but does not depend on the sample. The reason we have to trade these two errors off is that the richer the function class  $\mathcal{F}_n$ , the smaller the approximation error will be. However, that leads to a large estimation error. This trade-off is also known as the *bias-variance trade-off*. The bias-variance terminology comes from the regression with squared error case but tends to be used in the general loss setting as well.

### 1.14.2.3 Learnability with respect to a fixed class

Unlike universal consistency, which requires convergence to the minimum possible risk over all functions, learnability with respect to a fixed function class  $\mathcal{F}$  only demands that

$$\mathbb{E}[R(\hat{f}_n)] - R(f_{\mathcal{F}}^*) \rightarrow 0.$$

We can additionally require quantitative bounds on the number of samples needed to reach, with high probability, a given upper bound on excess risk relative to  $f_{\mathcal{F}}^*$ . The *sample complexity* of a learning rule  $\hat{f}_n$  is the minimum number  $n_0(\varepsilon, \delta)$  such that for all  $n \geq n_0(\varepsilon, \delta)$ , we have

$$R(\hat{f}_n) - R(f_{\mathcal{F}}^*) \leq \varepsilon$$

with probability at least  $1 - \delta$ . We now see how we can arrive at sample complexity bounds for ERM via *uniform convergence* of empirical means to true expectations.

We mention some examples of functions classes that arise often in practice.

*Linear Functions:* This is one of the simplest functions classes. In any finite dimensional Euclidean space  $\mathbb{R}^d$ , define the class of real valued functions

$$\mathcal{F} = \{x \mapsto \langle w, x \rangle : w \in \mathcal{W} \subseteq \mathbb{R}^d\},$$

where  $\langle w, x \rangle = \sum_{j=1}^d w_j x_j$  denotes the standard *inner product*. The *weight vector* might be additionally constrained. For instance, we may require  $\|w\| \leq W$  for some norm  $\|\cdot\|$ . The set  $\mathcal{W}$  takes care of such constraints.

*Linear Threshold Functions or Halfspaces:* This is class of binary valued function obtained by thresholding linear functions at zero. This gives us the class

$$\mathcal{F} = \{x \mapsto \text{sign}(\langle w, x \rangle) : w \in \mathcal{W} \subseteq \mathbb{R}^d\}.$$

*Reproducing Kernel Hilbert Spaces:* Linear functions can be quite restricted in their approximation ability. However, we can get a significant improvement by first mapping the inputs  $x \in \mathcal{X}$  into a feature space through a *feature mapping*  $\Phi : \mathcal{X} \rightarrow \mathcal{H}$  where  $\mathcal{H}$  is a very high dimensional Euclidean space (or an infinite dimensional *Hilbert space*) and then considering linear functions in the feature space:

$$\mathcal{F} = \{x \mapsto \langle w, \Phi(x) \rangle_{\mathcal{H}} : w \in \mathcal{W}\},$$

where the inner product now carries the subscript  $\mathcal{H}$  to emphasize the space where it operates. Many algorithms access the inputs only through pairwise inner products

$$\langle \Phi(x_i), \Phi(x_j) \rangle_{\mathcal{H}}.$$

In such cases, we do not care what the feature mapping is or how complicated it is to evaluate, provided we can compute these inner products efficiently.

This idea of using only inner products leads us to reproducing kernel Hilbert space. We say that a function  $K : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$  is symmetric positive semidefinite (psd) if it satisfies the following two properties.

*Symmetry:* For any  $x, x' \in \mathcal{X}$ , we have  $K(x, x') = K(x', x)$ .

*Positive Semidefiniteness:* For any  $(x_1, \dots, x_n) \in \mathcal{X}^n$ , the symmetric matrix

$$\mathbf{K} = (K(x_i, x_j))_{i,j} \in \mathbb{R}^{n \times n}$$

is psd.<sup>2</sup> The matrix  $\mathbf{K}$  is often called the *Gram matrix*.

Note that, given a feature mapping  $\Phi$ , it is trivial to verify that

$$K(x, x') = \langle \Phi(x), \Phi(x') \rangle_{\mathcal{H}}$$

is a symmetric psd function. However, the much less trivial converse is also true. Every symmetric psd function arises out of a feature mapping. This is a consequence of the *Moore-Aronszajn theorem*. To state the theorem, we first need a definition. A *reproducing kernel Hilbert space or RKHS*  $\mathcal{H}$  is a Hilbert space of functions  $f : \mathcal{X} \rightarrow \mathbb{R}$  such that there exists a kernel  $K : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$  satisfying the properties:

- For any  $x \in \mathcal{X}$ , the function  $K_x = K(x, \cdot)$  is in  $\mathcal{H}$ .
- For any  $x \in \mathcal{X}$ ,  $f \in \mathcal{H}$ , the *reproducing property* holds:  $f(x) = \langle f, K_x \rangle_{\mathcal{H}}$ .

**Theorem 3 (Moore-Aronszajn).** *Given a symmetric psd function  $K : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$ , there is a unique RKHS  $\mathcal{H}$  with reproducing kernel  $K$ .*

This theorem gives us the feature mapping easily. Starting from a symmetric psd function  $K$ , we use the Moore-Aronszajn theorem to get an RKHS  $\mathcal{H}$  whose reproducing kernel is  $K$ . Now, by the reproducing property, for any  $x, x' \in \mathcal{X}$ ,

$$K(x, x') = K_x(x') = \langle K_x, K_{x'} \rangle_{\mathcal{H}}$$

which means that  $\Phi : \mathcal{X} \mapsto \mathcal{H}$  given by  $\Phi(x) = K_x$  is a feature mapping we were looking for. Given this equivalence between symmetric psd functions and RKHSes, we will use the word *kernel* for a symmetric psd function itself.

*Convex Hulls:* This example is not about a function class but rather about a means of obtaining a new function class from an old one. Say, we have class  $\mathcal{F}$  of binary valued functions  $f : \mathcal{X} \rightarrow \{\pm 1\}$ . We can consider functions that take a *majority vote* over a subset of functions in  $\mathcal{F}$ . That is,

$$f'(x) = \text{sign} \left( \sum_{\ell=1}^L f_{\ell} \right), \quad f_{\ell} \in \mathcal{F}.$$

---

<sup>2</sup>Recall that a symmetric matrix  $\mathbf{K} \in \mathbb{R}^{n \times n}$  is psd iff for all  $u \in \mathbb{R}^n$ ,  $\langle u, \mathbf{K}u \rangle \geq 0$ .

More generally, we can assign weights  $w_\ell \geq 0$  to  $f_\ell$  and consider a weighted majority

$$f'(x) = \text{sign} \left( \sum_{\ell=1}^L w_\ell f_\ell \right).$$

Constraining the weights to sum to no more than  $W$  gives us the scaled convex hull

$$W \cdot \text{conv}(\mathcal{F} \cup \{0\}) = \left\{ \sum_{\ell=1}^L w_\ell f_\ell : L \in \mathbb{N}, w_\ell \geq 0, \sum_\ell w_\ell \leq W \right\}.$$

The class above can, of course, be thresholded to produce binary valued functions.

#### 1.14.2.4 ERM and uniform convergence

The excess risk of ERM relative to  $f_{\mathcal{F}}^*$  can be decomposed as

$$R(\hat{f}_n) - R(f_{\mathcal{F}}^*) = (R(\hat{f}_n) - \hat{R}(\hat{f}_n)) + (\hat{R}(\hat{f}_n) - \hat{R}(f_{\mathcal{F}}^*)) + (\hat{R}(f_{\mathcal{F}}^*) - R(f_{\mathcal{F}}^*)).$$

By the definition of ERM, the difference  $\hat{R}(\hat{f}_n) - \hat{R}(f_{\mathcal{F}}^*)$  is non-positive. The difference  $\hat{R}(f_{\mathcal{F}}^*) - R(f_{\mathcal{F}}^*)$  is also easy to deal with since it deals with a fixed (i.e. non-random) function  $f_{\mathcal{F}}^*$ . Using Hoeffding's inequality (see Section 1.14.3.1), we have, with probability at least  $1 - \delta$ ,

$$\hat{R}(f_{\mathcal{F}}^*) - R(f_{\mathcal{F}}^*) \leq \sqrt{\frac{\log(1/\delta)}{2n}}.$$

This simply reflects the fact that as the sample size  $n$  grows, we expect the empirical average of  $f_{\mathcal{F}}^*$  to converge to its true expectation.

The matter with the difference  $R(\hat{f}_n) - \hat{R}(\hat{f}_n)$  is not so simple since  $\hat{f}_n$  is a random function. But we do know  $\hat{f}_n$  lies in  $\mathcal{F}$ . So we can clearly bound

$$R(\hat{f}_n) - \hat{R}(\hat{f}_n) \leq \sup_{f \in \mathcal{F}} (R(f) - \hat{R}(f)). \quad (14.1)$$

This provides a *generalization bound* (or, more properly, a *generalization error bound*) for ERM. A generalization bound is an upper bound on the true expectation  $R(\hat{f}_n)$  of a learning rule in terms of its empirical performance  $\hat{R}(\hat{f}_n)$  (or some other performance measure computed from data). A generalization bound typically involves additional terms that measure the statistical complexity of the class of functions that the learning rule uses. Note the important fact that the bound above is valid not just for ERM but for any learning rule that outputs a function  $\hat{f}_n \in \mathcal{F}$ .

The measure of complexity in the bound (14.1) above is the maximum deviation between true expectation and empirical average over functions in  $\mathcal{F}$ . For each *fixed*  $f \in \mathcal{F}$ , we clearly have

$$R(f) - \hat{R}(f) \rightarrow 0$$

both in probability (weak law of large numbers) and almost surely (strong law of large numbers). But in order for

$$\sup_{f \in \mathcal{F}} R(f) - \hat{R}(f) \rightarrow 0$$

the law of large numbers has to hold *uniformly* over the function class  $\mathcal{F}$ .

To summarize, we have shown in this section that, with probability at least  $1 - \delta$ ,

$$R(\hat{f}_n) - R(f_{\mathcal{F}}^*) \leq \sup_{f \in \mathcal{F}} (R(f) - \hat{R}(f)) + \sqrt{\frac{\log(1/\delta)}{2n}}. \quad (14.2)$$

Thus, we can bound the excess risk of ERM if we can prove uniform convergence of empirical means to true expectations for the function class  $\mathcal{F}$ . This excess risk bound, unlike the generalization error bound (14.1), is applicable only to ERM.

### 1.14.2.5 Bibliographic note

There are several book length treatments of learning theory that emphasize different aspects of the subject. The reader may wish to consult Anthony and Biggs [12], Anthony and Bartlett [13], Devroye et al. [14], Vapnik [15], Vapnik [6], Vapnik [16], Vidyasagar [17], Natarajan [18], Cucker and Zhou [19], Kearns and Vazirani [20], Cesa-Bianchi and Lugosi [21], Györfi et al. [22], and Hastie et al. [23].

## 1.14.3 Uniform convergence of empirical means

Let us consider the simplest case of a finite function class  $\mathcal{F}$ . In this case, Hoeffding's inequality (see Theorem 5) gives us for any  $f \in F$ , with probability at least  $1 - \delta/|\mathcal{F}|$ ,

$$R(f) - \hat{R}(f) \leq c \sqrt{\frac{\log(|\mathcal{F}|/\delta)}{n}}.$$

Therefore, denoting the event that the above inequality fails to hold for function  $f$  by  $A_f$ , we have

$$P(\exists f \in \mathcal{F}, A_f \text{ holds}) \leq \sum_{f \in \mathcal{F}} P(A_f) \leq |\mathcal{F}| \cdot \frac{\delta}{|\mathcal{F}|} = \delta.$$

The first inequality is called a *union bound* in probability theory. It is exact if and only if all the events it is applied to are pairwise disjoint, i.e.,  $A_f \cap A_{f'} = \emptyset$  for  $f \neq f'$ . Clearly, if there are functions that are “similar” to each other, the bound above will be loose. Nevertheless, the union bound is an important starting point for the analysis of uniform convergence of empirical means and for a finite class, it gives us the following result.

**Theorem 4.** *Consider a finite class  $\mathcal{F}$  and a loss function bounded by 1. Then, we have, with probability at least  $1 - \delta$ ,*

$$\sup_f (R(f) - \hat{R}(f)) \leq \sqrt{\frac{\log |\mathcal{F}| + \log(1/\delta)}{2n}}.$$

Therefore, using (14.2), we have the following result for ERM. With probability at least  $1 - 2\delta$ ,

$$R(\hat{f}_n) - R(f_{\mathcal{F}}^*) \leq \sqrt{\frac{\log |\mathcal{F}|}{2n}} + \sqrt{\frac{2 \log(1/\delta)}{n}}.$$

It is instructive to focus on the first term on the right hand side. First, it decreases as  $n$  increases. This means that ERM gets better as it works with more data. Second, it increases as the function class  $\mathcal{F}$  grows in size. But the dependence is logarithmic and hence mild.

However, the bound above is useless if  $|\mathcal{F}|$  is not finite. The goal of the theory we will build below (often called “VC theory” after its architects Vapnik and Chervonenkis) will be to replace  $\log |\mathcal{F}|$  with an appropriate measure of the *capacity* of an infinite function class  $\mathcal{F}$ .

### 1.14.3.1 Concentration inequalities

Learning theory uses *concentration inequalities* heavily. A typical concentration inequality will state that a certain random variable is tightly concentrated around its mean (or in some cases median). That is, the probability that they deviate far enough from the mean is small.

The following concentration inequality, called *Hoeffding’s inequality*, applies to sums of iid random variables.

**Theorem 5.** *Let  $Z_i \in [0, 1]$  be bounded iid random variables with common expectation  $\mu$ . Then we have, for  $\varepsilon > 0$*

$$\mathbb{P} \left[ \mu - \frac{1}{n} \sum_{i=1}^n Z_i > \varepsilon \right] \leq \exp(-2n\varepsilon^2).$$

This can be restated as follows. For any  $\delta \in (0, 1)$ ,

$$\mathbb{P} \left[ \mu - \frac{1}{n} \sum_{i=1}^n Z_i \leq \sqrt{\frac{\log(1/\delta)}{2n}} \right] > 1 - \delta.$$

A couple of remarks are in order. First, even though we have stated Hoeffding’s inequality as applying to bounded iid random variables, only the boundedness and independence are really needed. It is possible to let the  $Z_i$ ’s have different distributions. Second, the above result provides probability upper bounds for deviations below the mean  $\mu$  but a similar result holds for deviations of  $\frac{1}{n} \sum_{i=1}^n Z_i$  above  $\mu$  as well.

In fact, Hoeffding’s inequality can be considered a special case of the following inequality that is often called *McDiarmid’s inequality* or the *bounded differences inequality*.

**Theorem 6.** *Let  $F : \mathcal{X}^n \rightarrow \mathbb{R}$  be a function that satisfies the bounded differences property: for all  $i \in [n]$  and  $x_{1:n} \in \mathcal{X}^n$ ,  $x'_i \in \mathcal{X}$ ,*

$$|f(x_1, \dots, x_i, \dots, x_n) - f(x_1, \dots, x'_i, \dots, x_n)| \leq c_i$$

for some constants  $c_i$ . Then, for any independent  $X_1, \dots, X_n$ , the random variable  $Z = f(X_1, \dots, X_n)$  satisfies,

$$\mathbb{P}[Z - \mathbb{E}Z \geq \varepsilon] \leq \exp \left( -\frac{2\varepsilon^2}{\sum_{i=1}^n c_i^2} \right)$$

as well as

$$\mathbb{P}[Z - \mathbb{E}Z \leq -\varepsilon] \leq \exp \left( -\frac{2\varepsilon^2}{\sum_{i=1}^n c_i^2} \right)$$

for any  $\varepsilon > 0$ .

### 1.14.3.2 Rademacher complexity

Let us recall that we need to control the following quantity:

$$\sup_{f \in \mathcal{F}} R(f) - \widehat{R}(f).$$

Since this satisfies the conditions of McDiarmid's inequality with  $c_i = 1/n$ , we have, with probability at least  $1 - \delta$ ,

$$\sup_{f \in \mathcal{F}} R(f) - \widehat{R}(f) \leq \mathbb{E} [\sup_{f \in \mathcal{F}} R(f) - \widehat{R}(f)] + \sqrt{\frac{\log(1/\delta)}{2n}}.$$

Now, we can appeal to a powerful idea known as *symmetrization*. The basic idea is to replace

$$\sup_{f \in \mathcal{F}} R(f) - \widehat{R}(f)$$

with

$$\sup_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^n (\mathbb{E}[\ell(f(X'_i), Y'_i)] - \ell(f(X_i), Y_i)),$$

where  $(X'_1, Y'_1), \dots, (X'_n, Y'_n)$  are samples drawn from the distribution  $P$  that are independent of each other and of the original sample. The new sample is often referred to as the *ghost sample*. The point of introducing the ghost sample is that, by an application of Jensen's inequality, we get

$$\begin{aligned} \mathbb{E} [\sup_{f \in \mathcal{F}} R(f) - \widehat{R}(f)] &= \mathbb{E} \left[ \sup_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^n (\mathbb{E}[\ell(f(X'_i), Y'_i)] - \ell(f(X_i), Y_i)) \right] \\ &\leq \mathbb{E} \left[ \sup_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^n (\ell(f(X'_i), Y'_i) - \ell(f(X_i), Y_i)) \right]. \end{aligned}$$

Now, the distribution of

$$\sup_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^n (\ell(f(X'_i), Y'_i) - \ell(f(X_i), Y_i))$$

is invariant under exchanging any  $X_i, Y_i$  with an  $X'_i, Y'_i$ . That is, for any fixed choice of  $\pm 1$  signs  $\epsilon_1, \dots, \epsilon_n$ , the above quantity has the same distribution as

$$\sup_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^n \epsilon_i (\ell(f(X'_i), Y'_i) - \ell(f(X_i), Y_i)).$$

This allows us introduce even more randomization by making the  $\epsilon_i$ 's themselves random. This gives,

$$\begin{aligned}
 \mathbb{E} [\sup_{f \in \mathcal{F}} R(f) - \widehat{R}(f)] &\leq \mathbb{E}_{\epsilon, X, Y, X', Y'} \left[ \sup_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^n \epsilon_i (\ell(f(X'_i), Y'_i) - \ell(f(X_i), Y_i)) \right] \\
 &\leq \mathbb{E}_{\epsilon, X', Y'} \left[ \sup_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^n \epsilon_i \ell(f(X'_i), Y'_i) \right] \\
 &\quad + \mathbb{E}_{\epsilon, X, Y} \left[ \sup_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^n (-\epsilon_i) \ell(f(X_i), Y_i) \right] \\
 &= 2 \cdot \mathbb{E}_{\epsilon, X, Y} \left[ \sup_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^n \epsilon_i \ell(f(X_i), Y_i) \right].
 \end{aligned}$$

This directly yields a bound in terms of the *Rademacher complexity*:

$$\mathfrak{R}_n(\ell \circ \mathcal{F}) = \mathbb{E}_{\epsilon, X, Y} \left[ \sup_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^n \epsilon_i \ell(f(X_i), Y_i) \right],$$

where  $\epsilon_i$  is a *Rademacher random variable* that is either -1 or +1, each with probability  $\frac{1}{2}$ . The subscript below the expectation serves as a reminder that the expectation is being taken with respect to the randomness in  $X_i$ ,  $Y_i$ 's, and  $\epsilon_i$ 's. We have thus proved the following theorem.

**Theorem 7 (Symmetrization).** *For a function class  $\mathcal{F}$  and loss  $\ell$ , define the loss class*

$$\ell \circ \mathcal{F} = \{(x, y) \mapsto \ell(f(x), y) : f \in \mathcal{F}\}.$$

We have,

$$\mathbb{E} [\sup_{f \in \mathcal{F}} R(f) - \widehat{R}(f)] \leq 2\mathfrak{R}_n(\ell \circ \mathcal{F}).$$

An interesting observation is that the sample dependent quantity

$$\widehat{\mathfrak{R}}_n(\ell \circ \mathcal{F}) = \mathbb{E}_{\epsilon} \left[ \sup_{f \in \mathcal{F}} \frac{1}{n} \sum_{i=1}^n \epsilon_i \ell(f(X_i), Y_i) \right]$$

also satisfies the bounded differences condition with  $c_i = 1/n$ . This is the *empirical Rademacher average* and the expectation in its definition is only over the Rademacher random variables. Applying McDiarmid's inequality, we have,

$$\mathfrak{R}_n(\ell \circ \mathcal{F}) \leq \widehat{\mathfrak{R}}_n(\ell \circ \mathcal{F}) + \sqrt{\frac{\log(1/\delta)}{2n}}$$

with probability at least  $1 - \delta$ .

To prove a bound on the Rademacher complexity of a finite class, the following lemma, due to [24], is useful.

**Lemma 8 (Massart's finite class lemma).** Let  $\mathcal{A}$  be a finite subset of  $\mathbb{R}^n$  and  $\epsilon_1, \dots, \epsilon_n$  be independent Rademacher random variables. Let  $r = \max_{a \in \mathcal{A}} \|a\|_2$ . Then, we have,

$$\mathbb{E} \left[ \sup_{a \in \mathcal{A}} \frac{1}{n} \sum_{i=1}^n \epsilon_i a_i \right] \leq \frac{r \sqrt{2 \log |\mathcal{A}|}}{n}.$$

Therefore, for any finite class  $\mathcal{F}$  consisting of functions bounded by 1,

$$\widehat{\mathfrak{R}}_n(\mathcal{F}) \leq \sqrt{\frac{2 \log |\mathcal{F}|}{n}}.$$

Since the right hand side is not random, the same bound holds for  $\mathfrak{R}_n(\mathcal{F})$  as well.

The Rademacher complexity, and its empirical counterpart, satisfy a number of interesting structural properties.

**Theorem 9 (Structural Properties of Rademacher Complexity).** Let  $\mathcal{F}, \mathcal{F}_1, \dots, \mathcal{F}_k$  and  $\mathcal{H}$  be classes of real valued functions. Then  $\mathfrak{R}_n(\cdot)$  (as well as  $\widehat{\mathfrak{R}}_n(\cdot)$ ) satisfies the following properties:

*Monotonicity:* If  $\mathcal{F} \subseteq \mathcal{H}$ ,  $\mathfrak{R}_n(\mathcal{F}) \leq \mathfrak{R}_n(\mathcal{H})$ .

*Convex Hull:*  $\mathfrak{R}_n(\text{conv}(\mathcal{F})) = \mathfrak{R}_n(\mathcal{F})$ .

*Scaling:*  $\mathfrak{R}_n(c\mathcal{F}) = |c|\mathfrak{R}_n(\mathcal{F})$  for any  $c \in \mathbb{R}$ .

*Contraction:* If  $\phi : \mathbb{R} \rightarrow \mathbb{R}$  is Lipschitz with constant  $L_\phi$ , then  $\mathfrak{R}_n(\phi \circ \mathcal{F}) \leq L_\phi \mathfrak{R}_n(\mathcal{F})$ .

*Translation:* For any bounded function  $h$ ,  $\mathfrak{R}_n(\mathcal{F} + h) = \mathfrak{R}_n(\mathcal{F})$ .

*Subadditivity:*  $\mathfrak{R}_n\left(\sum_{i=1}^k \mathcal{F}_i\right) \leq \sum_{i=1}^k \mathfrak{R}_n(\mathcal{F}_i)$ .

For proofs of these properties, see [25]. However, note that the Rademacher complexity is defined there such that an extra absolute value is taken before the supremum over  $f \in \mathcal{F}$ . That is,

$$\mathfrak{R}_n^{\text{abs}}(\mathcal{F}) = \mathbb{E} \left[ \sup_{f \in \mathcal{F}} \left| \frac{1}{n} \sum_{i=1}^n f(X_i) \right| \right].$$

Nevertheless, the proofs given there generalize quite easily to definition of Rademacher complexity that we are using. For example, see [26], where the Rademacher complexity as we have defined it here (without the absolute value) is called *free Rademacher complexity*.

Using these properties, it is possible to directly bound the Rademacher complexity of several interesting functions classes. See [25] for examples. The contraction property is a very useful one. It allows us to transition from the Rademacher complexity of the loss class to the Rademacher complexity of the function class itself (for Lipschitz losses).

The Rademacher complexity can also be bounded in terms of another measure of complexity of a function class: namely covering numbers.

### 1.14.3.3 Covering numbers

The idea underlying covering numbers is very intuitive. Let  $(\mathcal{D}, \rho)$  be any (pseudo-) metric space and fix a subset  $T \subseteq \mathcal{D}$ . A set  $T' \subseteq \mathcal{D}$  is said to be an  $\alpha$ -cover of  $T$  if

$$\forall f \in T, \exists g \in T' \text{ s.t. } \rho(f, g) \leq \alpha.$$

In other words “balls” of radius  $\alpha$  placed at elements of  $T'$  “cover” the set  $T$  entirely. The *covering number* (at scale  $\alpha$ ) of  $T$  is defined as the size of the smallest cover of  $T$  (at scale  $\alpha$ ).

$$\mathcal{N}(T, \rho, \alpha) = \min \{|T'| : T' \text{ is an } \alpha\text{-cover of } T\}.$$

The logarithm of covering number is called *entropy*.

Given a sample  $x_{1:n} = (x_1, \dots, x_n)$ , define the data dependent metric on  $\mathcal{F}$  as

$$\widehat{\rho}_p(f, g) = \left( \frac{1}{n} \sum_{i=1}^n |f(x_i) - g(x_i)|^p \right)^{1/p},$$

where  $p \in [1, \infty)$ . Taking the limit  $p \rightarrow \infty$  suggests the metric

$$\widehat{\rho}_\infty(f, g) = \max_{i \in [n]} |f(x_i) - g(x_i)|.$$

These metrics gives us the  $p$ -norm covering numbers

$$\mathcal{N}_p(\mathcal{F}, x_{1:n}, \alpha) = \mathcal{N}(\mathcal{F}, \widehat{\rho}, \alpha).$$

These covering numbers increase with  $p$ . That is, for  $p \in [1, \infty]$ ,

$$\mathcal{N}_1(\mathcal{F}, x_{1:n}, \alpha) \leq \mathcal{N}_p(\mathcal{F}, x_{1:n}, \alpha) \leq \mathcal{N}_\infty(\mathcal{F}, x_{1:n}, \alpha).$$

Finally, we can also define the worst case (over samples)  $p$ -norm covering number

$$\mathcal{N}_p(\mathcal{F}, n, \alpha) = \sup_{x_{1:n} \in \mathcal{X}^n} \mathcal{N}_p(\mathcal{F}, x_{1:n}, \alpha).$$

A major result connecting Rademacher complexity with covering numbers is due to [27].

**Theorem 10 (Dudley's entropy integral bound).** *For any  $\mathcal{F}$  consisting of real valued functions bounded by 1, we have*

$$\widehat{\mathfrak{R}}_n(\mathcal{F}) \leq \alpha + 12 \int_\alpha^1 \sqrt{\frac{\log \mathcal{N}_2(\mathcal{F}, X_{1:n}, \beta)}{n}} d\beta.$$

Therefore, using Jensen's inequality, we have

$$\mathfrak{R}_n(\mathcal{F}) \leq \alpha + 12 \int_\alpha^1 \sqrt{\frac{\log \mathbb{E} \mathcal{N}_2(\mathcal{F}, X_{1:n}, \beta)}{n}} d\beta.$$

#### 1.14.3.4 Binary valued functions: VC dimension

For binary function classes  $\mathcal{F} \subseteq \{\pm 1\}^{\mathcal{X}}$ , we can provide distribution free upper bounds on the Rademacher complexity or covering numbers in terms of a combinatorial parameter called the *Vapnik-Chervonenkis (VC) dimension*.

To define it, consider a sequence  $x_{1:n} = (x_1, \dots, x_n)$ . We say that  $x_{1:n}$  is *shattered* by  $\mathcal{F}$  if each of the  $2^n$  possible  $\pm 1$  labelings of these  $n$  points are realizable using some  $f \in \mathcal{F}$ . That is,  $x_{1:n}$  is shattered by  $\mathcal{F}$  iff

$$|\{(f(x_1), \dots, f(x_n)) : f \in \mathcal{F}\}| = 2^n.$$

The *VC dimension* of  $\mathcal{F}$  is the length of the longest sequence that can be shattered by  $\mathcal{F}$ :

$$\text{VCdim}(\mathcal{F}) = \max \{n : \exists x_{1:n} \in \mathcal{X}^n \text{ s.t. } x_{1:n} \text{ is shattered by } \mathcal{F}\}.$$

The size of the restriction of  $\mathcal{F}$  to  $x_{1:n}$  is called the *shatter coefficient*:

$$\mathbb{S}(\mathcal{F}, x_{1:n}) = |\{(f(x_1), \dots, f(x_n)) : f \in \mathcal{F}\}|.$$

Considering the worst sequence gives us the *growth function*

$$\mathbb{S}(\mathcal{F}, n) = \max_{x_{1:n} \in \mathcal{X}^n} \mathbb{S}(\mathcal{F}, x_{1:n}).$$

If  $\text{VCdim}(\mathcal{F}) = d$ , then we know that  $\mathbb{S}(\mathcal{F}, n) = 2^n$  for all  $n \leq d$ . One can ask: what is the behavior of the growth function for  $n > d$ ? The following combinatorial lemma proved independently by Vapnik and Chervonenkis [28], Sauer [29], and Shelah [30], gives the answer to this question.

**Lemma 11.** *If  $\text{VCdim}(\mathcal{F}) = d$ , then we have, for any  $n \in \mathbb{N}$ ,*

$$\mathbb{S}(\mathcal{F}, n) = \sum_{i=0}^d \binom{n}{i}.$$

In particular, if  $d > 2$ ,  $\mathbb{S}(\mathcal{F}, n) \leq n^d$ .

Thus, for a class with finite VC dimension, the Rademacher complexity can be bounded directly using Massart's lemma.

**Theorem 12.** *Suppose  $2 < \text{VCdim}(\mathcal{F}) = d < \infty$ . Then, we have,*

$$\widehat{\mathfrak{R}}_n(\mathcal{F}) \leq \sqrt{\frac{2 \log \mathbb{S}(\mathcal{F}, n)}{n}} \leq \sqrt{\frac{2d \log n}{n}}.$$

It is possible to shave off the  $\log n$  factor in the bound above plugging an estimate of the entropy  $\log N_2(\mathcal{F}, n, \alpha)$  for VC classes due to [31] into Theorem 10.

**Theorem 13.** *Suppose  $\text{VCdim}(\mathcal{F}) = d < \infty$ . We have, for any  $n \in \mathbb{N}$ ,*

$$\mathcal{N}_2(\mathcal{F}, n, \alpha) \leq Cd \log \frac{1}{\alpha}$$

for a universal constant  $C$ .

These results show that for a class  $\mathcal{F}$  with finite VC dimension  $d$ , the sample complexity required by ERM to achieve  $\varepsilon$  excess risk relative to  $f_{\mathcal{F}}^*$  is, with probability at least  $1 - \delta$ ,  $O\left(\frac{d}{\varepsilon^2} + \log \frac{1}{\delta}\right)$ . Therefore, a finite VC dimension is *sufficient* for learnability with respect to a fixed functions class. In fact, a finite VC dimension also turns out to be necessary (see, for instance, [14, Chapter 14]). Thus, we have the following characterization.

**Theorem 14.** *In the binary classification setting with 0–1 loss, there is a learning algorithm with bounded sample complexity for every  $\varepsilon, \delta \in (0, 1)$  iff  $\text{VCdim}(\mathcal{F}) < \infty$ .*

Note that, when  $\text{VCdim}(\mathcal{F}) < \infty$ , the dependence of the sample complexity on  $1/\varepsilon$  is polynomial and on  $1/\delta$  is *logarithmic*. Moreover, such a sample complexity is achieved by ERM. On the other hand, when  $\text{VCdim}(\mathcal{F}) = \infty$ , then no learning algorithm, including ERM, can have bounded sample complexity for arbitrarily small  $\varepsilon, \delta$ .

### 1.14.3.5 Real valued functions: fat shattering dimension

For real valued functions, getting distribution free upper bounds on Rademacher complexity or covering numbers involves combinatorial parameters similar to the VC dimension. The appropriate notion for determining learnability using a finite number of samples turns out to be a *scale sensitive* combinatorial dimension known as the *fat shattering dimension*.

Fix a class  $\mathcal{F}$  consisting of bounded real valued functions  $f : \mathcal{X} \rightarrow [0, 1]$  and a scale  $\alpha > 0$ . We say that a sequence  $x_{1:n} = (x_1, \dots, x_n)$  is  $\alpha$ -shattered by  $\mathcal{F}$  if there exists a witness sequence  $s_{1:n} \in \mathbb{R}^n$  such that, for every  $\epsilon_{1:n} \in \{\pm 1\}^n$ , there is an  $f \in \mathcal{F}$  such that

$$\epsilon_i(f(x_i) - s_i) \geq \alpha .$$

In words, this means that, for any of the  $2^n$  possibilities for the sign pattern  $\epsilon_{1:n}$ , we have a function  $f \in \mathcal{F}$  whose values at the points  $x_i$  is above or below  $s_i$  depending on whether  $\epsilon_i$  is  $+1$  or  $-1$ . Moreover, the gap between  $f(x_i)$  and  $s_i$  is required to be at least  $\alpha$ .

The fat-shattering dimension of  $\mathcal{F}$  at scale  $\alpha$  is the size of the longest sequence that can be  $\alpha$ -shattered by  $\mathcal{F}$ :

$$\text{fat}_\alpha(\mathcal{F}) = \max\{n : \exists x_{1:n} \in \mathcal{X}^n \text{ s.t. } x_{1:n} \text{ is } \alpha\text{-shattered by } \mathcal{F}\}.$$

A bound on  $\infty$ -norm covering numbers in terms of the fat shattering dimension were first given by Alon et al. [32].

**Theorem 15.** *Fix a class  $\mathcal{F} \subseteq [0, 1]^{\mathcal{X}}$ . Then we have, for any  $\alpha > 0$ ,*

$$\mathcal{N}_\infty(\mathcal{F}, n, \alpha) \leq 2 \left( \frac{4n}{\alpha^2} \right)^{d \log(en/d\alpha)} ,$$

where  $d = \text{fat}_{\alpha/2}(\mathcal{F})$ .

Using this bound, the sample complexity of learning a real valued function class of bounded range using a Lipschitz loss<sup>3</sup>  $\ell$  is  $O(\frac{d}{\varepsilon^2} \log \frac{1}{\varepsilon} + \log \frac{1}{\delta})$  where  $d = \text{fat}_{ce}(\mathcal{F})$  for a universal constant  $c > 0$ . The importance of the fat shattering dimension lies in the fact that if  $\text{fat}_\alpha(\mathcal{F}) = \infty$  for some  $\alpha > 0$ , then no learning algorithm can have bounded sample complexity for learning the functions for arbitrarily small values of  $\varepsilon, \delta$ .

**Theorem 16.** *In the regression setting with either squared loss or absolute loss, there is a learning algorithm with bounded sample complexity for every  $\varepsilon, \delta \in (0, 1)$  iff  $\forall \alpha > 0, \text{fat}_\alpha(\mathcal{F}) < \infty$ .*

---

<sup>3</sup>By this we mean  $\ell(\cdot, y)$  is Lipschitz for all  $y$ .

Note that here, unlike the binary classification case, the dependence of the sample complexity on  $1/\varepsilon$  is not fixed. It depends on how fast  $\text{fat}_\alpha \mathcal{F}$  grows as  $\alpha \rightarrow 0$ . In particular, if  $\text{fat}_\alpha(\mathcal{F})$  grows as  $1/\alpha^p$  then the sample complexity is polynomial in  $1/\varepsilon$  (and logarithmic in  $1/\delta$ ).

### 1.14.4 Model selection

In general, model selection refers to the task of selecting an appropriate model from a given family based on available data. For ERM, the “model” is the class  $\mathcal{F}$  of functions  $f : \mathcal{X} \rightarrow \mathcal{Y}$  that are intended to capture the functional dependence between the input variable  $X$  and the output  $Y$ . If we choose too small an  $\mathcal{F}$  then ERM will not have good performance if  $f^*$  is not even well approximated by any member of  $\mathcal{F}$ . On the other hand, if  $\mathcal{F}$  is too large (say all functions) then the estimation error will be so large that ERM will not perform well even if  $f^* \in \mathcal{F}$ .

#### 1.14.4.1 Structural risk minimization

Consider the classification setting with 0–1 loss. Suppose we have a countable sequence of nested function classes:

$$\mathcal{F}^{(1)} \subset \mathcal{F}^{(2)} \subset \dots \subset \mathcal{F}^{(k)} \dots ,$$

where  $\mathcal{F}^{(k)}$  has VC dimension  $d_k$ . The function  $\hat{f}_n^{(k)}$  chosen by ERM over  $\mathcal{F}_k$  satisfies the bound

$$R\left(\hat{f}_n^{(k)}\right) \leq \widehat{R}\left(\hat{f}_n^{(k)}\right) + O\left(\sqrt{\frac{d_k \log n}{n}}\right)$$

with high probability. As  $k$  increases, the classes become more complex. So, the empirical risk term will decrease with  $k$  whereas the VC dimension term will increase. The principle of *structural risk minimization (SRM)* chooses a value of  $k$  by minimizing the right hand side above.

Namely, we choose

$$\hat{k} = \operatorname{argmin}_k \widehat{R}\left(\hat{f}_n^{(k)}\right) + C \sqrt{\frac{d_k \log n}{n}}, \quad (14.3)$$

for some universal constant  $C$ .

It can be shown (see, for example, [14, Chapter 18]) that SRM leads to universally consistent rules provided appropriate conditions are placed on the functions classes  $\mathcal{F}_k$ .

**Theorem 17 (Universal Consistency of SRM).** *Let  $\mathcal{F}^{(1)}, \mathcal{F}^{(2)}, \dots$  be a sequence of classes such that for any distribution  $P$ ,*

$$\lim_{k \rightarrow \infty} R(f_{\mathcal{F}^{(k)}}^*) = R(f^*).$$

*Assume also that  $\text{VCdim}(\mathcal{F}^{(1)}) < \text{VCdim}(\mathcal{F}^{(2)}) < \dots$  are all finite. Then the learning rule  $\hat{f}_n^{(\hat{k})}$  with  $\hat{k}$  chosen as in (14.3) is strongly universally consistent.*

The penalty term in (14.3) depends on the VC dimension of  $\mathcal{F}^{(k)}$ . It turns out that it is not essential. All we need is an upper bound on the risk of ERM in terms of the empirical risk and some measure of the complexity of the function class. One could also imagine proving results for regression problems by

replacing the VC dimension with fat-shattering dimension. We can think of SRM as *penalizing* larger classes by their capacity to overfit the data. However, the penalty in SRM is fixed in advance and is not data dependent. We will now look into more general penalties.

#### 1.14.4.2 Model selection via penalization

Given a (not necessarily nested) countable or finite collection of models  $\{\mathcal{F}^{(k)}\}_k$  and a penalty function  $\text{pen} : \mathbb{N} \rightarrow \mathbb{R}_+$ , define  $\hat{k}$  as the minimizer of

$$\hat{R}\left(\hat{f}_n^{(k)}\right) + \text{pen}(k).$$

Recall that  $\hat{f}_n^{(k)}$  is the result of ERM over  $\mathcal{F}^{(k)}$ . Also note that the penalty can additionally depend on the data. Now define the *penalized estimator* as

$$\tilde{f}_n = \hat{f}_n^{(\hat{k})}.$$

The following theorem shows that any probabilistic upper bound  $U_{n,k}$  on the risk  $R(\hat{f}_n)$  can be used to design a penalty for which a performance bound can be given.

**Theorem 18.** *Assume that there are positive numbers  $c$  and  $m$  such that for each  $k$  we have the guarantee*

$$\forall \varepsilon > 0, \mathbb{P}\left[R\left(\hat{f}_n^{(k)}\right) > U_{n,k} + \varepsilon\right] \leq c \exp(-2m\varepsilon^2).$$

Then the penalized estimator  $\tilde{f}_n$  with

$$\text{pen}(k) = U_{n,k} - \hat{R}\left(\hat{f}_n^{(k)}\right) + \sqrt{\frac{\log k}{m}}$$

satisfies

$$\mathbb{E}[R(\tilde{f}_n)] - R(f^*) \leq \min_k \left\{ \mathbb{E}[\text{pen}(k)] + (R(f_{\mathcal{F}^{(k)}}^*) - R(f^*)) \right\} + \sqrt{\frac{\log (ce)}{2m}}.$$

Note that the result says that the penalized estimator achieves an almost optimal trade-off between the approximation error  $R(f_{\mathcal{F}^{(k)}}^*) - R(f^*)$  and the expected complexity  $\mathbb{E}[\text{pen}](k)$ . For a good upper bound  $U_{n,k}$ , the expected complexity will be a good upper bound on the (expected) estimation error. Therefore, the model selection properties of the penalized estimator depend on how good an upper bound  $U_{n,k}$  we can find.

Note that structural risk minimization corresponds to using a distribution free upper bound

$$U_{n,k} = \hat{R}\left(\hat{f}_n^{(k)}\right) + O\left(\sqrt{\frac{d_k \log n}{n}}\right).$$

The looseness of these distribution free upper bounds has prompted researchers to design data dependent penalties. We shall see an examples based on empirical Rademacher averages in the next section.

**Proof.** For any  $\varepsilon > 0$ ,

$$\begin{aligned}
 & \mathbb{P} \left[ R(\tilde{f}_n) - (\widehat{R}(\tilde{f}_n) + \text{pen}(\widehat{k})) > \varepsilon \right] \\
 & \leq \mathbb{P} \left[ \exists k \text{ s.t. } R(\widehat{f}_n^{(k)}) - (\widehat{R}(\widehat{f}_n^{(k)}) + \text{pen}(k)) > \varepsilon \right] \\
 & \leq \sum_{k=1}^{\infty} \mathbb{P} \left[ R(\widehat{f}_n^{(k)}) - (\widehat{R}(\widehat{f}_n^{(k)}) + \text{pen}(k)) > \varepsilon \right] \\
 & = \sum_{k=1}^{\infty} \mathbb{P} \left[ R(\widehat{f}_n^{(k)}) - U_{n,k} > \sqrt{\frac{\log k}{m}} + \varepsilon \right] \\
 & \leq \sum_{k=1}^{\infty} c \exp \left( -2m(\varepsilon + \sqrt{\log k/m})^2 \right) \\
 & \leq \sum_{k=1}^{\infty} c \exp \left( -2m(\varepsilon^2 + \log k/m) \right) \\
 & = c \exp(-2n\varepsilon^2) \sum_{k=1}^{\infty} \frac{1}{k^2} \leq 2c \exp(-2m\varepsilon^2).
 \end{aligned}$$

By integrating the final upper bound with respect to  $\varepsilon$ , we get the bound

$$\mathbb{E} \left[ R(\tilde{f}_n) - (\widehat{R}(\tilde{f}_n) + \text{pen}(\widehat{k})) \right] \leq \sqrt{\frac{\log(ce)}{2m}}. \quad (14.4)$$

Also, for any  $k$ , we have

$$\begin{aligned}
 \mathbb{E} \left[ \widehat{R}(\tilde{f}_n) + \text{pen}(\widehat{k}) - R(f_{\mathcal{F}^{(k)}}^*) \right] & \leq \mathbb{E} \left[ \widehat{R}(\widehat{f}_n^{(k)}) + \text{pen}(k) - R(f_{\mathcal{F}^{(k)}}^*) \right] \\
 & \leq \mathbb{E} \left[ \widehat{R}(f_{\mathcal{F}^{(k)}}^*) + \text{pen}(k) - R(f_{\mathcal{F}^{(k)}}^*) \right] \\
 & = \mathbb{E} [\text{pen}(k)].
 \end{aligned}$$

The first inequality above follows by definition of  $\widehat{k}$  and  $\tilde{f}_n$ . The second holds because  $\widehat{f}_n^{(k)}$  minimizes the empirical risk over  $\mathcal{F}^{(k)}$ . Summing this with (14.4), we get, for any  $k$ ,

$$\mathbb{E} \left[ R(\tilde{f}_n) \right] \leq \mathbb{E} [\text{pen}(k)] + R(f_{\mathcal{F}^{(k)}}^*) + \sqrt{\frac{\log(ce)}{2m}}.$$

Now subtracting  $R(f^*)$  from both sides and minimizing over  $k$  proves the theorem.  $\square$

#### 1.14.4.3 Data driven penalties using Rademacher averages

The results of Section 1.14.3.2 tell us that there exists universal constants  $C, c$  such that

$$\mathbb{P}[R(\widehat{f}_n) > \widehat{R}(\widehat{f}_n) + 2\widehat{\mathfrak{R}}_n(\mathcal{F}^{(k)}) + \varepsilon] < c \exp(-2Cn\varepsilon^2).$$

Thus, we can use the data dependent penalty

$$\text{pen}(k) = 2\widehat{\mathfrak{R}}_n(\mathcal{F}^{(k)}) + \sqrt{\frac{\log k}{Cn}}$$

in Theorem 18 to get the bound

$$\mathbb{E}[R(\tilde{f}_n)] - R(f^*) \leq \min_k \left\{ 2\mathfrak{R}_n(\mathcal{F}^{(k)}) + (R(f_{\mathcal{F}^{(k)}}^*) - R(f^*)) + \sqrt{\frac{\log k}{Cn}} \right\} + \sqrt{\frac{\log (ce)}{2Cn}}.$$
